The reaction of the epoxide with a thiol group yields a thioether linkage, whereas reaction with a hydroxyl gives an ether and reaction with an amine results in a secondary amine bond. The relative reactivity of an epoxy group is thiol > amine > hydroxyl, and this is reflected by the optimal pH range for each reaction. In this case, the lower the reactivity of the functional group the higher the pH required to drive the reaction efficiently. Chapter 15, Section 2.3, contains a thorough discussion on coupling affinity ligands to epoxy activated supports.

GOPTS has been used to create a high-density PEG surface on glass slides for use in arrays (Piehler *et al*., 2000). It also has been used in the development of a high-throughput analyzer using biochip technology on aluminum oxide sheets (FitzGerald *et al*., 2005), in the activation of glass surfaces for detection of antibodies specific for hepatitis B and C viruses (Duan *et al*., 2005), and in the covalent attachment of biomolecules onto silicon nitride planar waveguide surfaces (Psarouli *et al*., 2011).

The following protocol is based on these methods. All operations should be done in a fume hood, including wearing proper protective clothing.

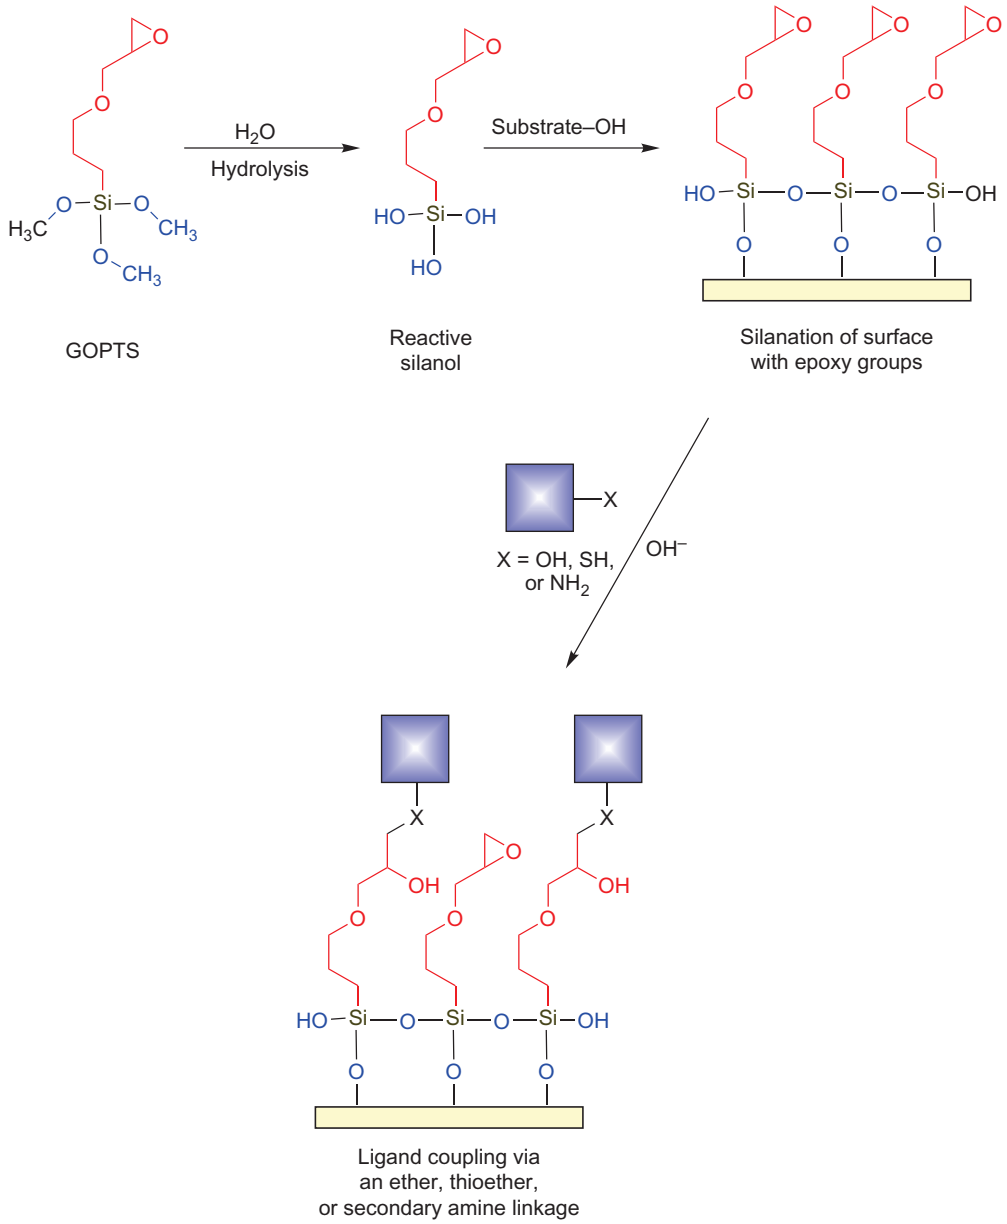
Protocol

1. Prepare glass slides by washing with acid (5% HCl) for several hours to remove non-binding metal ions, especially sodium, potassium, and calcium. Treatment with a mixture of 25% sulfuric acid and 15% hydrogen peroxide (piranha solution) for about 30 min is done to create a high density of hydroxyl functionalities suitable for silane modification. Glass slides also can be cleaned and washed prior to modification with a silane with DMSO, ethanol, and water, and then etched using 10% NaOH (w/w) in water for 1 h.
2. Prepare a GOPTS solution in *o*-xylene or 95% ethanol at a concentration of 2% (v/v). If the organic solvent is used, add 2 mg/ml *N*-ethyldiisopropylamine (DIPEA) as base.
3. Immerse the glass slides in the GOPTS solution and mix by stirring.
4. React at 37°C (for the ethanol solution) or 55°C (for the *o*-xylene solution) for at least 5 to 6 h with mixing.
5. Wash slides thoroughly with solvent and then dry in an oven at 135°C for 1 h (explosion-proof oven). The slides are now ready to couple ligands through their epoxy groups.

For protocol suggestions on conjugation to epoxy groups, see Chapter 3, Sections 1.8 and 4.1. Also, see Chapter 14, Section 4.2, for a method to attach affinity ligands to nanoparticle or microparticle surfaces that have been activated with epoxide groups.

2.5. Isocyanatopropyltriethoxysilane (ICPTES)

Isocyanate groups are extremely reactive toward nucleophiles and will hydrolyze rapidly in aqueous solution (Chapter 3, Sections 1.2 and 4.7). They especially are useful for covalent coupling to hydroxyl groups under nonaqueous conditions, which is appropriate for conjugation to many carbohydrate ligands.



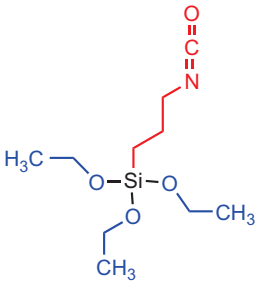


FIGURE 13.9 Epoxy-containing silane coupling agents form reactive surfaces that can be used to couple amine-, thiol-, or hydroxyl-containing ligands.

Isocyanatopropyltriethoxysilane (ICPTES) contains an isocyanate group at the end of a short propyl spacer, which is connected to the triethoxysilane group useful for attachment to inorganic substrates. Silanization can be accomplished in dry organic solvent to form reactive surfaces while preserving the activity of the isocyanates.

An isocyanate reacts with amines to form isourea linkages and with hydroxyls to form carbamate (urethane) bonds. Both reactions can take place in organic solvent to conjugate molecules to inorganic substrates (Figure 13.10). The solvent used for this reaction must be of high purity and should be dried using molecular sieves prior to adding the silane compound.

ICPTES;
Isocyanatopropyl-triethoxysilane
MW 247.36

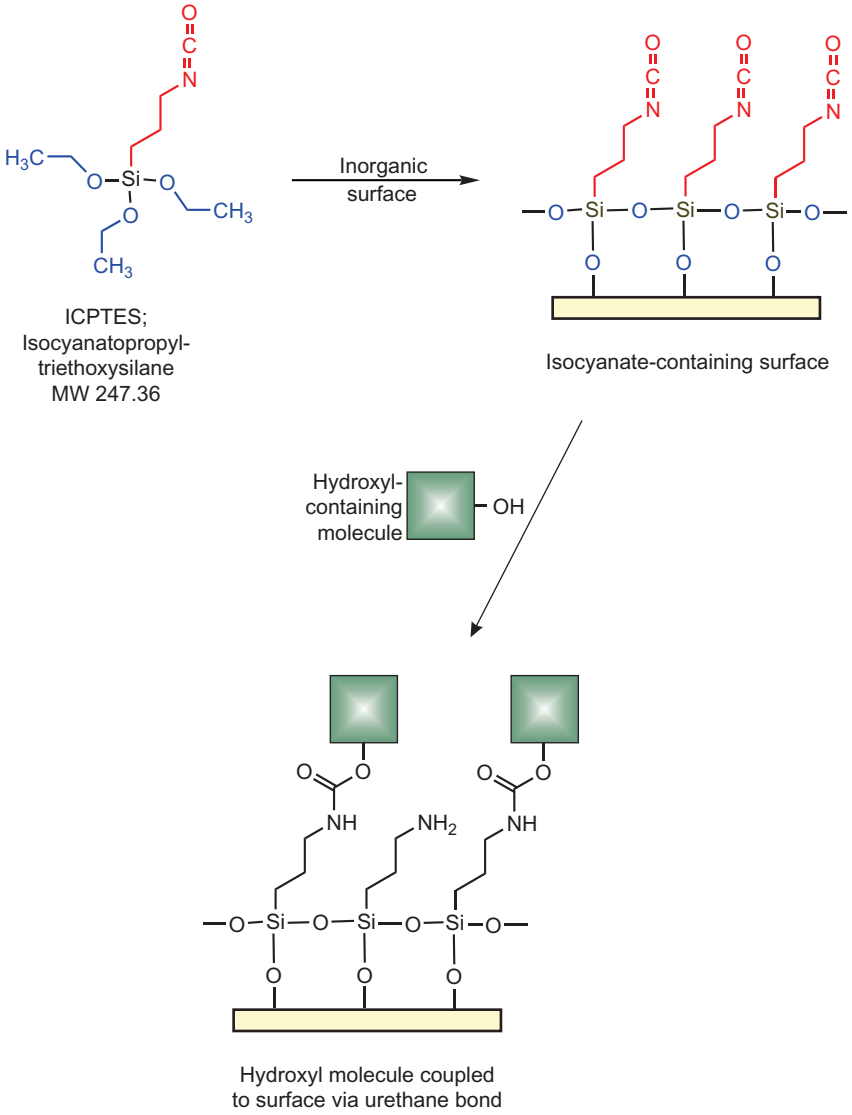

FIGURE 13.10 The isocyanate-containing silane coupling agent can be used to couple hydroxyl-containing molecules to inorganic surfaces. The reactions should be carried out in dry organic solvent to prevent hydrolysis of the reactive group.

Silva *et al*. (2005) used ICPTES to create novel chitosan–siloxane hybrid polymers by coupling the isocyanate groups to the functional groups of the carbohydrate and forming a silica polymer using the triethoxysilane backbone. Boev *et al*. (2005) used this functional silane coupling agent to prepare CdS fluorescent nanoparticles in a urea–silicate matrix. ICPTES and APTS have been used in combination to create organically modified silica xerogels through carboxylic acid solvolysis that formed hybrid materials with luminescent properties (Fu *et al*., 2006). In addition, Wu *et al*. (2011) used ICPTES to modify carbon nanotubes, Fu *et al*. (2011) created a glucose biosensor by immobilizing an enzyme using it, and Yu *et al*. (2011) developed a magnetic NIR luminescent nanocomposite using the silane compound.

The following protocol is based on the method of FitzGerald *et al*. (2005), who used the technology to develop aluminum oxide-based biochips for high-throughput analysis.

Protocol

1. In a fume hood, dissolve ICPTES in anhydrous toluene at a concentration of 5% (v/v) and also containing 1% DIPEA base.
2. Clean and prepare an inorganic substrate to remove unreactive metal salts and to create –OH sites for coupling the silane compound. For glass, this can be done using acid or base washes. Formation of –OH groups on glass typically is done using piranha solution, which is 25% sulfuric acid and

15% hydrogen peroxide. For cleaning aluminum oxide sheets, use an alkaline detergent solution and apply sonication for 1 h, then wash with water.

3. Treat the inorganic substrate with the ICPTES solution by immersion and react at 50°C overnight with mixing.
4. Wash the derivatized substrate with toluene at least twice and then rinse a final time with acetone.
5. Dry the modified substrate at 120°C for 30 min in an explosion-proof oven.

Many other functional silane coupling agents are available from commercial suppliers, including hydroxyl, aldehyde, acrylate and methacrylate, and anhydride compounds. Substrate modification procedures similar to those discussed above can be used with these reagents to link a biomolecule to an inorganic surface or particle.

CHAPTER

14

Microparticles and Nanoparticles

The use of particles in biological assays and other applications dates back many decades (Singer and Plotz, 1956). Assays and detection systems made by coupling affinity ligands to particles of nanometer or micrometer diameter have been used in diagnostic tests and numerous other research procedures. Latex microspheres and gold nanoparticles were perhaps the earliest examples of solid-phase spheres used for these purposes. With the recent explosion in nanotechnology, the relevant particle size has shrunk by 2 to 3 orders of magnitude and the applications for particles have dramatically expanded. Nanoparticles and microparticles are used in agglutination tests and assays, particle capture ELISA methods, lateral flow tests, solid-phase assays, scintillation proximity assays, polymerase chain reaction (PCR) tests, superparamagnetic-based assays and magnetic separation systems and biosensors; as enhancers of Raman spectral signals; in light-scattering assays; in drug delivery applications; and as fluorescent labels or stains for detecting biological molecules (Bulte and Modo, 2008; Carregal-Romero *et al.*, 2012; Otsuka *et al.*, 2012; Wang *et al.*, 2012; Yurt *et al.*, 2012).

1. PARTICLE TYPES

The types of particles used in biological applications are extremely varied. Most often, they are nonporous in nature and spherical in shape. However, the material science revolution in nanotechnology has provided particle types and compositions of almost limitless shape and size, including spherical, amorphous, or aggregate particles, as well as elaborate geometric shapes like rods, tubes, cubes, triangles, and cones. In addition, new symmetrical organic constructs have emerged in the nanometer range that include fullerenes (e.g., Buckyballs), carbon nanotubes, and dendrimers, which are highly defined synthetic structures used as bioconjugation scaffolds in various applications. These specialized nanoparticle-like constructs are discussed in more detail in Chapter 8; Chapter 10, Section 10; and Chapter 16.

The chemical composition of particles can be just as varied as their shape. Commercial particles can consist of polymers or copolymers, inorganic constructs, metals, semiconductors, superparamagnetic composites, biodegradable constructs, synthetic dendrimers, and dendrons. Often, both the composition of a particle and its shape govern its suitability for a particular purpose. For instance, composite particles containing superparamagnetic iron oxide typically are used for small-scale affinity separations, especially for cell separations followed by flow cytometry analysis or fluorescence-activated cell sorting (FACS). Core-shell semiconductor particles, by contrast, are the basis for quantum dot nanoparticle labels, which provide intensely fluorescent detection reagents.

The original polymeric latex particles are still widely used for separation and detection. Polymers provide a matrix that can be swollen for embedding other molecules in their core, such as organic dyes or fluorescent molecules. Even nanoparticle quantum dots can be incorporated into larger latex particles to form highly fluorescent composite microparticles.

Such fluorescent or dyed latex particles are useful in multiplexed detection systems using suspension arrays (e.g., Luminex technology) (Armstrong *et al.*, 2000). In this application, dyes are incorporated within the beads having a range of different spectral properties to create a series of different colored particles. In addition, changing the amount of dye molecules within the beads or blending two or more dyes in a single particle population can form a gradient of different color compositions. Particle subpopulations of a particular color or emission wavelength and intensity can then be used to identify the type of target being measured in a suspension assay. Mixing together in a single solution such particle subpopulations having different colors permits multiple targets to be assayed simultaneously, wherein each particle type is identified by its color and correlated to the analyte being targeted. Flow-cytometry-based instruments are then used to detect and measure the particle color and assay result.

Dyed particles also are commonly used in diagnostic lateral flow tests (like the common home pregnancy test), as the colors can be seen with the eye without the need for special detectors. In this type of assay, antibodies or antigens are coupled to the dyed particles and a sample solution applied to the test strip carries them along within a membrane. The particles then are captured at points in the membrane that represent either a control or a positive sample result. Large numbers of color particles docking at these points within the membrane create the visual lines associated with these disposable tests.

Polymeric particles can be constructed from a number of different monomers or copolymer combinations. Some of the more common ones include polystyrene (traditional "latex" particles), poly(styrene/divinylbenzene) copolymers, poly(styrene/acrylate) copolymers, polymethylmethacrylate (PMMA), poly (hydroxyethyl methacrylate) (pHEMA), poly (vinyltoluene), poly(styrene/butadiene) copolymers, and poly(styrene/vinyltoluene) copolymers. In addition, by mixing into the polymerization reaction combinations of functional monomers, one can create reactive or functional groups on the particle surface for subsequent coupling to affinity ligands. One example of this is a poly(styrene/acrylate) copolymer particle, which creates carboxylate groups within the polymer structure, the number of which is dependent on the ratio of monomers used in the polymerization process.

Many of the common polymer particle types present a surface with hydrophobic character, such as the poly-aromatic styrene-containing ones. These in particular are better used with modifications on the particle surface to add charge or hydrophilicity, which masks the underlying polymer core. Some constructs of this type provide a grafted hydrophilic surface to limit the degree of nonspecific binding and form a more biocompatible particle that will not denature or bind protein through unwanted hydrophobic interactions. Some polymer particles are made from hydrophilic monomers and display better biocompatibility. Poly-HEMA is very hydrophilic due to an abundance of hydroxyl groups, and its properties are extremely biocompatible without further surface derivatization.

Inorganic particles are used extensively in various bioapplications, too. Gold nanoparticles long have been used as detection labels for immunohistochemical (IHC) staining and lateral flow diagnostic testing. These dark, dense particles provide single particle detection capability for sensitive staining techniques, especially in microscopy applications. In addition, the ease with which clumps of gold particles can be seen visually makes their use in diagnostic strip tests a very popular alternative to dyed latex particles (see Section 6 for a thorough review of gold conjugation methods).

Invariably, the use of particles in bioapplications involves the attachment of affinity capture ligands to their surface, by either passive adsorption or covalent coupling. The coupling of an affinity ligand to such particles creates the ability to bind selectively biological targets in complex sample mixtures. The affinity particle complexes can thus be used to separate and isolate proteins or other biomolecules or to specifically detect the presence of these targets in cells, tissue sections, lysates, or other complex biological samples.

The reactions used for coupling affinity ligands to nanoparticles or microparticles are basically the same as those used for bioconjugation of molecules or for immobilization of ligands onto surfaces or chromatography supports (see Chapter 15). However, with particles, size can be a major factor in how a reaction is performed and in its resultant reaction kinetics. Since particle types can vary from the low-nanometer diameter to the micron size, there are dramatic differences in how such particles behave in solution and how the density of reactive groups or functional groups affects reactions.

2. PARTICLE CHARACTERISTICS AND STABILITY

Particle size, surface composition, and density directly affect how a particle behaves in suspension. This in turn affects coupling protocols, especially in the handling and washing techniques used for particles during the conjugation process. Larger particles of micron size will generally settle over time just in normal gravity. As particle size decreases, however, a point is reached where a true colloidal suspension may occur, wherein the particles will not separate, no matter how long they sit in suspension. This typically happens when particle size gets to about 100 nm, and Brownian motion causes water molecules to collide with particles with high enough force-to-mass ratios to prevent them from settling under gravity. Many dense particles of less than 100 nm, such as silica, can still be separated from solution using a bench-top centrifuge; however, as particles approach the size of biological macromolecules, or around 10 nm, an ultracentrifuge would be required for separation. For a comparison of particle sizes and how they contrast to biomolecules, see Figures 14.1 and 14.2.

The forces acting on particles in suspension can mainly be explained by the Derjaguin, Landau, Verwey, and Overbeek (DLVO) theory, which describes the attractive van der Waals forces and repulsive electrostatic forces affecting their stability (Derjaguin and Landau, 1941; Verwey and Overbeek, 1952). A corollary to this theory indicates that for hydrophobic

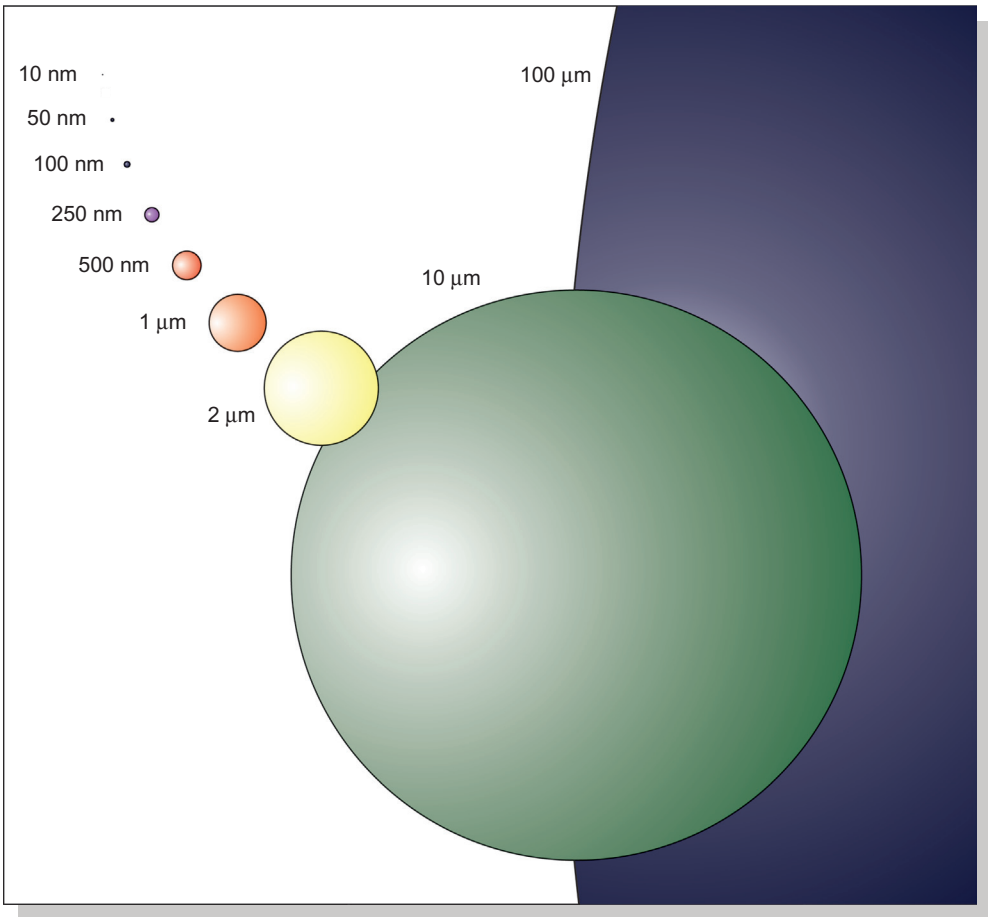

FIGURE 14.1 Particles commonly used in biological applications can range in size over three orders of magnitude, from as small as biological macromolecules (~10 nm) to approximately the diameter of cells and beyond (>10 µm). The diameter of a particle population can dramatically affect its behavior in solution.

surfaces, adding carboxylates can result in a stabilization of particles in solution and a prevention of aggregation through charge repulsion. Of course, this is true provided the pH of the solution is maintained above about pH 5, so that the carboxylates are not protonated, and their negative charge character is maintained. Often, without the presence of surface charge to create significant repulsive effects, many particles of commercial or research interest would aggregate and fall out of suspension rather quickly due to hydrophobic surface interactions and van der Waals forces (electrostatic attractions). The smaller the particle, the more significant the van der Waals attractive forces may become. See Figure 14.3.

By contrast, relatively hydrophilic particles like those made of pHEMA may maintain colloidal stability even at small size due to the "repulsive" effects of a water of hydration layer, which forms around each particle in aqueous solution and is energetically difficult to remove or penetrate. A closely bound water layer is apparently the result of hydrogen bonding and dipole interactions with polar surface groups, such as the hydroxyls on pHEMA particles. Many such hydrophilic particles can display stability at high salt concentrations, even if DLVO theory may predict aggregation (Molina-Bolívar, *et al.*, 1998).

The degree and type of surface charge can dramatically affect particle behavior in suspension. Latex particles that have a very low density of charged groups, for instance, may still present hydrophobic polymer surface areas large enough to cause instability. The type of charged groups on the particle surface can directly affect the magnitude of charge repulsion. In particular, the activation of carboxylate particles using an EDC/sulfo-NHS two-step reaction (Chapter 4, Section 1.2) will temporarily replace the negatively charged carboxylates with negatively charged sulfonates. The sulfonate groups on the sulfo-NHS ester intermediates create a stronger negative charge on the particle surface than the original carboxylates. In some cases, the increase in negative charge repulsion can result in an inability to pellet the particles by centrifugation after the activation step,

even if the particles could be separated by centrifugation before activation. This was true for 40-nm carboxylated silica nanoparticles in our hands (unpublished observations).

The charge repulsion effects between particles can be severely affected by the buffer and salt composition of the solution they are suspended in. Charges can be eliminated or neutralized by ionizable groups being protonated or unprotonated or by the concentration of ions in solution. For instance, lowering the pH of an aqueous solution below the pK_a of the surface carboxylates will result in them being protonated. With most particles, especially ones having hydrophobic surfaces, this will cause particle aggregation due to loss of surface negative charge. Similarly, a high salt concentration can effectively mask the charge character of a carboxylated particle by having too many positively charged ions associated with the surface negative charges. Most particle types that are stable in suspension due to like-charge repulsion can be made to aggregate if the pH is changed or the buffer or salt concentration is too high. Part of the challenge of successfully working with small particles is to maintain optimal solution characteristics to keep the particles dispersed throughout the conjugation process. This includes all activation, coupling, and washing steps that are used to conjugate an affinity ligand and subsequently use it in its intended application. Therefore, for each particle type being used to conjugate a ligand, one should first become knowledgeable of its physical and solution characteristics before performing any coupling reactions.

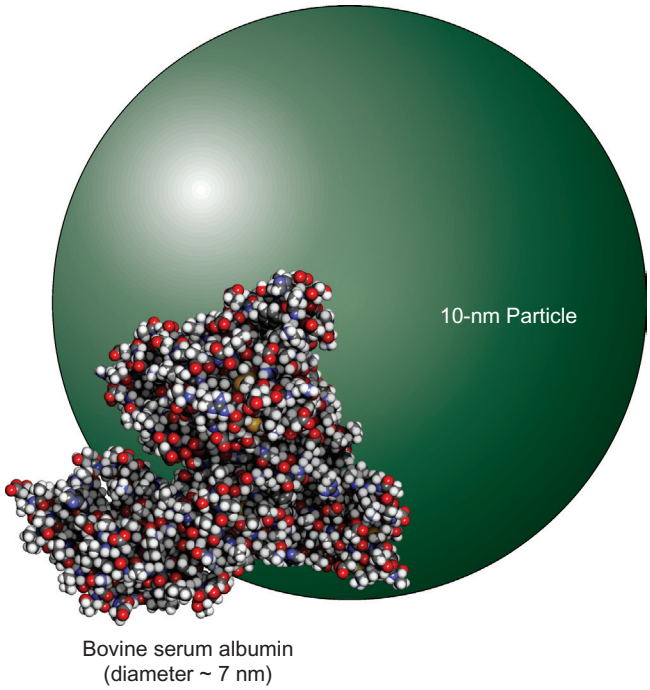

FIGURE 14.2 Comparison of the relative size of a 10-nm particle and the diameter of a typical protein, bovine serum albumin (BSA), at about 7 nm across its largest axis.

Another aspect of particle handling that should be worked out before actually coupling an affinity ligand is the best procedure to wash the particles and remove unreacted ligands or byproducts of a coupling reaction. With small quantities of particles, most often this can be done by centrifugation or, if working with very small nanoparticles, by gel filtration or size exclusion chromatography. Membrane filtration is also another option, especially for larger micron-sized particles. If the solution volume and quantity of particles are large enough, then tangential flow filtration is a viable alternative to other methods of separation.

Although many particle types can, in theory, be separated from solution by centrifugation, some particles may become irreversibly aggregated upon pelletting and should not be centrifuged under any circumstances. The relative hydrophobicity and degree of charge on a particle's surface directly affect their tendency to aggregate, and this property to a large extent governs whether the particle population can be resuspended successfully after centrifugation. In particular,

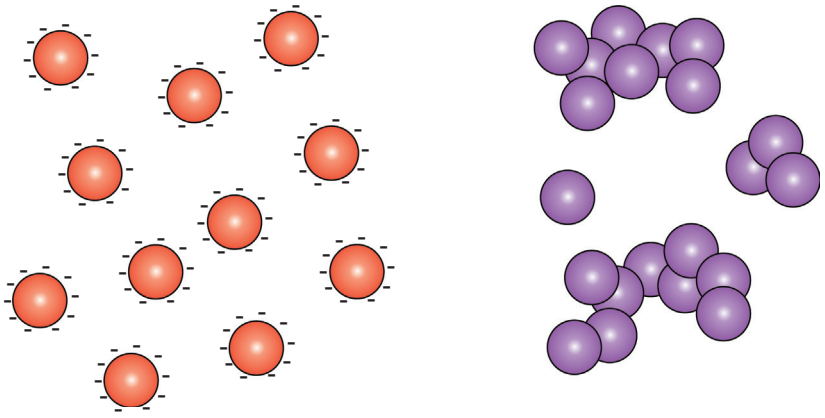

FIGURE 14.3 Small particles are often stabilized in aqueous solution by like-charge repulsion, which prevents particle aggregation and precipitation.

particles that contain higher densities of like surface charge, which functions to repulse and keep individual particles away from one another, typically can be resuspended successfully after centrifugation. To aid in resuspension, centrifuged particles should be subjected to sonication, by using either a bath sonicator or a sonic probe to disrupt the pellet. Vortex mixing should usually be avoided, as it is not very effective at re-dispersing small particles pelletted by centrifugation. Before using centrifugation or any other separation technique, it is best to contact the manufacturer to see whether they offer any guidelines for handling the particles.

3. PARTICLE CONCENTRATION

If individual particles in suspension are considered the equivalent of discrete molecules, then the molar concentration of a given particle suspension can be calculated based on the known particle diameter, density, and the mass of particles present. This allows particles to be treated similarly to other biomolecules with respect to determining concentration for conjugation purposes. However, there are important differences that should be recognized when working with particles as opposed to working with soluble macromolecules, like proteins. Since common commercial particles can vary in size from the molecular range (approximating the size of an antibody or ~10-nm diameter) to a scale 1000 times larger (or approaching the size of a cell at 10 µm), a change in diameter affects the concentration of particles as well as the effective concentration of surface functional groups present in suspension. Also potentially affected are the dispersion characteristics of particles as their size is changed (Suttiponparnit *et al.*, 2011).

In general, as particle size decreases, the molar concentration of particles in a constant volume of solution increases (for a given mass of particles). For instance, a 1-mg quantity of 1-µm latex microspheres represents far fewer particles than a 1-mg amount of 50-nm nanoparticles. Thus, the effective molar concentration of nanoparticles in solution will be much greater than the concentration of the same mass of microparticles (if both are suspended at the same mass quantity and in same volume of solution). In addition, as the diameter decreases for a given mass of particles, the ratio of a particle's surface area to mass increases. This means that the total surface area available for conjugation on the nanoparticles is much greater than the total surface area present on the microparticles. If both particles contain the same functional groups on their surfaces for coupling affinity ligands (i.e., carboxylates), then for the same mass of particles the effective concentration of these functional groups in solution is much greater for the nanoparticles than the concentration of the same groups in a given solution for the microparticles (assuming both have about the same surface density or "parking area" of the carboxylate functional groups).

Thus, conjugation reactions performed with nanoparticles should take into account a potentially greater reactivity than the same reactions performed using microparticles, due to the higher effective concentration of functional groups present in solution for the nanoparticles. As particle size decreases and particle concentrations increase, the available surface area increases, and the effective concentration of reactive groups increases along with it. All of these factors must be considered when optimizing conjugation reactions to particles. This means that an optimal protocol for coupling proteins to 1-µm carboxylated microspheres will most likely have to be re-optimized for use with carboxylated nanoparticles.

The following sections discuss many of the major particle types and provide bioconjugation options for the coupling of ligands to the surface of functionalized particles. Some additional nanoparticle constructs, including gold particles, dendrimers, carbon nanotubes, Buckyballs and fullerenes, and quantum dots are discussed more fully elsewhere (see Section 6 in this chapter, as well as Chapter 8; Chapter 10, Section 10; and Chapter 16).

4. POLYMERIC MICROSPHERES AND NANOSPHERES

Perhaps the most common particle type used for bioapplications is the polymeric microsphere or nanosphere, which consists basically of a spherical, nonporous, "hard" particle made up of long, entwined linear or crosslinked polymers. Creation of these particles typically involves an emulsion polymerization process that uses vinyl monomers, sometimes in the presence of divinyl crosslinking monomers (Kumacheva and Garstecki, 2011). Larger microparticles are usually built from successive polymerization steps through growth of much smaller nanoparticle seeds. The investigation of particle surfaces by high-resolution electron microscopy can often reveal the presence of numerous entangled, amorphous nanoparticles making up the morphology of much larger nanospheres or microspheres. Instead of being smooth spheres, the surfaces of most polymeric particles are actually torturous and made up of many craters, pits, and crevasses, which may appear featureless under lower-resolution imaging.

Some of the most common forms of polymeric particles consist of polystyrene or copolymers of styrene, like styrene/divinylbenzene, styrene/butadiene, styrene/acrylate, or styrene/vinyltoluene. Other common

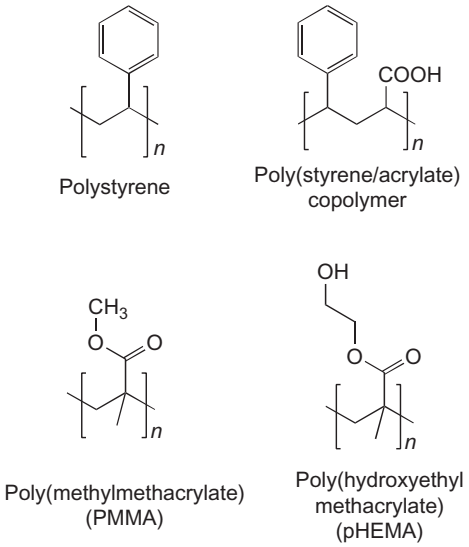

FIGURE 14.4 Some of the most common particles consist of these polymers.

polymer supports include polymethylmethacrylate (PMMA), polyvinyltoluene, poly(hydroxyethyl methacrylate) (pHEMA), and the copolymer poly(ethylene glycol dimethacrylate/2-hydroxyethylmetacrylate) [poly(EGDMA/HEMA)] (Ayhan *et al.*, 2002) (Figure 14.4). The types of monomers used to form the polymers ultimately govern the final particle characteristics. If the monomers are hydrophobic, such as those that form most of the styrene-based particles, then the resultant particle surfaces will be hydrophobic, as well. The inclusion of hydrophilic monomers, including charged groups and polar constituents, will create more hydrophilic character on the surface. In addition, since many particles are polymerized in the presence of detergents, particles typically have detergent molecules non-covalently adsorbed on their surfaces, unless they have been purposely removed by extensive cleaning after polymerization.

Polymeric particles traditionally have been called "latex" beads or spheres, probably from the classic definition of an "emulsion of rubber or plastic globules in water." However, due to the polymeric diversity of these particles, even those that consist of a styrene base, it is best to identify the particle type by its exact chemical composition.

Polymeric particles can also be further diversified by their surface compositions. Even traditional polystyrene particles contain additional groups on their surfaces due to the polymerization reaction used to create them. For instance, nearly all such particles contain some negatively charged sulfonate groups, which are the result of the catalyst, persulfate, used to initiate the polymerization process. In addition, many particles contain non-covalently adsorbed detergent molecules that can add amphipathic character to the particle surface, depending on the type of detergent used during the polymerization reaction. Detergents can be removed by extensive washing after the manufacturing process, but this may be a source of variability from manufacturer to manufacturer.

Another way of altering surface characteristics is through the purposeful addition of secondary polymers onto a polymeric core by graft copolymerization, adsorptive coating, or covalent attachment of another polymer type (Charleux *et al.*, 2011; Pichot *et al.*, 2011). Adding hydrophilic coatings onto hydrophobic particle cores is often carried out to promote biocompatibility and limit nonspecific interactions with proteins or other biomolecules. Examples of hydrophilic coat polymers that have been used for this purpose include poly(ethylene glycol) (PEG), poly(vinyl alcohol) (PVA), poly(acrylic acid), poly(methacrylic acid), poly(acrylamide), and poly(vinyl pyrrolidone). PEGylation of nanoparticles has been used to create biocompatible surfaces for imaging and therapy applications *in vivo* (Jokerst *et al.*, 2011). Hydrophilic modification of hydrophobic particle cores can aid in blocking the nonspecific binding potential that the core may have toward proteins or other biological molecules. It can also alleviate the tendency of particles to aggregate in aqueous solution by creating a hydrated shell around each particle, which helps keep them separated and in suspension. For example, Harper *et al.* (1995) described the copolymerization of a poly(ethylene oxide) methacrylate monomer (PEG-type) with styrene to create polystyrene particles with hydrophilic surfaces for the attachment of cells.

Covalent attachment of hydrophilic spacer arms to particles is another way of masking the hydrophobic character of the underlying surface while making a particle more biocompatible. Spacers of this type are typically short organic molecules containing a number of polar groups along the chain which are able to interact with the surrounding aqueous environment and limit non-specific protein adsorption on the particles. A common spacer arm construction consists of a PEG chain that may also include a short hydrophobic straight chain linker, which attaches to the particle surface. To provide an attachment site for affinity ligands to the spacer, a functional group can be included on the outer end of the PEG polymer, such as a carboxylate group. These functional groups provide sites for covalent coupling of affinity ligands, including proteins, while the unmodified PEG chains create a hydrophilic "lawn" to limit nonspecific interactions. The best configuration of this spacer type is to have about 10% of the spacers terminate in a carboxylate group while the rest of them terminate in a PEG hydroxyl or a PEG methyl ether group (mPEG). This design has been used with success

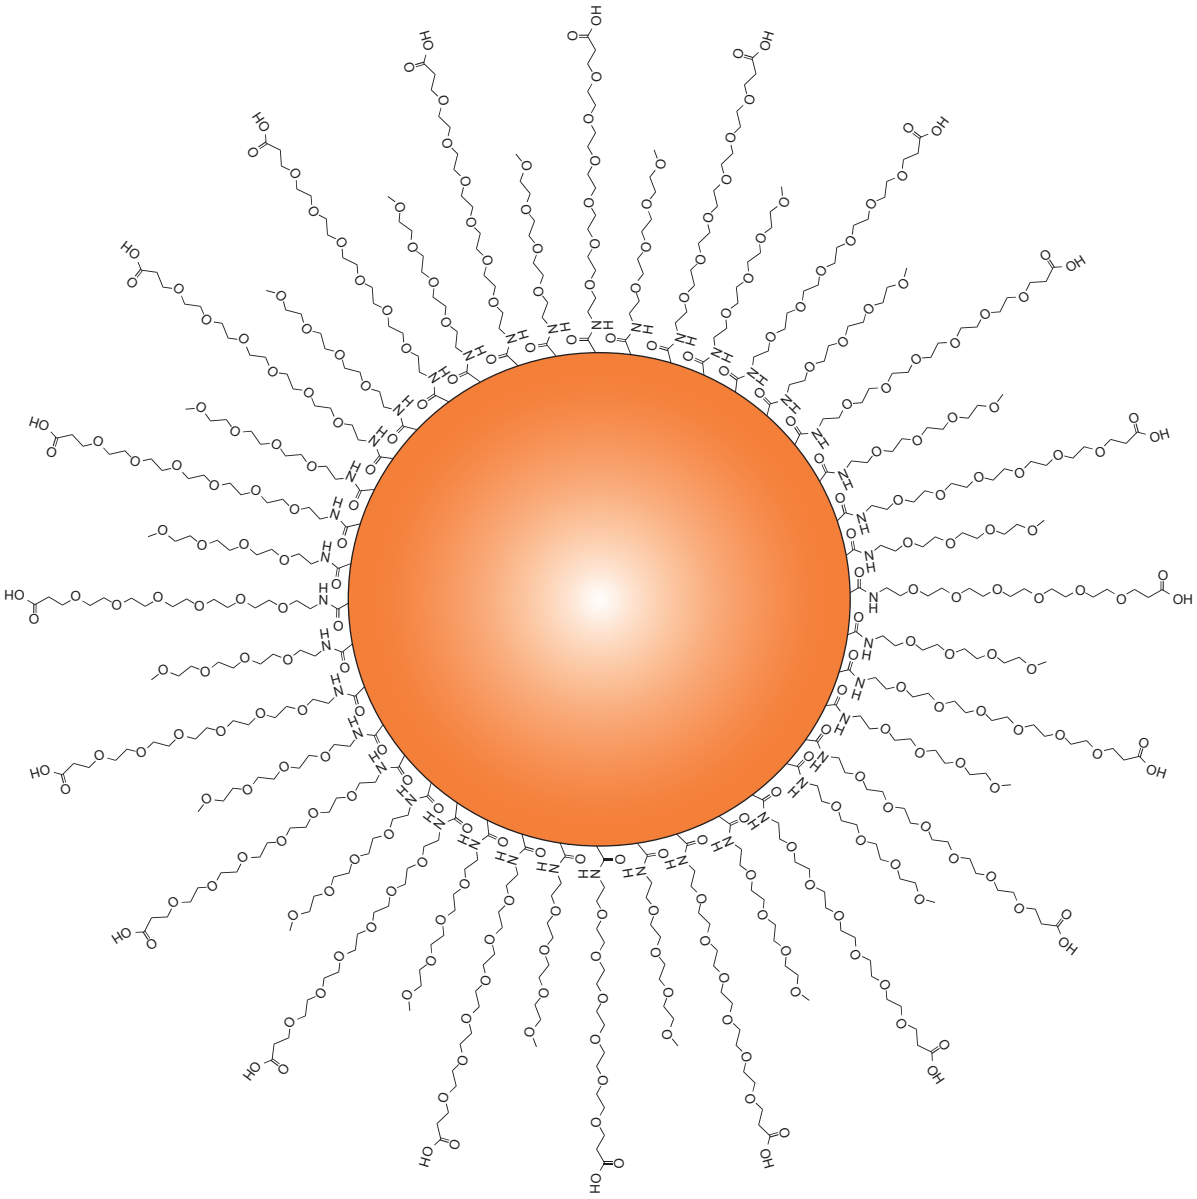

FIGURE 14.5 A method of making particles biocompatible includes the use of PEG-based spacers. A lawn of mPEG molecules is interspersed with some longer PEG chains that terminate in carboxylate groups for coupling amine-containing molecules. The result is an extremely hydrophilic surface with low non-specific binding character.

with other surface types, such as gold nanoparticles or planar surfaces (Prime and Whitesides, 1991), and it can be adapted to polymer particles with little difficulty (Figure 14.5).

4.1. Passive Adsorption

One of the simplest methods of attaching biomolecules to hydrophobic polymeric particles is the use of passive adsorption. Some of the earliest examples related to the use of particles in immunoassays include the use of non-covalently adsorbed antibody or antigen onto latex microspheres. Protein adsorption onto hydrophobic particles takes place through strong interactions of nonpolar or aromatic amino acid residues with the surface polymer chains on the particles with concomitant exclusion of water molecules. Since proteins usually contain hydrophobic core structures with predominately hydrophilic surfaces, their interaction with hydrophobic particles must involve significant conformational changes to create large-scale hydrophobic contacts. These conformational changes often result in complete denaturation of the first protein layer to be adsorbed onto the particles. Subsequent protein

molecules which bind and add to this initial layer are adsorbed through protein–protein binding or aggregation events, which ultimately result in the formation of protein clusters in which the outer layers of protein have more of a native conformation and activity (Butler, 2000a, 2000b).

Due to this tendency of proteins to form multilayer coatings on hydrophobic surfaces, the amount of excess protein beyond the particle saturation point (theoretical monolayer density for the protein type) added during adsorption processes should be limited. If extremely large excesses of protein are added to particles, highly unstable constructs may result which may continually leach off loosely adsorbed protein. Most protocols recommend a protein concentration of about 3- to 10-times excess of protein over the calculated monolayer concentration for the particles used. An estimate of the maximal amount of a given protein that can bind as a monolayer to a particle surface can be determined by the fact that bovine serum albumin (BSA) (MW 67 kDa) has an adsorption capacity of about 3 mg/m^2 of particle surface. A larger protein like an antibody (IgG; MW 150 kDa) has a maximal adsorption density of about 2.5 mg/m^2 of particle surface. To translate this into a real-world example, 1 g of 1-μm polystyrene microspheres can adsorb about 18 mg bovine serum albumin (BSA) or about 15 mg IgG (Cantarero *et al.*, 1980). Knowledge of a particle's surface area per gram will permit reasonable estimates of maximal adsorption capacity for a given protein relative to the size of an antibody or albumin molecule.

Passive adsorption has been studied extensively as it relates to the immobilization of antibody molecules onto microplates (polystyrene) or microspheres (hydrophobic beads of various compositions). Although the denaturing effect of passive adsorption of proteins onto surfaces was known since 1956 when Bull studied the adsorption of albumin onto glass, it was not widely recognized as being detrimental until a number of subsequent studies were published. See in particular Butler *et al.* (1992), which investigates the physical and functional behavior of capture antibodies adsorbed on polystyrene; Butler J.E. (2000a), which provides a summary of the effects of the adsorption of various proteins on hydrophobic surfaces; Cantarero *et al.* (1980), which discusses the adsorptive characteristics of proteins for polystyrene surfaces; and Butler *et al.* (1997), which compares the effect of passive adsorption on the antigen specificity of immobilized antibody molecules.

The detrimental effects on biomolecules as a result of passive adsorption onto hydrophobic surfaces can be dramatic. Butler *et al.* (1993) determined that over 90% of monoclonal antibodies and about 75% of polyclonal antibodies against fluorescein were denatured upon adsorption onto polystyrene surfaces. In addition, Bagchi and Birnbuam (1980) observed that IgG was optimally adsorbed to poly(vinyltoluene) particles at a pH value near the antibody's pI, indicating that the interactions were entirely hydrophobic in nature and did not depend on charge interactions. Once the antibody was adsorbed, however, it was tightly bound to the surface, provided that the pH was maintained at the initial adsorption point. If any pH cycling was done, such as may occur with some wash steps, the adsorbed antibody had a tendency to leach off the surface, demonstrating the non-covalent nature of the interaction.

Protein adsorption to hydrophobic polymer particles should thus be done at or near the isoelectric point of the particular protein to ensure that the highest density of protein is attached to the particles. Proteins at their isoelectric point exist in the most collapsed conformation possible, because charge repulsion effects do not play as significant a role on overall globular structure. Upon adsorption under isoelectric conditions, each protein then can bind to the polymer surface at maximal density. Therefore, most suggested buffer cocktails used for passive adsorption recommend pH conditions somewhere in the pI range of the protein. Since many proteins have a range of different biological modifications (post-translational) resulting in a range of pI values, some optimization may need to be done to determine the best pH conditions to use for an adsorption process.

Another factor to consider is the amount of protein available for adsorption. If expensive antibody in very small amounts is used to passively adsorb to polymeric particles, there is often not enough antibody available to saturate the particle surface. In this case, another carrier or blocking protein may be added to the mixture to take up otherwise unoccupied sites on the particle surface. This will prevent particle aggregation that may occur if low concentrations of protein are used in the adsorption process. Carrier proteins frequently used for this purpose include albumin or polyclonal IgG pools, such as bovine gamma globulin. Other standard protein blocking agents may also be used for blending with the desired antibody, such as casein, non-fat dried milk proteins, fish serum, etc.

The polymeric particle composition also plays a significant role in the amount of protein adsorbed and its stability and activity after immobilization. In general, copolymer blends in which a hydrophobic monomer is polymerized with a charged monomer (such as acrylic acid or methacrylate) create a surface that has both hydrophobic character along with areas of charge. Proteins adsorbed onto these copolymer particles interact with the surface through hydrophobic interactions and positive–negative charge attraction. The result is less protein denaturation upon adsorption and better retention of activity after

immobilization. A comparison of protein adsorption onto pure polystyrene and several other copolymer particle types by Bale *et al.* (1989) resulted in the following order of binding affinity: polystyrene > polystyrene/PMMA copolymer > PMMA > polystyrene/polyacrylic acid copolymer.

Thus, pure hydrophobic polymer compositions adsorb proteins very strongly but have the greatest tendency to denature protein at the initial protein–surface interface. Copolymers containing some polarity or negative charge character bind protein less avidly, but result in better retention of activity. The inclusion of some polar hydrophilic groups within an overall hydrophobic surface structure has been used with success for polystyrene microplates, as most of the so-called high binding plates contain a population of polar constituents on the well surfaces, allowing both hydrophobic and charge or dipole interactions to occur.

The following protocol for passive adsorption is based on methods reported for use with hydrophobic polymeric particles, such as polystyrene latex beads or copolymers of the same. Other polymer particle types may also be used in this process, provided they have the necessary hydrophobic character to promote adsorption. For particular proteins, conditions may need to be optimized to take into consideration maximal protein stability and activity after adsorption. Some proteins may undergo extensive denaturation after immobilization onto hydrophobic surfaces; therefore, covalent methods of coupling onto more hydrophilic particle surfaces may be a better choice for maintaining native protein structure and long-term stability.

Protocol

1. Dilute the particles to a mass concentration of 10 mg/ml (1%) in coating buffer at a pH near the pI of the protein being adsorbed. If particle aggregation becomes a problem, the initial particle concentration may be reduced to 5 mg/ml. Some typical coating buffer suggestions include: (a) 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4 (PBS); (b) 50-m*M* sodium borate, pH 8.5; (c) 50-m*M* sodium acetate, pH 3.6 to 5.6; (d) 25-m*M* MES, pH 6.1; or (e) 50-m*M* sodium bicarbonate, pH 8.5 to 9.5. NaCl may be added to any of these buffers at a final concentration of 0.15-*M* to promote protein stability, if required. However, avoid the use of detergents or chaotropic agents, as these will compete with protein adsorption or reduce the strength of hydrophobic interactions, thus limiting the yield.
2. Dissolve the protein to be adsorbed in coating buffer at a concentration such that when the solution is mixed with the particle suspension, the appropriate protein concentration is reached to obtain an excess of about 3 to 10 times over the maximal monolayer density for that protein on the particles (see previous discussion). Note: A good strategy is to perform a protein titration study, wherein a range of protein concentrations are tried with a given particle quantity. For instance, using a 300-nm latex particle, a suitable set of trial experiments would employ protein concentrations in the range of about 10 to 200 µg protein per mg particles. Plotting the amount of protein charged to the coating reaction *versus* the amount bound will provide data to identify the optimal protein concentration to be used.
3. With rapid mixing, add protein solution to the particle suspension. For small volumes, mixing can be performed by pulling the solution up and down in a pipette tip or by vortexing. For larger volumes, a stir bar or paddle may be used. Some protocols recommend adding the particles to the protein solution to obtain the best initial mixing rate, thus ensuring even particle coating throughout the particle suspension. The key is rapid and efficient mixing to create a homogeneous mixture of protein and particles, so adsorption can occur uniformly on each particle.
4. Mix the suspension for 1 h at room temperature.
5. Remove excess protein by centrifugation or tangential flow filtration. Many particles may be pelletted successfully using a tabletop centrifuge, especially if the particle size is above about 150 nm in diameter. If particle clumping is a problem upon pelletting or the particle size is too small to be effectively pelletted, then filtration is the better alternative. Centrifuge and wash the particles at least twice with coating buffer to ensure complete removal of non-bound protein. Complete re-suspension of the particles may be accomplished by the use of sonication, especially through the use of a sonic probe dipped into the solution.
6. Resuspend the particles to a final concentration of 1% in coating buffer containing a preservative. Avoid changing the composition of the storage buffer from that used to coat the protein, as any pH or compositional changes often result in elution of some of the adsorbed protein.
7. Determine the amount of adsorbed protein on the particles by using a suitable protein assay technique, such as the bicinchoninic acid (BCA) protein assay (Thermo Fisher).

4.2. Covalent Coupling to Polymeric Particles

Many particle types contain functional groups that are built into the polymer backbone and displayed on their surface. The quantity of these groups can vary widely depending on the type and ratios of monomers used in the polymerization process or the degree of secondary surface modifications that have been

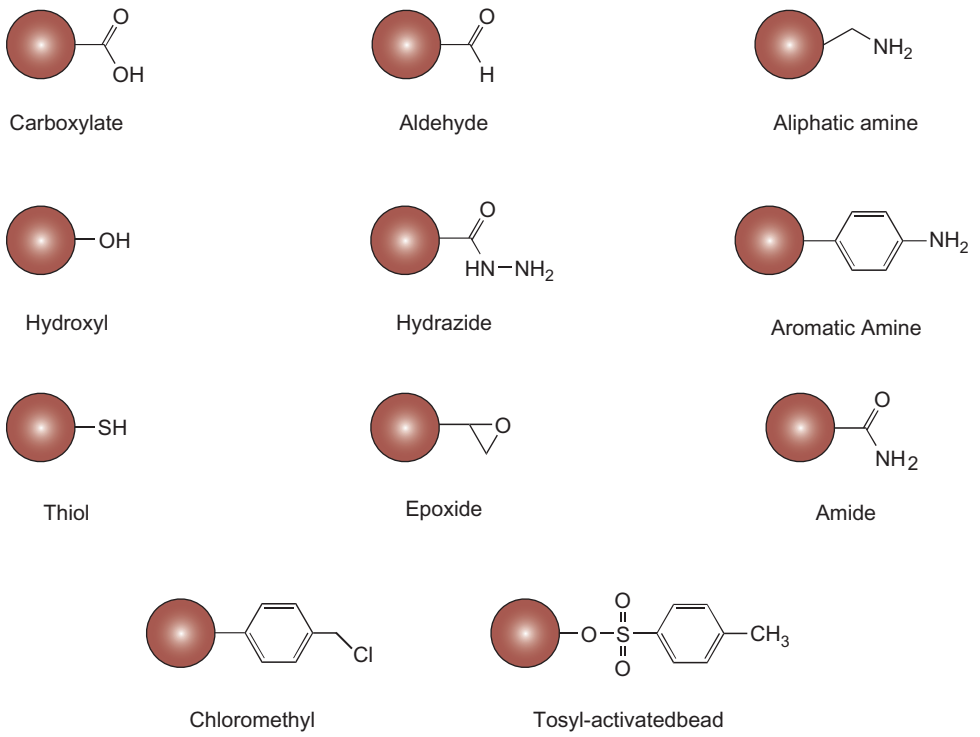

FIGURE 14.6 Common functional groups or reactive groups on particles that provide the ability to couple proteins or other ligands.

performed. Some common particle functionalities are shown in Figure 14.6. Many of these functionalized particles can be used to couple covalently biomolecules through the appropriate reaction conditions (Illum and Jones, 1985; Arshady, 1993). For each type of particle, manufacturers may offer several different densities of functional groups for different applications. The modification of particle surface characteristics and the functionalization of particles for covalent attachment of affinity ligands or targeting molecules requires the use of activation and coupling reactions to produce the most optimal particle derivatives for the intended application (Mout *et al.*, 2012). The following sections describe the reactive groups and immobilization methods that can be used with microparticles and nanoparticles. The reader also should refer to Chapter 15, which describes additional immobilization techniques and similar procedures for the coupling of affinity ligands onto porous chromatography supports.

Coupling to Carboxylate Particles

One of the more common particle types is the carboxylate particle, which is typically created by copolymerization or grafting with acrylic acid or methacrylic acid monomers. However, the characteristics of carboxylate particles can vary between manufacturers and particle sources due to the differences in surface density of carboxylate groups present. A measurement of chemical density on particle surfaces is called the "parking area," referring to the average area in $Å^2$ occupied by each functional group. A brief survey of carboxylate particles from different manufacturers indicates that the average carboxylate parking area can vary widely from about 10 $Å^2$ (0.1 nm^2) to over 125 $Å^2$ (1.25 nm^2). One carboxylate group every 125 $Å^2$ is equivalent to about one carboxylate for every square having dimensions of 11.1 Å × 11.1 Å (1.11 nm × 1.11 nm), or the space that might be occupied by one small molecule on the particle surface. Note: The amino acid lysine occupies a space of about 8.7 × 4.8 Å, whereas a macromolecule such as albumin (67 kDa) has an effective molecular diameter of about 70 Å (7 nm), and an IgG molecule (150 kDa) has a diameter of about 110 Å (11 nm). A lone carboxylate functional group sticking off the surface of a particle has a diameter of about 2.2 Å. At a density of one carboxylate every 125 $Å^2$, there still is considerable uncharged polymer surface exposed, which could be a source for nonspecific binding, especially if the underlying polymer structure has hydrophobic character. A protein coupled to a carboxylate on such a particle could unfold through interactions with the exposed hydrophobic polymer surface and become denatured. Conversely, at the high end of carboxylate density, there would be about one carboxylate present for every 10 $Å^2$ (0.1 nm^2) of particle surface. For the covalent coupling of proteins, this high-density surface

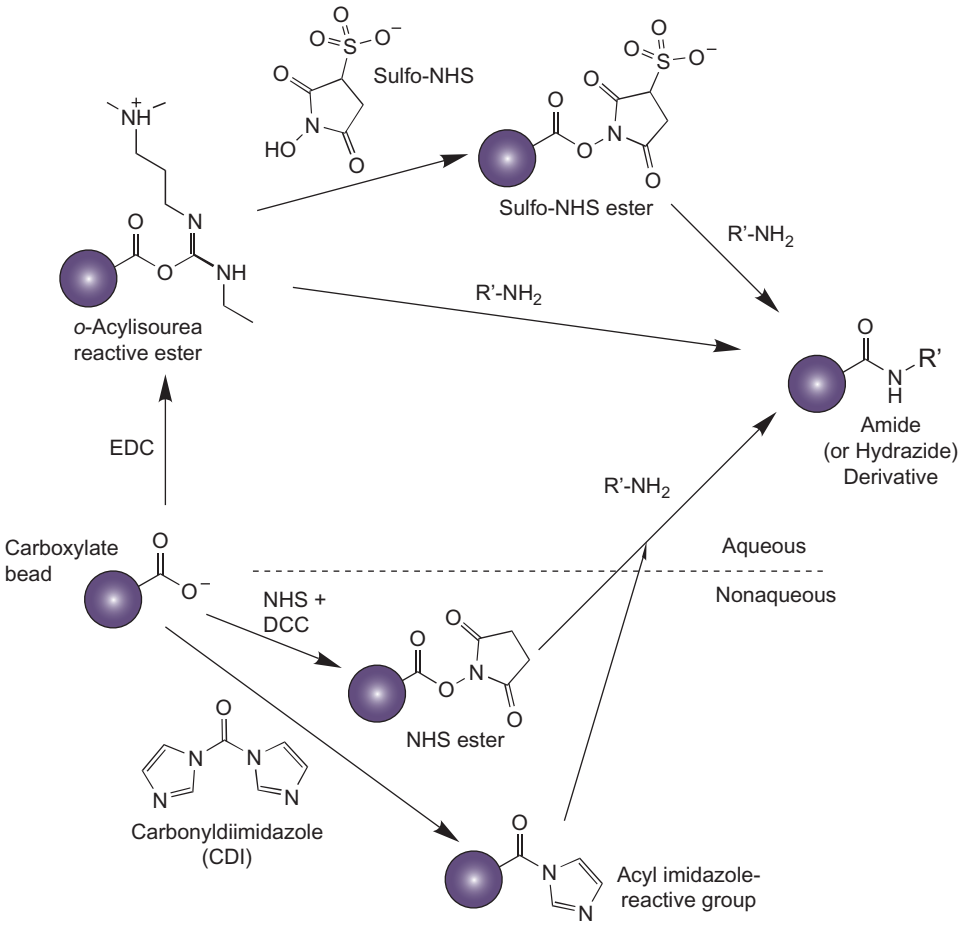

FIGURE 14.7 Carboxylate particles can be coupled to amine-containing molecules using a number of reaction strategies. The most frequently used method involves an aqueous two-step coupling process using EDC and NHS or sulfo-NHS to form an amide bond with a protein or other molecules. It proceeds through an intermediate (sulfo)NHS ester, which has better reactivity for coupling amines than the initial EDC reactive ester. Organic solvent activation processes using NHS esters or acyl imidazole reactive groups can also be used with solvent-stable particles to result in the same product with an amine-containing molecule.

would provide more reactive sites for conjugation, while more effectively masking the underlying polymer surface with negative charges. This may help to maintain a stable particle suspension through negative charge repulsion as well as prevent nonspecific binding or protein denaturation on the surface.

Carboxylate particles can be activated by a number of strategies that yield reactive intermediates capable of coupling with nucleophiles in proteins and other biomolecules. Figure 14.7 illustrates some of the reactions that can be used for coupling amine-containing molecules to carboxylate particles, all of which form stable amide linkages with the particle. The water soluble reactions can be carried out in entirely aqueous conditions, both for activation and coupling. For some reactions, however, the activation process must be carried out under nonaqueous conditions to prevent hydrolysis of the activator or active intermediate. Activation in organic solvent is an option for particles that remain stable in nonaqueous environments. Some polymer particles, especially non-crosslinked ones, may unacceptably swell or partially dissolve in organic solvent and become damaged by such treatment. Polymer particles prepared using a crosslinking monomer, however, can typically tolerate organic solvents without damage.

By far the most common reaction strategy for coupling proteins and other amine-containing molecules to carboxylate particles is through an aqueous, carbodiimide-mediated process using EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide). This reaction can be performed by use of a single-step coupling method (having all components in the reaction at once) or by use of a two-step reaction that better controls the immobilization course (see Chapter 4, Section 1.2, for additional information). Of all the crosslinking methods used in bioresearch applications today, this relatively simple coupling procedure is the most frequent conjugation reaction carried out with proteins and other

amine-containing molecules for immobilization onto carboxylate particles. During this reaction, the carboxylate groups on the particles first are activated with the water soluble carbodiimide to create intermediate EDC esters. These esters are reactive directly with amines on proteins or other molecules to create amide bond linkages, which is the desired outcome. However, there are other side reactions that can occur. In aqueous solution, the intermediate ester might hydrolyze back to a carboxylate without coupling ligand. Also, if the density of carboxylates is high on the polymeric particles (e.g., small parking area), then the EDC esters can also undergo reaction with a neighboring carboxylate group to form anhydrides (Wang *et al.*, 2011), but these groups also are very reactive toward amines (Chapter 4, Section 1.1). EDC activation of carboxylate particles also can be used with the addition of NHS or sulfo-NHS in a two-step reaction, which results in the formation of secondary intermediate reactive groups, which are NHS esters or sulfo-NHS esters, respectively. The formation of these secondary esters results in a more stable intermediate in aqueous solution than the one initially formed with EDC therefore, the subsequent coupling reaction with proteins typically proceeds with higher yield than with the use of EDC alone (Figure 14.7). In addition, by forming the secondary (sulfo)NHS esters, excess EDC can be removed from the particles before adding protein, thus preventing carbodiimide-mediated protein polymerization due to the presence of both amines and carboxylates on most proteins (Staros, 1982; Borque *et al.*, 1994; Bonfield *et al.*, 2005).

For particle conjugation, it is important to maintain a repulsive force between particles to stabilize the colloidal suspension, even during the activation and coupling reactions. For this reason, the use of sulfo-NHS instead of NHS in this reaction results in an intermediate ester that is strongly negatively charged. The sulfonates on the sulfo-NHS esters actually are more effective at keeping particles from aggregating than the original carboxylates; therefore, the reactive intermediate particles easily can be purified from excess reactants and then mixed with protein for coupling. If the nonsulfonated NHS is used in this reaction, the uncharged intermediate NHS ester may cause unacceptable particle aggregation, depending on the particle type, although uncharged NHS has been used widely with success.

The following protocols for coupling amine-containing molecules to carboxylated particles represent viable starting points for optimizing a method that works best for the particular molecule or protein being immobilized. The single-step method using EDC alone is appropriate for use in coupling molecules having one or more amines present without any carboxylates. It works especially well for small organic molecules, such as haptens, 5′-amino-modified oligonucleotides, and amine-containing steroid derivatives (Hager, 1974; Quash *et al.*, 1978; Nathan and Cohn, 1981; Fuller *et al.*, 2006). If the molecule being coupled has both amines and carboxylates, such as proteins, then it is best to use the two-step method, which eliminates excess EDC before the addition of ligand; otherwise, unacceptable ligand polymerization may take place.

Single-Step EDC Coupling Protocol

1. Wash particles (e.g., 100 mg of 1-µm carboxylated latex beads) into coupling buffer (i.e., 50-m*M* MES, pH 6.0, or 50-m*M* sodium phosphate, pH 7.2; buffers with pH values from pH 4.5 to 7.5 may be used with success; however, as the pH increases the reaction rate will decrease). Suspend the particles in 5 ml coupling buffer. The addition of a dilute detergent solution may be carried out to increase particle stability (e.g., final concentration of 0.01% SDS). Avoid the addition of any components containing carboxylates or amines (such as acetate, glycine, Tris, imidazole, etc.). Also, avoid the presence of thiols (e.g., dithiothreitol (DTT), 2-mercaptoethanol), as these will react with EDC and effectively inactivate it.
2. Dissolve the amine-containing ligand to be coupled in 5 ml coupling buffer at a concentration sufficient to provide a 1- to 10-fold molar excess of ligand over the maximal calculated carboxylate group concentration for the amount and type of beads used. For particle manufacturers reporting a carboxylate concentration in meq/g, this is equivalent to µmoles/mg.
3. Combine the ligand solution with the particle suspension and mix thoroughly.
4. Add 100 mg EDC and mix to dissolve. To facilitate faster dissolution, EDC may be dissolved immediately before use as a concentrated stock solution in reaction buffer and then an aliquot of this solution added to the particle suspension to obtain the correct final concentration.
5. React at room temperature 2 to 4 h with mixing.
6. Wash the beads and resuspend them in coupling buffer containing 100-m*M* of an amine-containing, hydrophilic quenching molecule to block excess reactive sites (i.e., ethanolamine or Tris).
7. Wash beads and store in an appropriate buffer containing a preservative.

Two-Step EDC/Sulfo-NHS Coupling Protocol

An alternative to this procedure was used by Kulin *et al.* (2002) for coupling antibodies to carboxylated microspheres, which provides different buffer conditions and activation with EDC without the use of sulfo-NHS or NHS.

Activation

1. Wash particles (e.g., 100 mg of 1-μm carboxylated latex beads) into coupling buffer (50-m*M* MES, pH 6.0). Suspend in 5 ml coupling buffer. The addition of a dilute detergent solution may be done to increase bead stability and prevent clumping (e.g., 0.01% SDS). Avoid the addition of any components containing carboxylates or amines (such as acetate, glycine, Tris, imidazole, etc.). Also, avoid the presence of thiols (e.g., DTT, 2-mercaptoethanol), as these will react with EDC and effectively inactivate it.
2. Add 100 mg of EDC and 100 mg of sulfo-NHS. Mix to dissolve. To facilitate faster dissolution, EDC and sulfo-NHS may be dissolved immediately before use as a concentrated stock solution in reaction buffer and then an aliquot of this solution added to the particle suspension to obtain the correct final concentration.
3. React for 15 min at room temperature.
4. Quickly wash beads 2 times with coupling buffer using centrifugation and resuspend using a sonic probe in 5 ml of the same buffer.

Coupling

5. Dissolve protein to be coupled in 5 ml coupling buffer at a concentration sufficient to provide 1- to 10-fold molar excess of ligand over the maximal calculated monolayer concentration for the amount and type of beads used. For particle manufacturers reporting a carboxylate concentration in meq/g, this is equivalent to μmoles/mg. The optimal protein concentration should be optimized. Note: Too low a protein concentration may result in particle crosslinking. For coupling of expensive antibodies that may not be available in enough quantity to reach the optimal molar ratio on the particles, another protein (i.e., bovine gamma globulin or BSA) may be added to take up remaining reactive sites.
6. Combine the protein solution with particles and mix thoroughly.
7. React at room temperature 2 to 4 h with mixing.
8. Wash beads with coupling buffer and resuspend in the same buffer containing 100-m*M* of an amine-containing, hydrophilic quenching molecule to block excess reactive sites (i.e., ethanolamine or Tris).
9. Wash beads and resuspend in an appropriate buffer for storage.

Coupling to Amine Particles

Primary amine-containing polymeric particles are available from a number of manufacturers and have either aliphatic or aryl amine groups on their surface. Occasionally, a particle type may have secondary or tertiary amines present, but these should be avoided for covalent coupling, as primary amines typically give better reaction yields than secondary amines and tertiary amines are unreactive.

Primary amine particles may be used for covalent immobilization using a number of reaction routes (Figure 14.8). A carbodiimide-mediated coupling process may be used, as described above for carboxylate particles, but this time it is done by activation of a carboxylate group on the ligand and subsequent amide bond formation with the amines on the particles. A single-step EDC reaction strategy will work well for small ligands containing one or more carboxylates with no amines. However, for carbodiimide-mediated protein coupling to amine particles, the protein should first be activated with EDC and sulfo-NHS according to the method of Grabarek and Gergely (1990) and then the activated intermediate added to the amine particles for conjugation (see Chapter 4, Section 1.2, for the activation protocol). This type of two-step reaction will prevent protein polymerization during the coupling process. Add a quantity of activated protein to the amine particles to result in a 1- to 10-times molar excess over the total molar quantity of amines present on all the particles used in the reaction.

Coupling to Amine Particles Using Crosslinking Agents

Another possible route to coupling ligands to amine particles is to use a bifunctional crosslinking agent to react with the amines and provide another reactive group at the other end to couple with the ligand. In this approach, virtually any reactive group desired can be formed on the particles (Trindade and da Silva, 2011). Two strategies can be used with crosslinking agents: (1) use of a homobifunctional reagent that contains the same reactive groups on either end, or (2) use of a heterobifunctional compound that contains different reactive groups on each end.

A homobifunctional amine-reactive compound can be used initially to modify the amine groups on particles, while leaving the remaining amine-reactive groups available to couple with ligands. This type of reaction must be carried out with the crosslinker in great excess to prevent polymerization of the amine particles themselves. There must be enough crosslinker present during the activation stage to avert the free end from attaching to another particle before that particle's amines are modified with other crosslinkers.

Once the amine particles are modified with a homobifunctional crosslinker, the excess reagent is removed so that when the ligand is added, it doesn't become polymerized, particularly if it has more than one amine (e.g., proteins). Homobifunctional crosslinkers containing NHS esters, imidoesters, or aldehyde groups on each end can be used for this type of coupling process. The following protocol illustrates this method using glutaraldehyde.

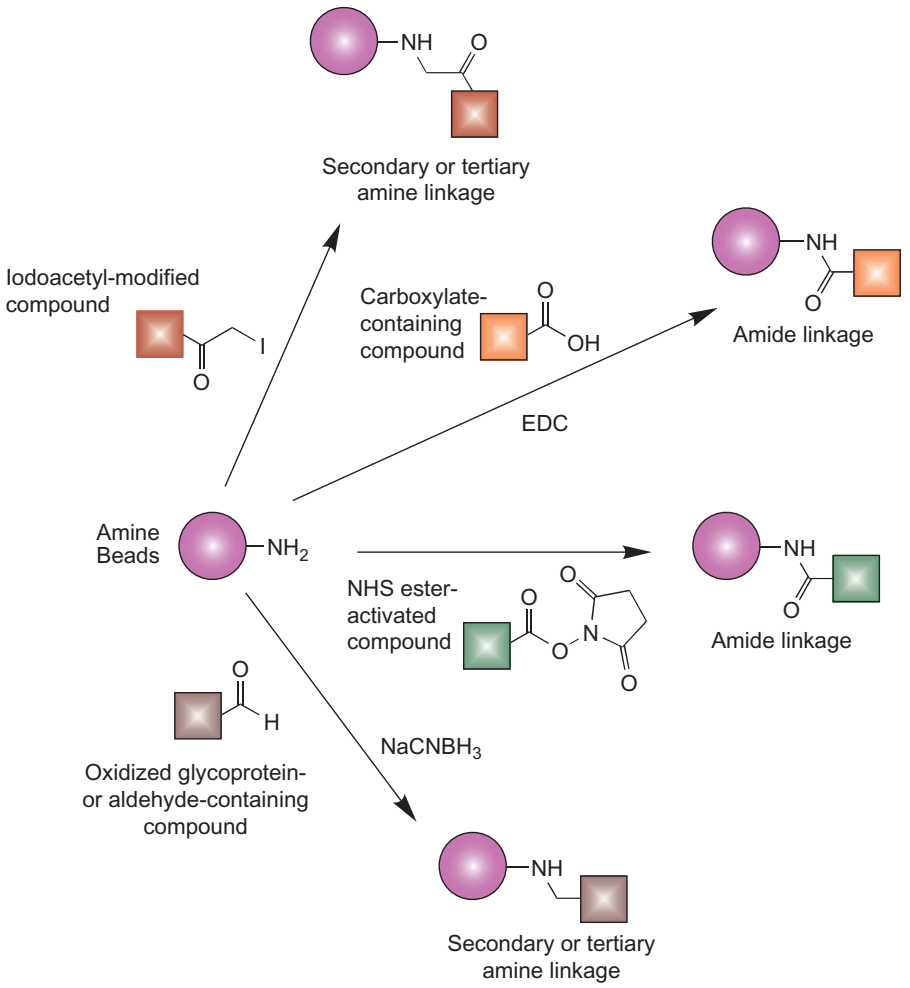

FIGURE 14.8 Amine-containing particles can be conjugated using alkylation or acylation reactions to result in secondary or tertiary amine linkages or amide bonds.

Glutaraldehyde

In one of the simplest methods, a homobifunctional amine-reactive crosslinker may be used to activate the surface of an amine particle for coupling with an amine-containing ligand. This has been done with success using glutaraldehyde or polyglutaraldehyde (Rembaum *et al.*, 1976; Rembaum *et al.*, 1978; Margel *et al.*, 1979; Kaplan *et al.*, 1983). More recent studies have found that glutaraldehyde can undergo intra- and intermolecular transformations in aqueous solution which involve the production of a number of reactive intermediates (see Chapter 15, Section 2.1, for a detailed discussion). In particular, two main forms of glutaraldehyde can be successfully used to activate particles for coupling amine-containing affinity ligands. In particular, the formation of a cyclic hemiacetal ring or a hemiacetal/aldol bicyclic ring structure create reactive derivatives that are useful for particle activation (Figure 14.9). Despite its potential shortcomings, glutaraldehyde is still being used to immobilize many different ligands onto particles of every size (Xu *et al.*, 2011; Alahakoon *et al.*, 2012).

The following protocol describes a two-step coupling method using glutaraldehyde on amine particles that makes use of either of these glutaraldehyde forms; it is based on the procedures of Betancor *et al.* (2006). The reaction mechanism can be controlled by modulating the pH of the reaction as well as the concentration of glutaraldehyde in solution. The monomeric hemiacetal activation method involves the use of highly dilute glutaraldehyde in a relatively brief activation process. The dimeric hemiacetal/aldol activation method uses a more concentrated glutaraldehyde solution for an extended activation time.

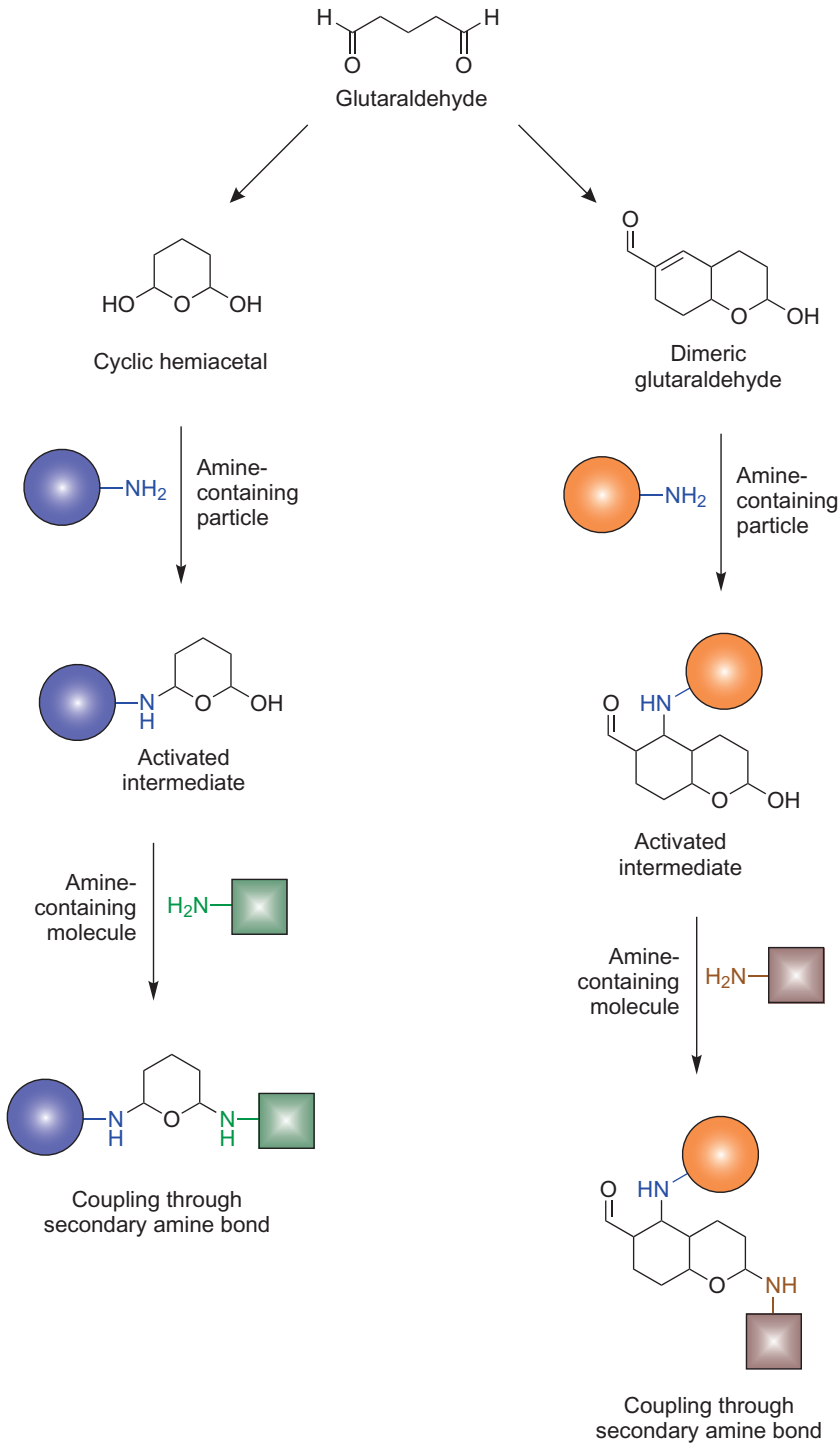

FIGURE 14.9 Glutaraldehyde-mediated immobilization onto amine particles can be performed with some control using two main reaction routes. The use of a cyclic hemiacetal glutaraldehyde species in aqueous solution can be used to activate the amino groups by coupling with one of the anomeric carbons on the ring and forming a reactive intermediate. After washing off excess reagent, the activated particles can be used to immobilize an amine-containing protein or ligand through secondary amine linkages. A similar reaction scheme can be carried out using a dimeric glutaraldehyde species that first reacts with the amine groups on particles by addition to the double bond. The final amine-containing ligand then is immobilized through a secondary amine bond to the anomeric carbon of the hemiacetal ring.

Protocol

1. Wash 100 mg of amine particles 3 times with 0.1-m*M* sodium phosphate, pH 7.0 (activation buffer).
2. After the final wash, suspend the particles in 10 ml of coupling buffer containing 0.5% glutaraldehyde (for monomeric activation) or 15% glutaraldehyde (for dimeric activation) and mix well to create a homogeneous suspension.
3. React with mixing for 1 h (for monomeric) or 15 h (for dimeric) at room temperature.
4. Wash the particles with coupling buffer at least several times using centrifugation to remove excess glutaraldehyde. Resuspend in 5 ml of coupling buffer (25-m*M* sodium phosphate, pH 7.0). Note: The activated particles can be stored at 4°C in water until used.
5. Add the protein to be coupled to the particle suspension in an amount equal to 1- to 10-times molar excess over the calculated particle monolayer for the protein type to be coupled. Mix thoroughly to dissolve. Low concentrations of protein may result in particle aggregation, because a single protein molecule can react with more than one particle.
6. React with mixing at room temperature for 2 to 4 h.
7. Add to the particle suspension a final concentration of 0.2-*M* glycine (or another amine-containing quench molecule, such as ethanolamine or Tris). The blocking agent will couple to any remaining glutaraldehyde reactive sites. Excess aldehyde groups on the support also may be block by the addition of 50-m*M* hydroxylamine, which will react with the aldehydes to create stable oxime linkages.
8. Remove excess protein and reactants by washing with coupling buffer at least three times using centrifugation. Storage of the modified particles may be done at 4°C in a suitable buffer containing a preservative.

SPDP Coupling to Amine Particles

Another crosslinker-based method that has been used for coupling proteins to amine particles involves the use of *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP). This reagent contains an amine-reactive NHS ester and a thiol-reactive pyridyl disulfide group (Chapter 6, Section 1.1). Amine-containing particles can be activated by reaction with SPDP to form thiol-reactive derivatives (Xie *et al.*, 2011). Thiol-containing proteins, such as partially disulfide-reduced antibodies, can be coupled to the activated particles in a two-step reaction. An alternative method outlined by Illum and Jones (1985) that was based on Barbet *et al.* (1981) couples SPDP-modified amine particles to antibodies that were also modified with SPDP and then the pyridyl disulfide group reduced to form thiols. Mixing the thiolated antibody with the SPDP-activated particles will result in covalent coupling *via* disulfide linkages (Figure 14.10).

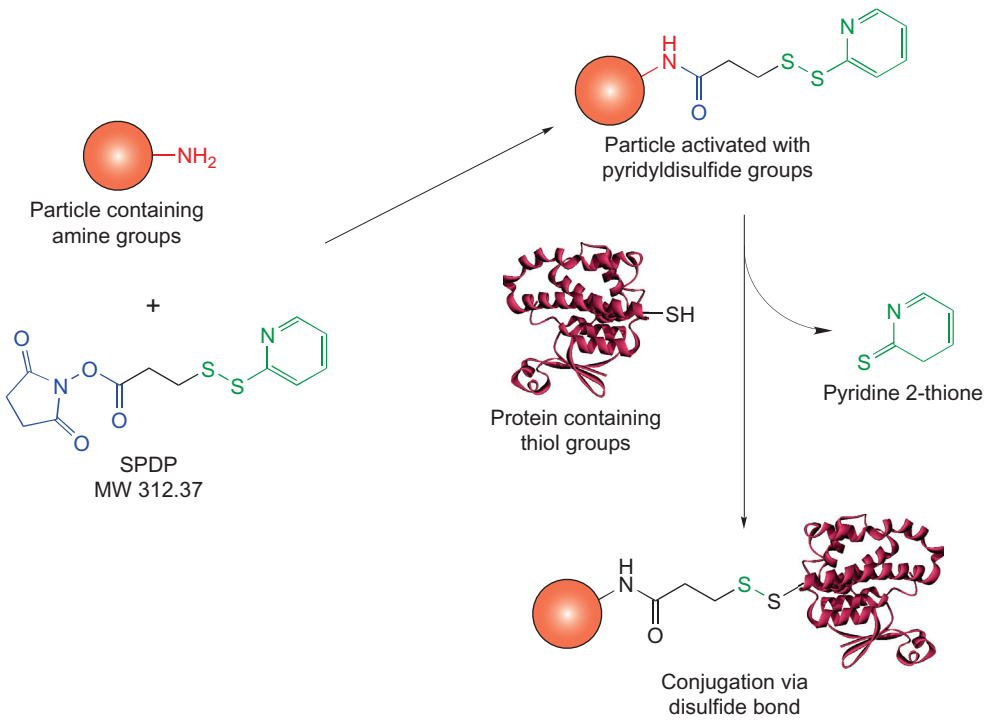

FIGURE 14.10 The crosslinker SPDP can be reacted with amine particles to create thiol-reactive pyridyl disulfide groups on the surface. Thiol-containing proteins or other thiol molecules can be reacted with these activated particles to result in disulfide linkages, which are reversible by reduction.

Unlike the use of homobifunctional crosslinkers, heterobifunctional compounds usually do not have to be used in large excess with amine particles to prevent aggregation. This is due to the fact that only one of the ends of the crosslinker can react with the amines on the particles.

Protocol

1. Wash 10 mg of amine particles into 10-m*M* sodium phosphate, pH 7.2, using centrifugation. Resuspend the particles in 1 ml of the same buffer.
2. Dissolve SPDP in dimethylformamide (DMF) at a concentration of 6.2 mg/ml (makes a 20-m*M* stock solution). Add 50 µl of the SPDP solution to the 1-ml particle suspension and mix to dissolve. Note: The small quantity of DMF in a polymeric particle suspension should not affect particle stability, even if the polymer type is susceptible to swelling in pure DMF. Other particle types, such as metallic or silica based, usually are not affected by organic solvent addition, unless their surfaces are non-covalently coated with a dissolvable polymer.
3. React for 30 min at room temperature with mixing.
4. Wash particles with coupling buffer at least three times using centrifugation and resuspend in the same buffer using a sonic probe to fully disperse the particles.
5. Add 1 to 10 mg of a protein or antibody containing an available thiol group to the particle suspension. Alternatively, add the protein to be coupled to the particle suspension in an amount equal to 1- to 10-times molar excess over the calculated monolayer for the protein type to be coupled. The optimal amount of protein to be added should be determined experimentally. Creating thiol groups from disulfides in proteins may be achieved by using a reducing agent or through the use of a thiolation reagent (Chapter 2, Section 4.1).
6. React with mixing for 2 h at room temperature. At the completion of the reaction, cysteine may be added at 50-m*M* to block excess pyridyl disulfide reactive sites.
7. Remove excess protein and reactants by washing with coupling buffer at least three times. Storage of particles may be done in a suitable buffer at 4°C containing a preservative.

NHS–PEG$_n$–Maleimide Coupling to Amine Particles

An alternative method for coupling thiol-containing proteins or antibodies to amine particles is to use a heterobifunctional crosslinker containing an amine-reactive NHS ester at one end and a thiol-reactive maleimide group on the other end (Chapter 6, Section 1). Unlike the pyridyl dithiol reaction with a sulfhydryl as in the SPDP protocol described previously, a maleimide group forms a stable thioether linkage with a sulfhydryl-containing ligand, which is not cleavable by reduction.

A common choice of crosslinker for this type of reaction is sulfo-SMCC (sulfosuccinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate), which has been used extensively for antibody conjugation (Chapter 6, Section 1.3). However, perhaps a better option for particle conjugation is to use a similar crosslinker design, but one which contains a hydrophilic PEG spacer arm to promote particle hydrophilicity after modification. The modification of an amine particle with an NHS–PEG$_n$–maleimide reagent can create a surface that is essentially coated with PEG spacers (Chapter 18, Section 1.2). This helps to mask any hydrophobic character that the particle surface may have, while providing terminal thiol-reactive maleimides for coupling ligands (Figure 14.11).

If an NHS–PEG$_n$–maleimide compound is used for this type of activation and coupling, the intermediate maleimide-activated particle should be quickly washed free of excess crosslinker and used to couple ligand immediately. This is due to the fact that the maleimide hydrolyzes in aqueous solution at a higher rate than that of a maleimide on an SMCC-type crosslinker, because of the extreme hydrophilicity of the PEG spacer arm compared to the cyclohexane spacer of SMCC.

NHS–PEG$_n$–maleimide crosslinkers are available in a number of spacer lengths depending on the size of the polymer chain in the PEG component (Chapter 18, Section 1.2). Long-chain crosslinkers of this type use PEG polymers of molecular weight approximately 2000 to 5000 Daltons, containing from about 45 to over 100 repeating polyethylene oxide units (Chapter 18, Section 2.1). These full-length polymers are polydisperse and actually consist of a broad range of polymer lengths, which makes reproducibility of the crosslinker size nearly impossible to achieve. Modifying a particle with this type of polymer diversity causes variability in the length of the crosslinkers displayed on the surface, which may be detrimental for coupling some ligands.

However, shorter, discrete crosslinkers containing PEG spacers of known chain length are now available (Thermo Fisher, Quanta BioDesign). These reagents are designed to contain an exact number of PEG units, typically from between 2 repeating units and 24 repeating units. The following protocol may be used with any of these compounds with the appropriate adjustments in the quantity of crosslinker added to the reaction to take into account differences in molecular weight due to the PEG length. The longer of these discrete NHS–PEG$_n$–maleimide crosslinkers will provide the greatest degree of hydrophilicity after modification of an amine particle surface (see Chapter 18 for additional details on discrete PEG compounds.

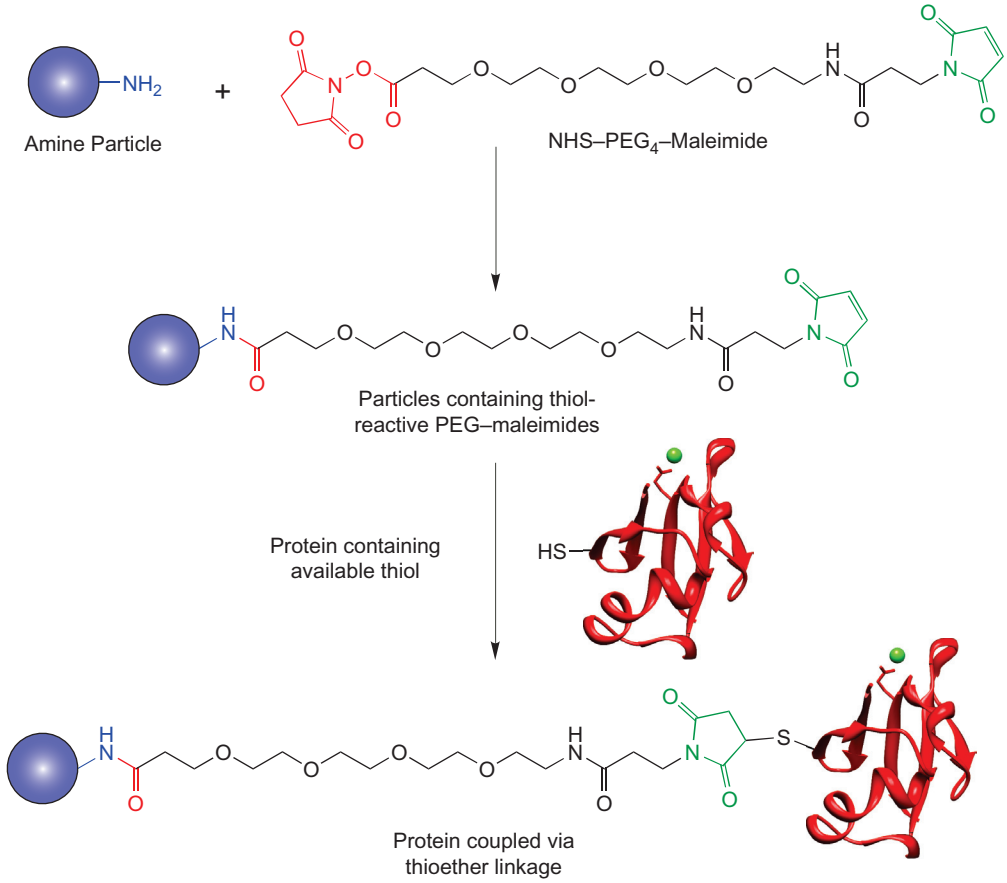

FIGURE 14.11 The modification of amine-containing particles with NHS–PEG_4–maleimide produces hydrophilic PEG spacers containing terminal thiol-reactive groups. Coupling of thiol-containing proteins then results in the formation of thioether linkages.

Protocol

1. Wash 10 mg of amine particles into 10-m*M* sodium phosphate, pH 7.2 (coupling buffer) using centrifugation. Resuspend the particles in 1 ml of the same buffer.
2. Dissolve NHS–PEG_6–maleimide (MW 601.6) into DMSO at a concentration of 20-m*M*. PEG type crosslinkers often exist as a thick oily mass, and preparing the solution may involve dissolving an entire vial of the compound into DMSO to accurately determine the required concentration.
3. Add 50 µl of the NHS–PEG_6–maleimide solution to the 1 ml particle suspension and mix thoroughly to dissolve.
4. React for 1 h at room temperature with mixing.
5. Quickly wash the particles with coupling buffer at least twice using centrifugation.
6. Add 1 to 10 mg of a protein or antibody containing an available thiol group to the particle suspension. Alternatively, add the protein to be coupled to the particle suspension in an amount equal to 1- to 10-times molar excess over the calculated monolayer for the protein type to be coupled. The optimal amount of protein to be added should be determined experimentally. Creating thiol groups on proteins or peptides may be done from disulfides by reduction. Alternatively, a thiolation reagent may be used to add thiols to the protein surface for coupling (see the protocols in Chapter 2, Section 4.1).
7. React with mixing for 2 h at room temperature. At the completion of the reaction, cysteine may be added at 50-m*M* to block excess maleimide reactive sites.
8. Remove excess protein and reactants by washing with coupling buffer at least three times using centrifugation. Storage of the particles may be done in a suitable buffer at 4°C containing a preservative.

Coupling to Hydroxyl Particles

Polymeric particles containing hydroxyl groups are often created from copolymers or composites of poly(hydroxyethyl methacrylate) (pHEMA), frequently with other more rigid polymer cores, such as polystyrene (Figure 14.12). pHEMA particles have surfaces that contain an abundance of primary hydroxyls, which tend to produce favorable hydrophilic surface characteristics (Ahmad *et al.*, 2003; Tauer *et al.*, 2005). The

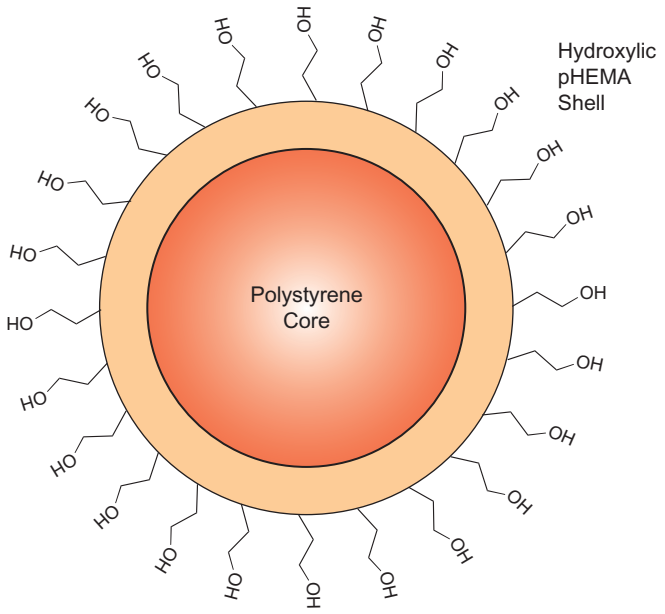

FIGURE 14.12 A core/shell polymeric particle made of a hydrophobic polystyrene core that is capped with a hydrophilic pHEMA shell, which contains numerous hydroxyl groups for hydrophilicity and biocompatibility.

hydroxyls can hydrogen bond with a layer of water molecules in aqueous solution, which forms an interface between individual particles and stabilizes them against aggregation, even in the presence of relatively high salt concentrations. The typical lack of interaction potential of biomolecules with pHEMA particles usually lowers nonspecific binding potential compared to particles of more hydrophobic polymer construction. This enhanced hydrophilicity of pHEMA particles translates into a high degree of biocompatibility, which is important for decreasing background in particle-based assays and in preventing denaturation of immobilized proteins on the particle surface. Horák *et al.* (2011) used a copolymerization process with HEMA and glycidyl methacrylate in the presence of Fe_3O_4 to produce magnetic nanoparticles suitable for affinity targeting. Cui *et al.* (2012) used a similar copolymer preparation to produce pHEMA-containing magnetic microspheres for the immobilization of lipase enzymes.

Although hydroxyls are not spontaneously reactive toward functional groups on biomolecules, they can be activated for covalent coupling by a number of known reaction mechanisms. Most of the reactions that can result in covalent attachment of ligands to hydroxylic or pHEMA particles originated in the development of immobilization technology for affinity chromatography using larger hydroxyl-containing porous beads (for reviews, see Chapter 15 and Hermanson *et al.*, 1992).

Most activation strategies for hydroxylic particles are carried out under nonaqueous conditions, because the activating agent and the intermediate reactive group are typically susceptible to hydrolysis. A convenient method of activation is to form a reactive carbonyl group on the hydroxyl particle using compounds such as carbonyl diimidazole (CDI) (Bethell *et al.*, 1979) or disuccinimidyl carbonate (DSC) (Miron and Wilchek, 1993). These activating agents create imidazole carbamates (using CDI) or NHS–carbonates (using DSC) on the particle surface, which are then spontaneously reactive toward amines (see Figures 14.13 and 14.14). After washing away excess activating agent in organic solvent, the particles are centrifuged to remove most solvent and then resuspended in aqueous buffer containing the amine ligand to be coupled (e.g., a protein). These activation and coupling reactions can also be used to prepare reactive dextran-coated silica nanoparticles for a variety of uses (Schulz *et al.*, 2011).

The imidazole carbamate group is more stable to hydrolysis in aqueous buffer than the NHS–carbonate group, which is similar in reactivity to an NHS ester. However, this means that the imidazole carbamate is also slower to react and couple with amines. NHS–carbonate reactions usually go to completion within 1 to 2 h at room temperature, whereas imidazole carbamates typically require higher pH conditions and overnight incubations to get maximal yield of ligand coupling.

The following protocols involve the activation of hydroxylic pHEMA particles in organic solvent using either CDI or DSC and the subsequent coupling of amine-containing molecules using aqueous buffer conditions. Various solvents may be used for the activation step as long as the activation agents are soluble in them and the particles do not get damaged due to solvent exposure. Only water-miscible solvents should be used to facilitate exchange into and out of aqueous conditions. However, the solvents should be anhydrous to prevent hydrolysis of the activating agent or the subsequent reactive group formed on the particles after activation.

Protocol for Activation Using CDI

This method is derived from that of Bethell *et al.* (1979) and Colvin *et al.* (1988). See Figure 14.15.

1. Solvent exchange pHEMA particles into anhydrous THF using centrifugation and resuspension with sequential exchange into greater percentages of THF in water until the particles are suspended in 100% THF. Wash several times with anhydrous THF to eliminate any remaining traces of water, letting the particles agitate in solvent between each centrifugation step. After the final THF wash centrifuge the particles and remove excess solvent.

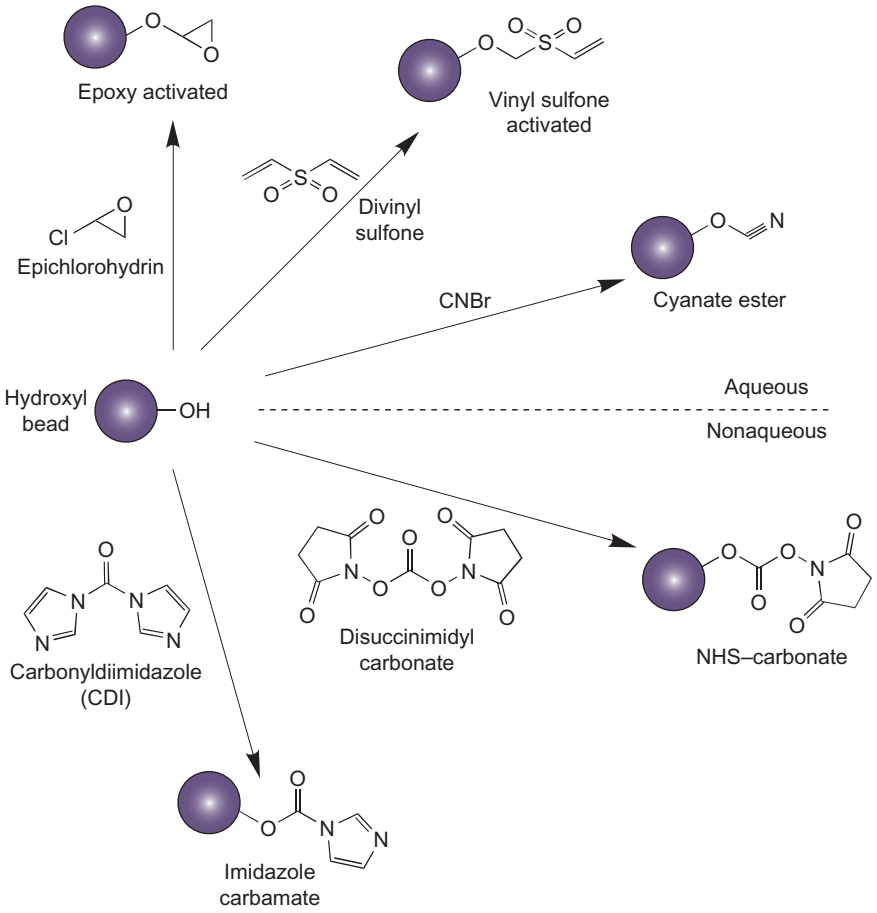

FIGURE 14.13 Hydroxyl-containing particles can be activated for coupling ligands using a number of strategies, which involve either aqueous or nonaqueous reactions. Epoxy and vinyl sulfone activation procedures provide reactive groups able to couple with amine-, thiol-, or hydroxyl-containing ligands. Cyanogen bromide activation and the CDI and DSC methods provide reactive groups for coupling amines.

2. Resuspend the particles as a 5% suspension in anhydrous THF containing CDI at a concentration of 50 mg/ml (0.3-*M*).
3. React with mixing for 2 h at room temperature.
4. Wash the activated particles three times with anhydrous THF to remove excess CDI and reaction byproducts. After the final wash, remove the solvent and perform a quick wash with ice-cold water to remove most traces of solvent in the particle pellet. Finally, resuspend the particles at 10 mg/ml in cold 0.1-*M* sodium phosphate, pH 8.2, or 0.1-*M* sodium carbonate, pH 9.5 (coupling buffer). The higher pH coupling buffer will result in greater reactivity of the imidazole carbamate and greater coupling yields for proteins.
5. Add 1 to 10 mg of a protein or antibody containing an available thiol group to the particle suspension in coupling buffer and mix to dissolve. Alternatively, add the protein to the particle suspension in an amount equal to 1- to 10-times molar excess over the calculated monolayer for the protein type to be coupled. The optimal amount of protein to be added should be determined experimentally.
6. React with mixing for at least 18 h at 4°C. Longer reaction times (24–48 h) may be necessary when using the pH 8.2 coupling buffer. Room temperature reactions will increase the reaction rate.
7. Add ethanolamine to the particle suspension at a final concentration of 0.1-*M* to quench any remaining active groups and react with mixing for several hours.
8. Centrifuge and wash the particles at least three times with buffer to remove unreacted protein and ethanolamine. Finally, suspend the particles in a suitable storage buffer containing a preservative.

Protocol for Activation Using DSC

This method is derived from that of Miron and Wilchek (1993) for the activation of hydroxyl groups on PEG molecules and Wilchek and Miron (1985) for the activation of agarose chromatography beads (see Chapter 15). Many types of hydroxyl-containing

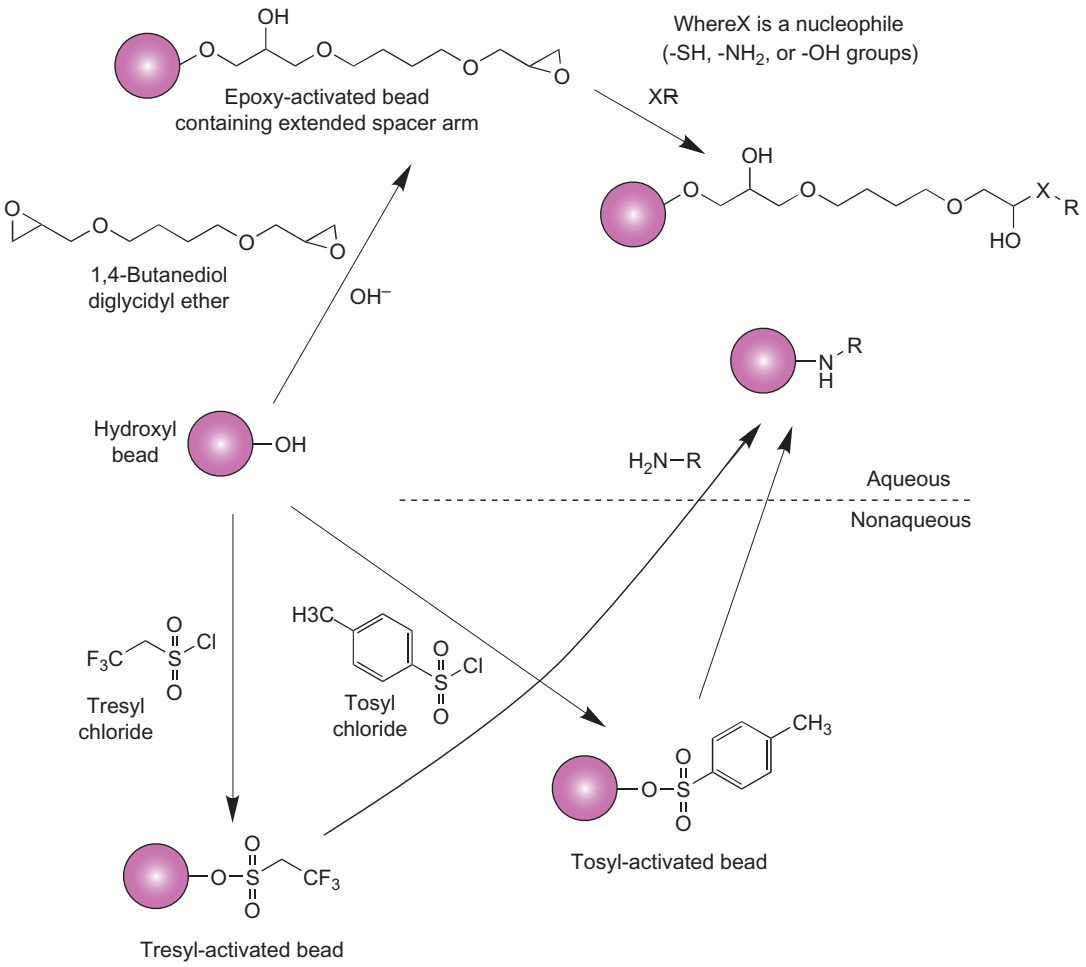

FIGURE 14.14 Additional hydroxyl particle activation methods include *bis*-epoxide modification, tosyl activation, and tresyl activation methods. The tosyl chloride and tresyl chloride activation procedures must be carried out in dry organic solvent, but the coupling of an amine-containing ligand can be performed either in organic solvent or aqueous buffer.

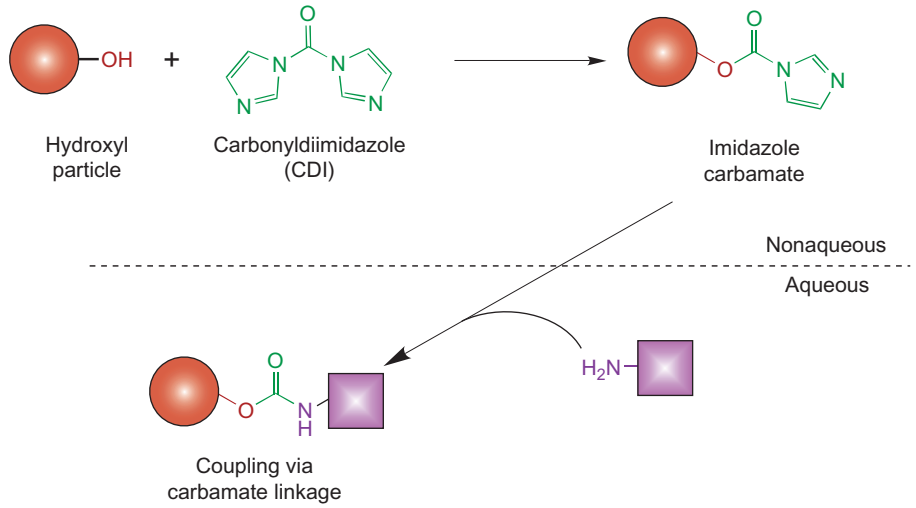

FIGURE 14.15 CDI can be used to activate hydroxyl particles in organic solvent and then the intermediate reactive imidazole carbamate brought into aqueous solution for coupling amine-containing ligands.

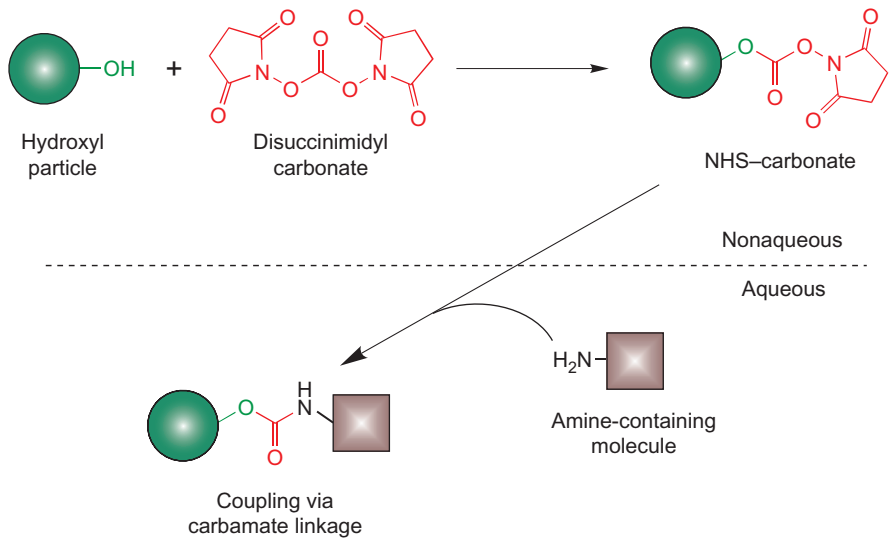

FIGURE 14.16 DSC can be used to activate hydroxyl particles to a reactive NHS–carbonate derivative. The subsequent coupling of amine-containing ligands can be carried out in either organic solvent or aqueous conditions.

particles may be used in this procedure, provided that the solvent used for the activation step does not deleteriously affect particle integrity. See Figure 14.16.

1. Solvent exchange pHEMA particles into anhydrous acetone, dioxane, acetonitrile, THF, or DMF (having very low amine content) using centrifugation and resuspension with sequential exchange into greater percentages of solvent in water until the particles are suspended in 100% organic solvent. Wash several times with anhydrous solvent to eliminate any remaining traces of water, letting the particles agitate in solvent between each centrifugation step. After the final solvent wash, centrifuge the particles and remove excess solvent.
2. Resuspend the particles as a 5% suspension in anhydrous solvent containing DSC at a concentration of 50 mg/ml (0.2-*M*).
3. React with mixing for 2 h at room temperature.
4. Wash the activated particles three times with anhydrous solvent to remove excess DSC and reaction byproducts. After the final wash, remove the solvent and perform a quick wash with ice-cold water to remove most traces of solvent in the particle pellet.
5. Immediately resuspend the particles at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, pH 7.2 (coupling buffer), containing 1 to 10 mg of a protein or antibody and mix to dissolve. Alternatively, add the protein to the particle suspension in an amount equal to 1- to 10-times molar excess over the calculated monolayer for the protein type to be coupled. The optimal level of protein to be added should be determined experimentally.
6. React with mixing for at least 2 h at room temperature or twice as long at 4°C.
7. Add ethanolamine to the particle suspension at a final concentration of 0.1-*M* to quench any remaining active groups and react with mixing for 1 h. Other amine-containing quenchers may be used, too, such as Tris buffer. Note: DSC-activated sites on the particles that completely hydrolyze will revert back to the original hydroxyls.
8. Centrifuge and wash the particles at least three times with buffer to remove unreacted protein and quenching agent. Finally, suspend the particles in a suitable storage buffer containing a preservative.

Protocol for Activation Using Cyanogen Bromide

Cyanogen bromide can be used to activate hydroxyl groups on particles to create reactive cyanate esters, which then can be coupled to amine-containing ligands to form an isourea bond (Figure 14.17). CNBr activation also can produce cyclic imidocarbonate groups, which are less reactive than the cyanate ester, but can form imidocarbonate bonds. The exact reactive species formed by the reaction is dependent on the structure of the hydroxylic support being activated (Kohn and Wilchek, 1982).

Unlike the previous methods for activation of hydroxyls on particles, cyanogen bromide is used under aqueous conditions, thus eliminating the need for organic solvents. This method originated in the activation and coupling of ligands to agarose supports for affinity chromatography (Axen *et al.*, 1967), and it was subsequently used to couple antibodies to hydroxyl-containing latex particles (Yen *et al.*, 1979) and more

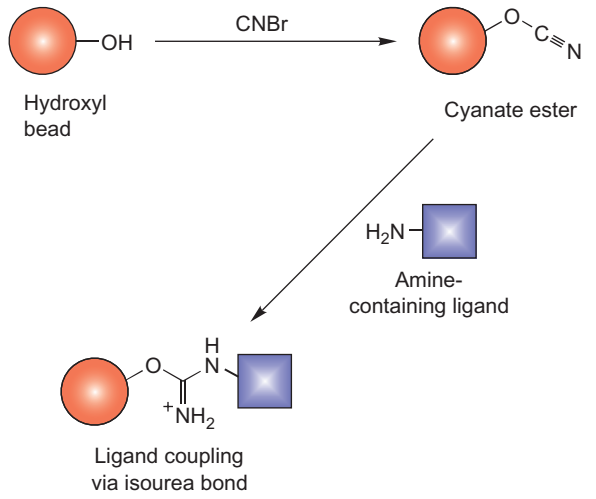

FIGURE 14.17 Cyanogen bromide can be used to activate a hydroxyl particle to a reactive cyanate ester, which can then be used to couple amine-containing ligands.

recently to immobilize protein A onto pHEMA particles (Denizli *et al.*, 1995).

Cyanogen bromide is an extremely toxic chemical and should be used only in a well-ventilated fume hood while using the appropriate personal protective gear. The following protocol is based on the method of March *et al.* (1974), as recommended by Bangs Laboratories.

All operations should be performed in a fume hood.

1. Wash 100 mg of hydroxyl-containing particles two times using centrifugation with 0.1-*M* sodium carbonate, pH 8.5 (coupling buffer). After the second wash, resuspend the particles at 10 mg/ml in 2-*M* sodium carbonate (activation buffer; no pH adjustment necessary).
2. Dissolve an amount of protein in 10 ml of coupling buffer equal to 1- to 10-times excess over the calculated monolayer for the type of particles being used.
3. In a fume hood, dissolve 1 g of cyanogen bromide in 0.5 ml of acetonitrile (highly toxic!).
4. Add a drop of the cyanogen bromide solution at a time to the particle suspension with constant mixing at room temperature. The entire solution should be added to the particles over the course of about 10 s.
5. Activate the particles with mixing for exactly 2 min at room temperature.
6. Quickly wash the particles with ice-cold deionized water and then with a volume of cold coupling buffer. Resuspend the particles in the protein solution prepared in step 2.
7. React for 24 h at 4°C with mixing.
8. Wash the particles with coupling buffer and block excess reactive groups by resuspending in 50-m*M* ethanolamine, pH 9.0. React for 1 h at room temperature with mixing.
9. Thoroughly wash the particles with storage buffer (e.g., PBS, pH 7.5, or other suitable buffer) and resuspend them at 10 mg/ml in storage buffer containing a preservative.

Coupling to Hydrazide Particles

Hydrazide particles can be made from carboxylate particles by modification with a *bis*-hydrazide compound using the carbodiimide reaction with EDC. Suitable bifunctional hydrazides include the small carbohydrazide compound or the longer adipic dihydrazide (Chapter 5, Section 8). A *bis*-hydrazide compound is reacted with a carboxylate particle population in large excess to prevent particle polymerization during the reaction. The resultant hydrazide particles may be used to couple to carbonyl-containing ligands, such as carbohydrates or glycans at their reducing ends or after the formation of aldehydes on carbohydrates using oxidation with sodium periodate (Chapter 2, Section 4.4).

Perhaps a better design for a *bis*-hydrazide compound to modify carboxylate particles would include a short PEG spacer arm between the two hydrazide groups. This type of linker would result in a hydrophilic surface due to the presence of the PEG spacers, while providing the terminal hydrazide functionality necessary for coupling to carbonyl compounds. Unfortunately, this type of compound is not currently available, so the aliphatic *bis*-hydrazides are the only choice.

Another route to the formation of a hydrazide on a surface is to use an aldehyde-containing particle (such as HEMA/acrolein copolymers) and subsequently modify the aldehydes to form hydrazone linkages with *bis*-hydrazide compounds, which then can be stabilized by reduction with sodium cyanoborohydride (Chapter 3, Section 5). The resulting derivative contains terminal hydrazides for immobilization of carbonyl ligands (see Figure 14.18).

Hydrazide-containing particles provide functional groups for the coupling of aldehyde or ketone containing ligands through a dehydration reaction to form hydrazone linkages (a type of Schiff base). However, a single hydrazone bond between a ligand and the particle surface may not provide enough stability to prevent leaching of ligand due to hydrolysis. There are two routes to overcome this instability: (1) reduce the hydrazone linkage using sodium cyanoborohydride, or (2) create multiple hydrazone linkages between the ligand and the particle surface. Multi-site attachment provides sufficient ligand stability, because not all the hydrazones will hydrolyze simultaneously to release ligand, and when one hydrazone bond breaks it will have enough time to reform before the other

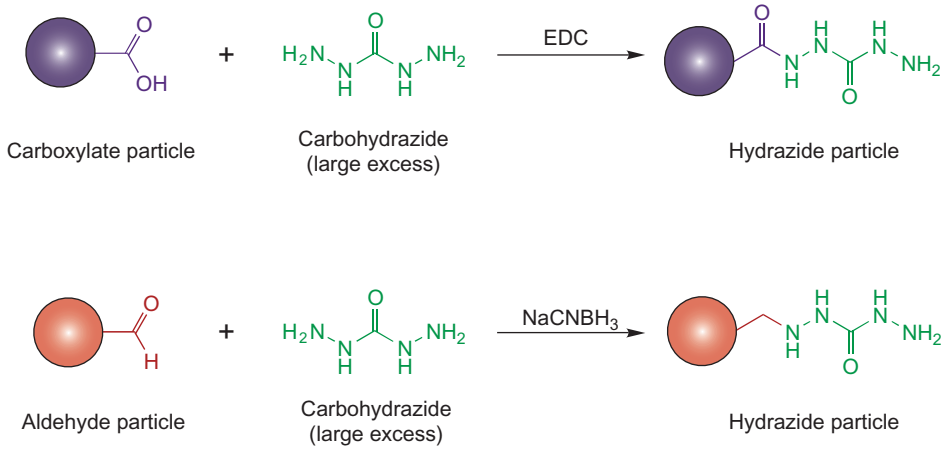

FIGURE 14.18 Carboxylate particles or aldehyde particles can be modified with carbohydrazide in excess to create a hydrazide particle that can be used to couple with aldehyde-containing molecules.

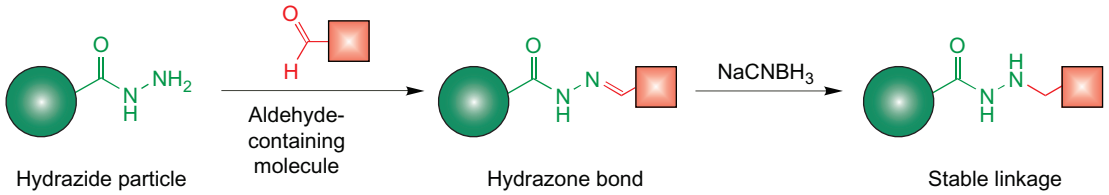

FIGURE 14.19 Aldehyde-containing molecules, such as periodate oxidized carbohydrates or glycoproteins, can be coupled to hydrazide particles to form a hydrazone bond. This bond can be further stabilized by reduction with sodium cyanoborohydride.

hydrazones hydrolyze. Thus, glycosylated proteins coupled after oxidation to hydrazide particles will most likely be stable due to the presence of more than one aldehyde group, but small ligands containing only a single carbonyl group should probably be treated with cyanoborohydride to stabilize the hydrazone bond.

The reactions involved with coupling carbonyl-containing ligands to hydrazide particles originated with the activation and coupling chemistry associated with the preparation of affinity chromatography supports (O'Shannessy and Wilchek, 1990). The application of this strategy to hydrazide-containing microparticles or nanoparticles is straightforward and will work well so long as accommodation is given to particle stability during the process. Using this method, a broad range of carbonyl-containing ligands can be coupled, such as reducing sugars or carbohydrates containing a reducing end, glycans after release from proteins, glycoproteins and other glycoconjugates, and small organic compounds containing an aldehyde or ketone group (Figure 14.19). Horak *et al.* (1999) used hydrazide–pHEMA particles to couple oxidized HRP in good yield and retention of enzymatic activity. Hydrazide particles are also a standard technique for the immobilization of antibodies through their carbohydrate portions after periodate oxidation to create aldehyde residues (Li and Ng, 2012).

The following protocol describes the oxidation of carbohydrate (glycans) on antibody molecules to form aldehydes and the subsequent coupling to hydrazide particles.

Protocol

1. Dissolve the antibody to be coupled in 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of 10 mg/ml. The antibody must be glycosylated to work in this procedure.
2. Prepare a solution of 0.1-*M* sodium periodate in water. Protect from light.
3. With mixing, add 0.1 ml of the periodate solution to each milliliter of the antibody solution.
4. React for 30 min at room temperature, protected from light.
5. The reaction may be quenched by the addition of 0.1 ml of glycerol per milliliter of reaction or by the addition of sodium bisulfite to a final concentration of 10-m*M*.
6. Remove excess reactants from the reaction mixture using size exclusion chromatography on a column of Sephadex G25 (or equivalent).
7. Wash 100 mg of hydrazide particles two times with 10 ml of 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5 (coupling buffer), using centrifugation.

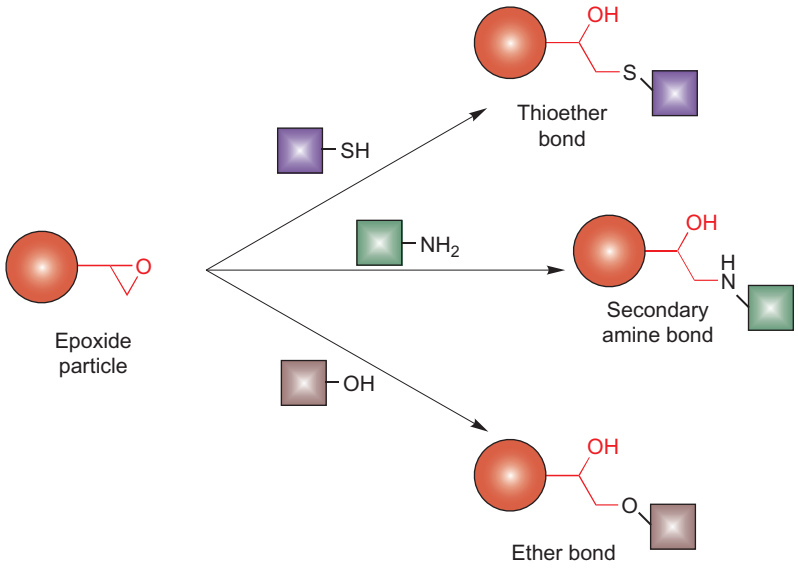

FIGURE 14.20 Particles containing reactive epoxy groups can be coupled with amine-, thiol-, or hydroxyl-containing molecules.

8. After the final wash, resuspend the particles at a concentration of 10 mg/ml in coupling buffer and add an appropriate amount of the solution from step 6, which contains the purified, oxidized antibody. The amount of oxidized antibody to add to the particles should be about 1 to 10 times over the amount of the calculated monolayer for the particle type used. Note: For 100 mg of 1-µm hydrazide particles, a monolayer equivalent of antibody will be about 1.5 mg, so the total amount added should be in the range of 1.5 to 15 mg for a 1- to 10-times excess.
9. React with mixing for at least 6 h at room temperature or overnight at 4°C.
10. Wash the beads at least several times with coupling buffer and resuspend in the same buffer containing 0.05 to 0.1% of a blocking molecule (such as BSA, gelatin, non-fat dried milk, PEG, PVP, etc.). The best blocking agent may be found by experimentation and testing of the antibody-coupled particles in the intended application.
11. Wash the particles several times with coupling buffer and store in an appropriate buffer containing a preservative at 4°C.

Coupling to Epoxy Particles

Polymeric particles containing epoxide groups can be used to couple thiol-, amino-, or hydroxyl-containing ligands *via* a ring opening reaction that is facilitated under alkaline conditions. This reactive group can be used to couple proteins, nucleic acids, sugars and carbohydrates, and other organic molecules containing these functionalities. Epoxide groups can be introduced into polymeric particles through free-radical copolymerization with oxirane-containing vinyl monomers, such as allyl glycidyl ether or glycidyl methacrylate, or they may be introduced by surface modification using a *bis*-epoxide compound, such as 1,4-butanediol diglycidyl ether (Sundberg and Porath, 1974). Horák *et al.* (2011) used a polymeric magnetic particle made from HEMA and glycidyl methacrylate to immobilize streptavidin through the epoxide groups through a secondary amine linkage. In addition, the polymerization of a glycidyl methacrylate shell onto an existing polymer particle can be performed by seeded emulsion polymerization, which creates reactive epoxides on the surface of otherwise unreactive core particles (Omer-Mizrahi and Margel, 2009). Epoxy activation also has been used extensively to immobilize affinity ligands onto porous beaded chromatography supports (see Chapter 15, Section 2.3), and it can be used with equal success to couple ligands to microparticles and nanoparticles.

Epoxide-containing particles can be used to couple thiol-containing ligands at slightly basic pH (pH 7.5–8.5), amine-containing ligands at higher pH values (pH 9–11), and hydroxyl-containing ligands at very high alkaline conditions (pH > 11). The following protocol can be used to couple thiol-, amine-, or hydroxyl-containing ligands with the proper pH adjustment of the carbonate coupling buffer (Figure 14.20).

Protocol

1. Wash 100 mg of epoxy particles with coupling buffer (i.e., 0.1-*M* sodium carbonate, pH 10, for coupling amine-containing ligands). Use higher pH conditions if coupling hydroxylic molecules and lower pH for coupling thiol-containing ligands. Suspend the particles at a 5% solution in coupling buffer.

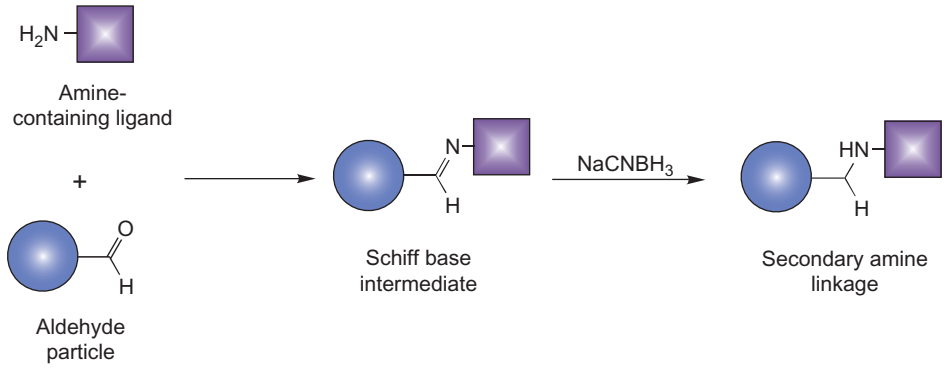

FIGURE 14.21 Aldehyde particles can be reacted with amine-containing proteins or other molecules to form intermediate Schiff bases, which can be stabilized by reduction with sodium cyanoborohydride to form secondary amine linkages.

2. With mixing, add to the particle suspension a quantity of ligand dissolved in coupling buffer in an amount that represents a 1- to 10-times excess over the molar quantity of epoxide groups present on the particles.
3. React at room temperature (for sensitive ligands) or at 45 to 60°C (for more stable ligands) for at least 20 h with mixing.
4. Block excess epoxy groups by the addition of cysteine to a final concentration of 50 mM. Other small molecules can be used for blocking, provided they will efficiently react with the excess epoxides and not result in a modification that could interfere with the subsequent use of the particles. Continue the reaction with mixing for at least 2 h.
5. Wash the particles thoroughly with coupling buffer and then into a more moderate pH storage buffer containing a preservative.

Coupling to Aldehyde Particles

Polymeric particles containing aldehydes are produced by two general routes: copolymers containing an aldehyde monomer (e.g., acrolein) or through periodate oxidation of diols incorporated onto the surface of particles. HEMA/acrolein derivatives are examples of copolymer aldehyde particles (Kumakura and Kaetsu, 1984; Chang *et al.*, 1986; Colvin *et al.*, 1988), which are hydrophilic due to the large number of hydroxyl groups and provide aldehydes for covalent attachment of amine-containing ligands. Epoxy particles also can be used to create surface aldehydes by opening up the epoxide ring through acid hydrolysis and subsequent oxidation of the resultant diols by sodium periodate (Schiel *et al.*, 2006).

Aldehyde particles are spontaneously reactive with hydrazine, hydrazide, or aminooxy derivatives, forming hydrazone or oxime linkages (see Chapter 15, Section 2.4) upon Schiff base formation (Abdelrahman, 2011). Reactions with amine-containing molecules, such as proteins, can be carried out through a reductive amination process using sodium cyanoborohydride (Figure 14.21).

Protocol

1. Wash 10 mg of aldehyde particles 3 times with 10-m*M* sodium phosphate, pH 7.4 (coupling buffer). Buffers of higher pH value e.g., carbonate buffer at pH 10) will result in more efficient Schiff base formation with amine-containing molecules than neutral pH conditions.
2. After the final wash, suspend the particles at 5 to 10 mg/ml in coupling buffer and add a protein to be coupled to the particle suspension in an amount equal to 1- to 10-times molar excess over the calculated monolayer for the protein type to be coupled. (Note: It takes about 18 mg of BSA or 15 mg of IgG to saturate 1 g of 1-μm particles, and more protein if the particles are smaller.) Mix thoroughly to dissolve. Low concentrations of protein may result in particle aggregation, because a single protein molecule can react and bridge more than one particle.
3. Incubate with mixing for 2 to 4 h at room temperature.
4. Add to the particle suspension a quantity of sodium cyanoborohydride in water to bring the final concentration up to 10-m*M*. If a high pH buffer was used for the initial incubation between the particles and the protein, perform a quick wash with 10-m*M* sodium phosphate, pH 7.4, to bring the pH down to a point in which the reducing agent is active. Mix for 30 min at room temperature. The reducing agent will convert all the resultant Schiff bases into stable secondary amine linkages.
5. Add to the particle suspension a quenching molecule (such as glycine, ethanolamine, or Tris) to give a final concentration of 0.2-*M*. The blocking agent will couple to any remaining aldehyde reactive sites.

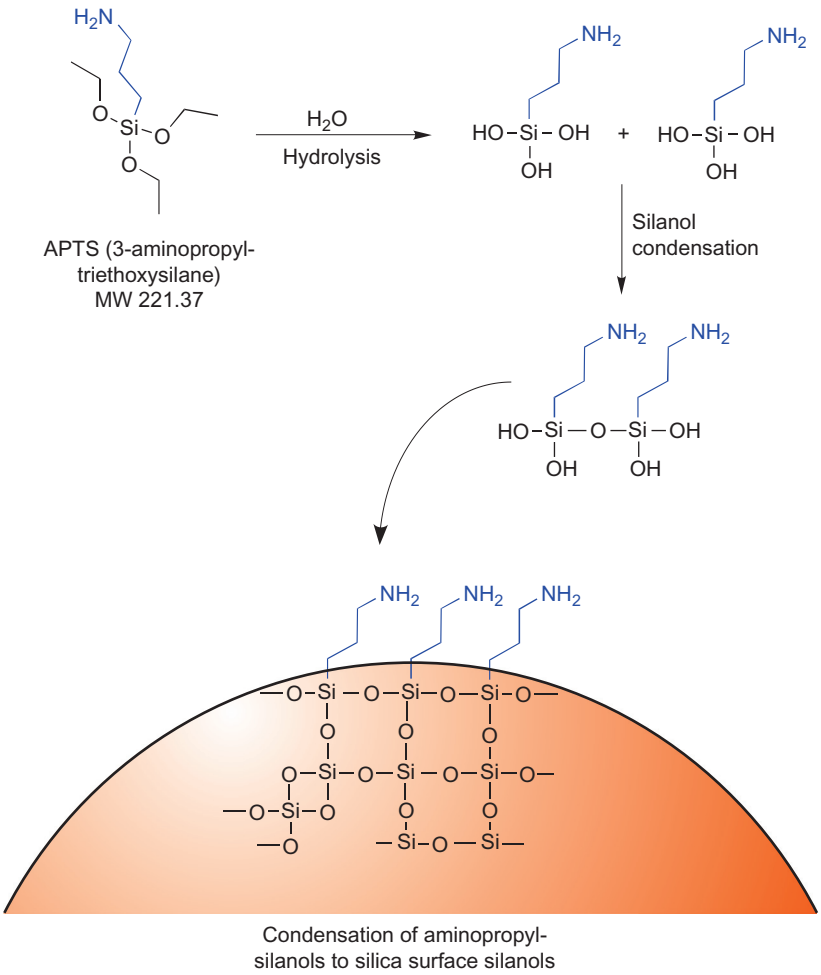

FIGURE 14.22 Silica particles can be functionalized to contain amine groups by reaction with APTS, which coats the particles with a silane layer containing numerous aminopropyl groups on the surface for further conjugation.

6. Remove excess protein and reactants by washing with coupling buffer at least three times using centrifugation. The particles may be stored in a suitable buffer containing a preservative at 4°C.

5. SILICA PARTICLES

The use of silica particles in bioapplications began with the publication by Stöber *et al.* in 1968 on the preparation of monodisperse nanoparticles and microparticles from a silica alkoxide monomer (e.g., tetraethyl orthosilicate, or TEOS). Subsequently, in the 1970s, silane modification techniques provided silica surface treatments that eliminated the nonspecific binding potential of raw silica for biomolecules (Regnier and Noel, 1976). Derivatization of silica with hydrophilic, hydroxylic silane compounds can thoroughly passivate the surface and make possible the use of both porous and nonporous silica particles in all areas of bioapplications (Schiel *et al.*, 2006). Silica nanoparticles or microparticles are routinely synthesized to contain functional groups for the covalent attachment of affinity ligands (del Campo *et al.*, 2005; Pattnaik, 2011).

The modification of silica particles to provide sites for coupling affinity ligands can be done similarly through covalent derivatization of the surface with a functional silane containing a side-chain reactive group or functional group (see Chapter 13). For instance, reaction of a silica particle with 3-aminopropyltriethoxysilane (APTS) under the appropriate conditions coats the surface with primary amino groups for conjugation with electrophilic groups (Pattnaik, 2011; Sen and Bruce, 2012). Reagents containing alkoxy silane groups can condense, particularly after hydrolysis to create reactive silanols, with the OH groups on standard silica particles to form stable siloxane linkages (or oxane bonds) (Figure 14.22). This reaction is typically catalyzed by heat or through the use of at least a partially aqueous environment, which forms the requisite silanols from

the alkoxy groups on the silane compound. Unlike other alkoxy silanes, trimethoxy silane compounds can react directly with particle silanols without the need for high-temperature conditions or hydrolysis to form siloxane linkages. The many options available in silane functional groups for surface modification can provide a broad range of silica particle properties for subsequent coupling of biomolecules or other affinity ligands (VanDerVoort *et al.*, 1996; Bruce and Sen, 2005; Gartmann *et al.*, 2010; Thanh and Green, 2010; Rother *et al.*, 2011).

Silica particles have some advantages over polymer particles. They have a higher density than polymeric particles (1.96 g/cm^3 *versus* 1.05 g/cm^3) and thus they can be washed using centrifugation, even when working with nanometer-sized particles. Typically, silica particles as small as 30 to 40 nm still can be separated from suspension using a benchtop microfuge, making handling and processing of silica particles potentially much simpler than polymeric particles of the same size.

Another advantage of using inorganic silica particles over polymer particles is that they do not shrink or swell when exposed to aqueous or nonaqueous environments. In the case of silica, nonaqueous solvents may be used for activation reactions without concern that softening or dissolving of polymeric structures will damage the particles, as silica does not dissolve in organic solvent environments.

A potential disadvantage of silica-based particles, however, is the tendency for the siloxane linkages between silicon atoms within the particle to dissolve hydrolytically, especially under alkaline conditions above pH 8.0. Surface treatment with organosilane derivatives can somewhat stabilize particles to hydrolysis, but long-term exposure to highly alkaline environments should still be avoided. It also is recommended that at least 0.05-*M* NaCl be maintained in the solution to increase stability of the particles in aqueous environments. The best stability for silica is obtained at neutral or acidic pH conditions containing a low concentration of salt.

5.1. Fluorescent Silica Particles

Silica particles have been exploited in virtually every assay or detection strategy that polymer particles have been used in for bioapplications purposes. Fluorescent dye-doped silica nanoparticles have been developed by a number of groups that have similar fluorescence characteristics to quantum dot nanocrystals (Chapter 10, Section 10). Fluorescent silica nanoparticles can be synthesized less expensively than quantum dots due to the fact that the silica particles incorporate standard organic dyes (Ow *et al.*, 2005; Wang *et al.*, 2006; Saleh *et al.*, 2011) and are not dependent on making reproducible populations of semiconductor particles with precise diameters to tune emission wavelengths.

The preparation of fluorescent silica particles can be carried out using a number of strategies. Santra *et al.* (2001) described a water-in-oil emulsion using detergent-mediated reverse micelle formation and controlled hydrolysis of TEOS to create mono-disperse silica nanoparticles (see also Arriagada and Osseo-Asare, 1995). Adding the water soluble fluorescent dye, Tris(2,2′-bipyridyl) dichlororuthenium (II) hexahydrate (Ru(II)bpy$_3^{2+}$) to this emulsion resulted in dye molecules being entrapped within the silica particle structure as it formed (Figure 14.23) (also see Chapter 24, Section 4.2, for additional properties of Ru(II)bpy$_3^{2+}$). Subsequent functionalization of the surface with silane derivatives can be done to facilitate ligand immobilization.

These Ru(II)bpy$_3^{2+}$ fluorescent silica nanoparticles have been used to detect single bacterial cells using

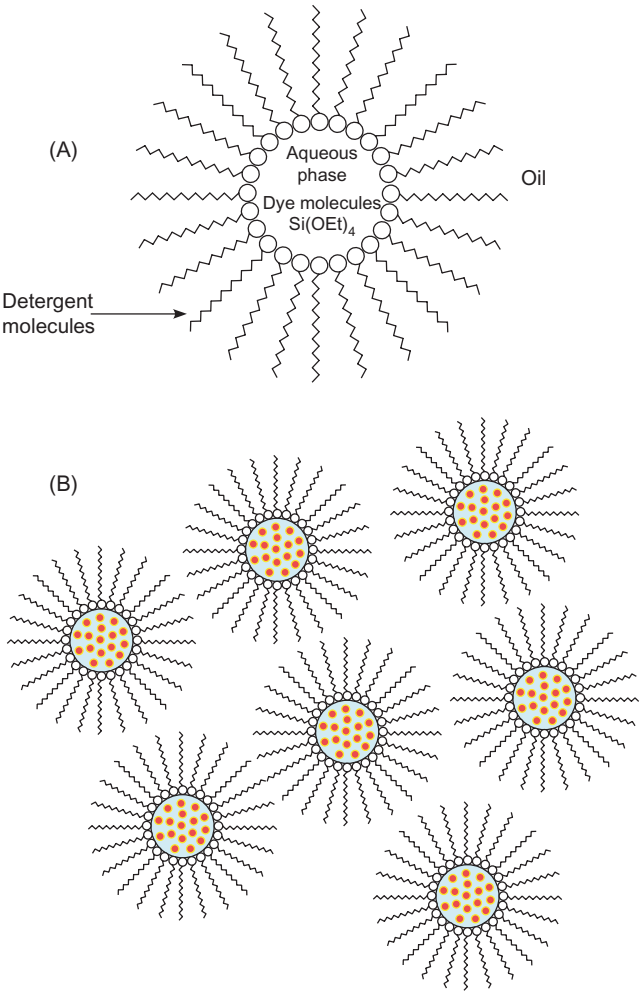

FIGURE 14.23 Silica nanoparticles containing fluorescent dye molecules can be prepared using a reverse micelle suspension process. (A) The water-in-oil emulsion is formed with the aqueous-phase droplets containing tetraethyl orthosilicate and dye molecules in detergent. (B) The final particles contain entrapped dye within the silica particle matrix, creating highly fluorescent particles.

antibodies conjugated to the surface after functionalization with trimethoxysilyl–propyldiethylenetriamine followed by succinylation to create terminal carboxylates. Specific antibody molecules against *E. coli* O157 were then coupled to this modified fluorescent particle using the carbodiimide method with EDC and NHS (Zhao *et al.*, 2004).

Another type of fluorescent silica particle was formed from silica bubbles created on the surface of gold nanoparticles (Liz-Marzan *et al.*, 1996; Makarova *et al.*, 1999). Fluorescein isothiocyanate (FITC) was adsorbed onto the gold nanoparticle surface and then reacted with 3-aminopropyltrimethoxy silane. The isothiocyanate groups on the adsorbed dye molecules coupled to the amine groups on the silane as it polymerized on the gold surface, effectively forming a silica shell around the gold particle. The gold core was then dissolved by reaction with cyanide ions to leave behind the silica nanobubbles filled with water, which also left the fluorescent molecules attached on the inner surface (Figure 14.24).

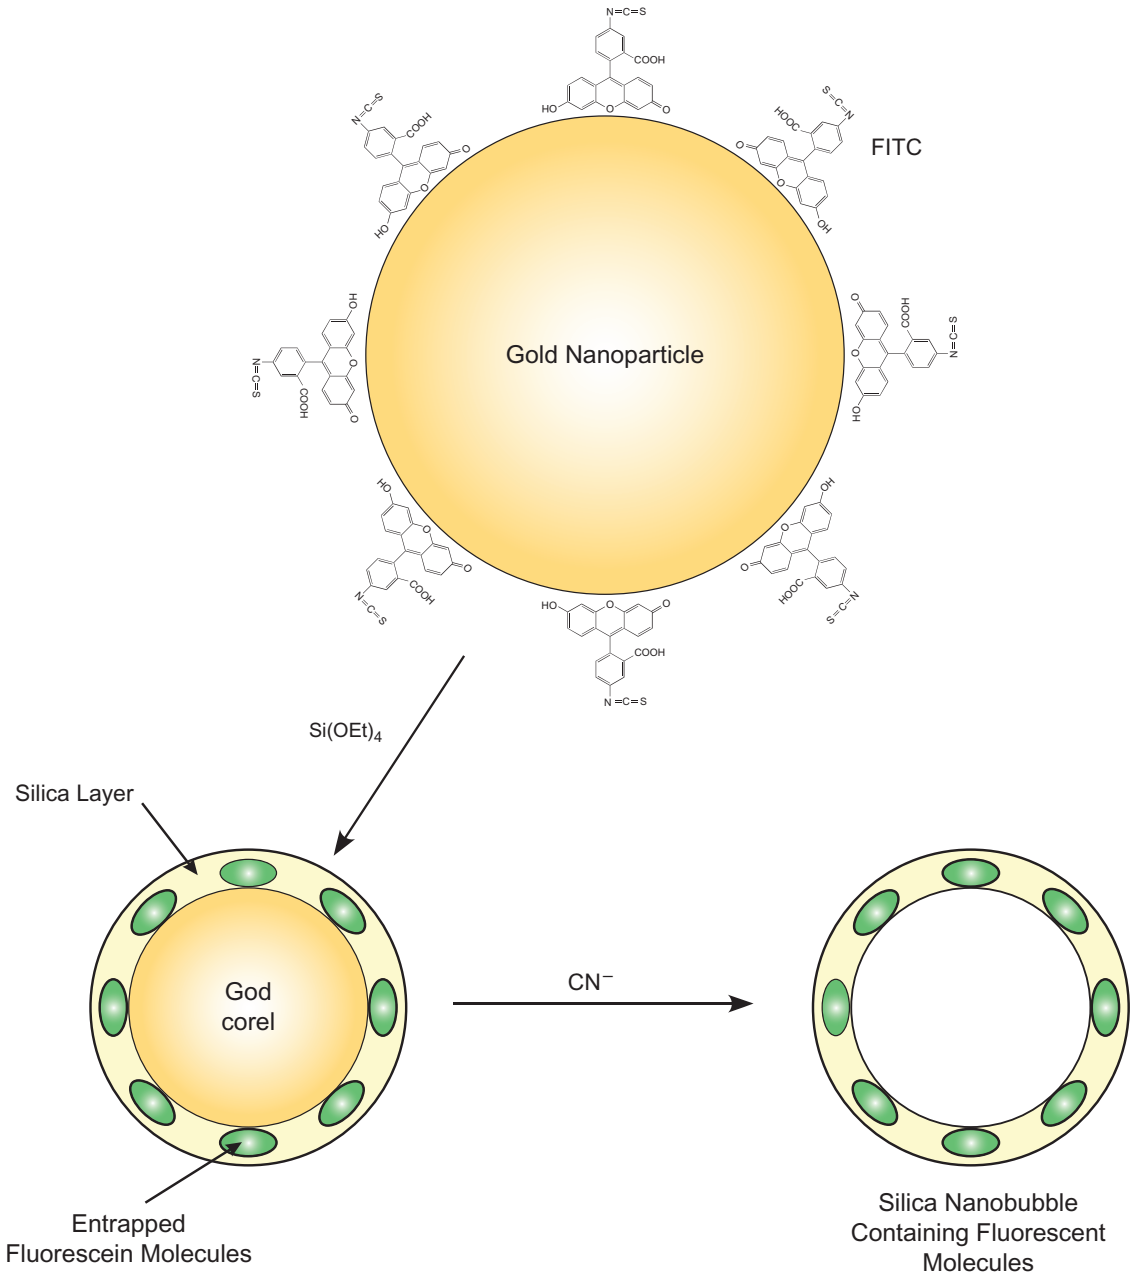

FIGURE 14.24 Fluorescent silica nanobubbles have been created using gold nanoparticle seeds that are initially coated by adsorption with a fluorescent dye. The particles then are capped by a layer of silica by polymerizing tetraethyl orthosilicate, which entraps the dye molecules within it. Finally, the gold core is dissolved by reaction with cyanide, leaving behind hollow fluorescent silica nanobubbles.

Fluorescent silica nanoparticles, called FloDots, were created by Yao *et al.* (2006) by two synthetic routes. Hydrophilic particles were produced using a reverse micro-emulsion process, wherein detergent micelles formed in a water-in-oil system form discrete nanodroplets in which the silica particles are formed. The addition of water soluble fluorescent dyes resulted in the entrapment of dye molecules in the silica nanoparticle. In an alternative method, dye molecules were entrapped in silica using the Stöber process, which typically results in hydrophobic particles. Either process resulted in luminescent particles that can then be surface modified with functional silanes to contain appropriate functionalities for coupling to affinity ligands or biomolecules. Ru(II)bpy$_3^{2+}$ or standard organic fluorescent dyes can be incorporated into such silica particles with high efficiency. In one example, a 70-nm particle containing Ru(II)bpy$_3^{2+}$ was found to be equal in fluorescence intensity to 39 quantum dots having an emission at 605 nm (Yao *et al.*, 2006). Another silica nanoparticle prepared using a rhodamine dye contained about 1290 molecules of the dye entrapped within each particle, which produced intensely fluorescent labels.

In a different method of producing dye-doped silica particles, van Blaaderen and Vrij (1992) and Verhaegh and van Blaaderen (1994) developed a method to covalently link amine-reactive dyes to 3-aminopropyltriethoxysilane (APTS) and then polymerize the resultant conjugate with tetraethyl orthosilicate (TEOS) in mixtures of ammonia, water, and ethanol to form fluorescent "organosilica" spheres. The dye molecules could be dispersed throughout the entire particle, contained in the core, or contained within discrete spherical regions within the particles. Either hydrophilic or hydrophobic particles could be created, depending on the surface treatment used subsequent to particle formation. Fluorescent particles consisting of either fluorescein or rhodamine dyes made by this method were shown to be susceptible to photobleaching similar to the organic dyes in solution.

Finally, fluorescent silica microspheres have been created by use of organosilane compounds forming particles in the presence of CdTe nanocrystals (quantum dots; see Chapter 10). This process loads numerous fluorescent nanoparticles into each silica microparticle (Liu and He, 2012). Using different colors of quantum dots for different preparations resulted in the formation of a range of different microparticles that had a broad spectrum of fluorescent characteristics. A single fluorescent quantum dot/silica particle was far brighter than individual fluorescent nanocrystals or any other organic dye used for detection applications.

The following protocol is based on the creation of fluorescent silica core/shell particles using the method of van Blaaderen and Vrij (1992).

Protocol for Formation of Dye Silica Core Particles

1. React APTS (11.5 mg) with FITC (10.6 mg) in anhydrous ethanol (1 ml) with mixing for 12 h (protect from light). The use of anhydrous conditions will prevent the hydrolysis of the APTS alkoxy groups, which would cause premature condensation.
2. Prepare a solution consisting of 75 ml of ethanol containing 8.5 ml of ammonia.
3. To the stirring ethanol/ammonia solution, add 3.3 ml of TEOS along with the completed reaction solution from step 1, which is now the conjugate of fluorescein and APTS linked through the amino group on the alkyl silane.
4. The reaction is allowed to continue for 24 h with slow stirring.
5. Wash the resultant core particles twice with the ethanol/ammonia solution using centrifugation.

Protocol for Formation of the Silica Shell

1. Dilute the particles to 1.2 l using a 10 : 1 mixture of ethanol:ammonia. Add 28 ml of TEOS to the particle suspension and mix to dissolve.
2. React for 24 h with slow mixing.
3. Wash the particles with the ethanol/ammonia solution several times using centrifugation. Finally, wash the particles into the desired solution (ethanolic or aqueous) without ammonia present to prevent silica hydrolysis upon storage.

Ow *et al.* (2004) developed an improved method of incorporating fluorescent molecules into silica particles using a modified Stöber synthesis, which resulted in both enhanced fluorescence and photostability of the encapsulated dyes. In this two-stage procedure, reactive organic dyes first are conjugated to a silane derivative and condensed to form a polysiloxane-dye-rich nanoparticle core structure. No TEOS is added at this point. These dyed core nanoparticles are then used as seed for the addition of silica sol-gel monomers to condense around the core and create a silica network (shell) around the dye-rich core (Figure 14.25). Nyffenegger *et al.* (1993) used a similar process to form fluorescein particles by first coupling FITC to 3-aminopropyltrimethoxy silane to form a thiourea derivative and then condensing the dye silane derivative with tetramethoxysilane to form the dyed silica particles.

The method developed by Ow and coworkers permits control over the size of the particles and allows the incorporation of virtually any organic dye into silica, provided it can first be conjugated to a silane derivative to form the core. Fluorescent particles made by this procedure may be made as monodisperse populations having diameters from less than 10 nm to over 1-μm spheres, with a high degree of precision. The core

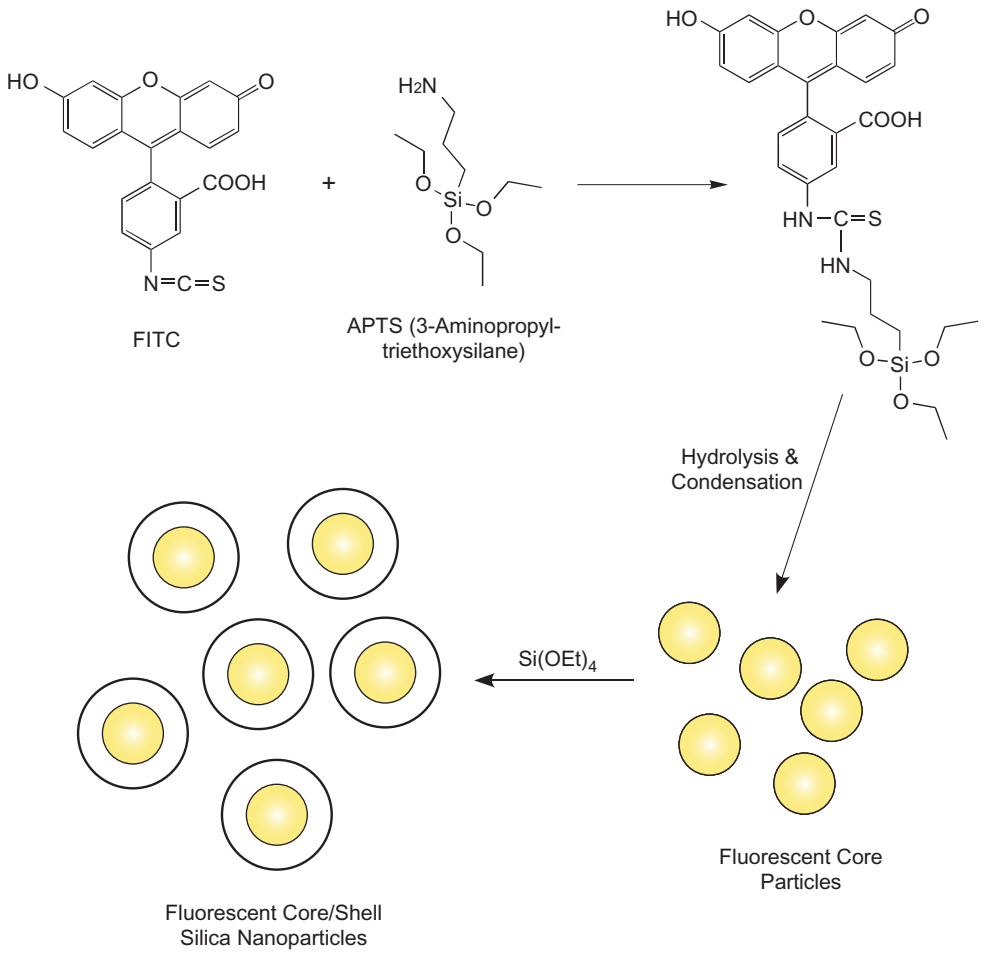

FIGURE 14.25 The preparation of highly controlled fluorescent silica nanoparticles can be done by first polymerizing APTS that has been covalently modified with an amine-reactive dye to form fluorescent core particles. The core then is capped by a shell of silica by polymerization of TEOS. The shell layer can be derivatized further with silane coupling agents to provide functional groups for conjugation.

size can also be varied by changing the concentration of the dye–silane derivative during the condensation process. The procedure for making these particles is similar to that described above using the method of van Blaaderen and Vrij (1992), but without the addition of TEOS for creation of the dye-silane core. Exact procedures are given in Wiesner *et al.* (2006).

In the preparation of 15-nm core-shell fluorescent silica particles, Ow *et al.* (2004) reported that the naked core (2.2 nm) alone produced a fluorescence intensity of less than the free dye in solution, presumably due to dye quenching. However, upon addition of the outer silica shell around the core, the brightness of the particles increased to 30 times that of the free dye (using tetramethylrhodamine-5-(and 6)-isothiocyanate (TRITC)). They speculate that the shell may protect the core from solvent effects, as evidenced by a lack of spectral shift upon changing the solvent in which the particles are suspended.

The enhanced photophysical properties of these fluorescent core-shell silica nanoparticles make them potentially as useful as semiconductor quantum dots for bioconjugation purposes. In this case, standard, commercially available, organic dyes can be incorporated into the silica nanoparticles to provide a range of emission properties as diverse as those available using the dyes alone. In addition, once encapsulated in the particles, the dyes display much better photostability and increased fluorescence (brightness) compared to the free dyes in solution. A major advantage of silica-based particles is that they are known to have greater biocompatibility than quantum dots in that they are nontoxic and hydrophilic and can be conjugated to proteins and other targeting molecules with relative ease. The ability to add any desired fluorescence characteristic to such particles simply by choosing the appropriate organic dye or metal chelate luminescent molecule makes dye-doped silica nanoparticles especially useful for bioapplications.

5.2. Silane Functionalization of Silica Particles

Surface functionalization of silica particles or fluorescent silica particles is typically done using functional alkyl silanes (Douroumis *et al.*, 2012; Lin *et al.*, 2012). The process may be used to add a reactive group to the surface of the particles for spontaneous coupling to biomolecules or it may be used to add the appropriate nucleophilic group to the surface, such as an amine or a carboxylate. Silane modification chemistry is discussed in more detail in Chapter 13.

The following protocol for modification of silica nanoparticles is based on the method of Zhao *et al.* (2004), which describes the addition of amine functionalities using trimethoxysilyl–propyldiethylenetriamine. Other functional silane modifications may be performed similarly.

Protocol

1. Add 32 mg of silica nanoparticles (fluorescent or plain) to 20 ml of 1-m*M* acetic acid containing 1% trimethoxysilyl–propyldiethylenetriamine with stirring. Other concentrations of silane derivatives used for particle modification typically range from 1% to 5% (w/w). Optimization of this concentration may have to be carried out for a particular silica particle size and type.
2. React with mixing for 30 min at room temperature.
3. Wash the amine-derivatized particles at least three times with water using centrifugation to remove excess reactants.
4. Store the particles in a suitable buffer at neutral or slightly acidic pH containing a preservative.

The amine-modified silica particles may be used to couple with carboxylate-containing ligands using a carbodiimide reaction. Similar coupling protocols may be used as that previously described for amine-containing polymer particles (Section 4, this chapter). The amine particles may also be further derivatized by reaction with succinic anhydride to create carboxylated particles for coupling to proteins or other amine-containing ligands.

5. To prepared the succinylated carboxylate derivative of the amine particles, wash the particles with water and then into DMF.
6. Suspend the amine particles in DMF containing 10% succinic anhydride.
7. React for 6 h under nitrogen gas with mixing.
8. Wash the carboxylated particles at least three times with DMF by centrifugation. Resuspend in water and wash three times with water to remove DMF. Store the particles in water or a suitable buffer at neutral or slightly acidic pH.

Carboxylated silica particles may be coupled with amine-containing ligands, such as proteins, using a carbodiimide reaction with EDC. A protocol similar to that previously described for coupling to carboxylate polymer particles may be used. The following protocol is based on the method of Zhao *et al.* (2004), which was used for immobilizing monoclonal antibodies to *E. coli* O157.

Protocol

1. Suspend the carboxylated silica particles from step 8, above, in 10 ml of 0.1-*M* MES, pH 6.8.
2. With mixing, add 500 mg of EDC and 500 mg of NHS (or sulfo-NHS).
3. React for 25 min at room temperature with stirring.
4. Quickly wash the activated particles with water using centrifugation to remove excess reactants. Resuspend the washed particles in 10 ml of 0.1-*M* sodium phosphate, pH 7.3.
5. Add a quantity of protein or antibody to the activated particles representing a 1- to 10-times excess of protein over the calculated monolayer for the type of particles used. For coupling a limiting amount of antibody to the activated fluorescent particles, something that may be desirable when using expensive monoclonals, the reaction should be carried out in very dilute particle suspension (i.e., 0.1 mg/ml) to prevent aggregation of particles due to the possibility of one antibody reacting with more than one particle. Zhao *et al.* (2004), used an antibody concentration of just 5 µg/ml to create antibacterial fluorescent particles.
6. React for 2 to 4 h at room temperature.
7. Add a blocking agent, such as a non-relevant protein (e.g., BSA) to a final concentration of 1% to mask any nonspecific binding sites and to couple with any remaining reactive groups on the silica particle surface. This is important especially if a limiting amount of antibody was initially reacted with the particles in step 5. React for 30 min to 1 h at room temperature.
8. Wash the particles several times with PBS, pH 7.2, to remove excess protein and reaction by products. Store the particles in neutral or slightly acidic buffer containing a preservative.

6. GOLD PARTICLES

As early as the first decade of the twentieth century colloidal gold sols containing particles of less than 10 nm were produced by chemical means (Zsigmondy, 1905). However, the application of these inorganic suspensions to protein labeling did not occur until 1971 when Faulk and Taylor invented the immunogold staining procedure. Since that time, the labeling of targeting molecules, especially proteins, with gold nanoparticles

has revolutionized the visualization of cellular or tissue components by electron microscopy (Horisberger *et al.*, 1975; Horisberger, 1979). The silver enhancement technique further broadened the application of gold labeling to include light microscopy (Holgate *et al.*, 1983). The electron-dense and visually opaque nature of gold labels also provided excellent detection qualities for such techniques such as blotting, flow cytometry, cytochemical staining, and hybridization assays (Jackson *et al.*, 1990; Gee *et al.*, 1991). Double- or triple-labeling systems have been constructed using immunogold methods in tandem with immunoenzymatic techniques to detect more than one antigen at the same time (Gillitzer *et al.*, 1990). Today, biosensing applications of gold nanoparticles have grown dramatically (Zeng *et al.*, 2011), and the methods of production and bioconjugation using gold are important aspects of particle-based methods to understand.

This section discusses the properties of gold particles as well as the common methods of labeling proteins and other biomolecules with them. The cited references should be consulted to obtain protocols for using these protein–gold complexes in assay and detection systems.

6.1. Properties and Use of Gold Conjugates

Colloidal gold suspensions consist of small granules (spheroids) of this transition metal in a stable, uniform dispersion. Viewed under the light or electron microscope, they appear as solid spheres of dense material. In electron microscopy the gold particles are visible as dense, dark markers usually black in appearance. In light microscopy, they can appear as light dots on a darker background due to the high reflectance of the particles or as an orange–red coating where they are localized in large conglomerates on cells or tissues. Colloidal gold particles act as efficient nuclei for deposition of silver, thus markedly enhancing their detection under light microscopy (Danscher and Rytter-Norgaard, 1983). The same silver–gold combination also provides increased sensitivity in blotting applications (Moeremans *et al.*, 1984).

Most preparations of colloidal gold consist of particles varying in diameter from about 5 nm to around 150 nm. The methods of forming small-particle gold suspensions of known diameter are discussed in Section 2.

The labeling of macromolecules with naked gold particles proceeds through a number of rather poorly understood processes. Preparing stable protein–gold complexes depends on several interactions: (1) the electronic attraction between the negatively charged gold particles and the abundant positively charged sites on the protein molecule; (2) an adsorption phenomenon involving hydrophobic pockets on the protein binding to the metal surface; and (3) the potential for binding of the gold with accessible sulfhydryl, oxygen, or nitrogen atoms *via* their unshared pairs of electrons to form dative bonds (see Chapter 3, Section 2.8) (Figure 14.26).

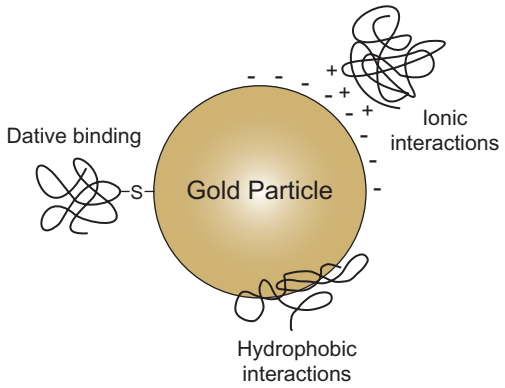

FIGURE 14.26 Protein binding to gold particles can occur through several types of interactions.

Deryagin and Landau (1941) and Verwey and Overbeek (1948) working independently developed a theory of the behavior of colloidal systems that aids in understanding macromolecular labeling with gold particles. Called the DLVO theory from the initials of the four authors, it views the particles in a sol as consisting of two components producing opposite effects in aqueous suspension. The overlap of the electrical double layer of each particle causes a negative charge on the surface, leading to particle–particle repulsion and stabilizing the sol from aggregation. The other phenomenon is electromagnetic in nature and leads to the potential for van der Waals attraction between the metal surface and other molecules.

In the colloidal suspension, a balance exists between the negative charge repulsion and the attractive forces which could cause coagulation. As particles approach each other, an energy barrier must be traversed to overcome the repulsive character of the negative surface and enter the region of van der Waals attraction. This barrier can be breached by the addition of electrolytes to the solution that can mask the negative charge on each particle. At a certain concentration of electrolytes, the colloid will begin to collapse as the gold particles adsorb onto one another, forming large aggregates and ultimately falling out of suspension.

Electrolyte-mediated coagulation forms the basis for creating all gold conjugates with other molecules. If macromolecules such as proteins are present in the colloidal suspension as the electrolyte concentration is raised to surpass the negative repulsion effects, then adsorption will occur with the protein molecules instead of with other gold particles. Thus, in place of aggregation and collapse of the suspension, labeling occurs.

The most common electrolyte additions in protein–gold labeling are NaCl or buffer salts. If no macromolecules are present, the addition of NaCl would itself cause gold particle coagulation. The aggregation is accompanied by a color change from orange–red to red–violet or blue (Roth and Binder, 1978), and it may be quantified spectrophotometrically by the change in absorbance at 580 nm (Horisberger *et al.*, 1976).

In practice, the addition of a protein to a gold sol will result in spontaneous adsorption on the surface of the gold particles due to electrostatic, hydrophobic, and van der Waals interactions. To prepare labeled proteins, initially the gold suspension is rapidly mixed while a quantity of protein is added. As the gold is bound to the protein molecules, a decrease in the absorbance at 580 nm occurs as the gold particles become stabilized and less coagulated. To check for the completeness of the adsorption process and to determine if the gold particles are totally blocked, a portion of the sol can be removed and an aliquot of NaCl added. If coagulation occurs upon addition of salt (increase in $A_{580\,nm}$), more protein should be added to completely stabilize the sol. Finally, many protocols further stabilize the colloidal suspension after protein binding by the addition of polyethylene glycol (PEG) or an immunochemical blocking agent, such as BSA or a solution of dried milk. These blocking agents completely mask any remaining sites of potential gold–gold or gold–protein interactions, thus preventing aggregation or nonspecific binding during assays.

To produce acceptable gold probes, it is often a common practice to add the minimum quantity of protein needed to prevent NaCl-induced aggregation plus about 10 to 20% excess (Horisberger and Rosset, 1977; De Mey *et al.*, 1981). Other investigators have reported that the addition of large excesses of protein to the amount of gold present yields conjugates of higher specific activity (Tokuyasu, 1983; Tinglu *et al.*, 1984). However, there is some evidence that overloading may cause leaching of loosely bound protein (Horisberger and Clerc, 1985).

As in any conjugation procedure, optimization of the ratios of reactants must be carried out to obtain the best probes. In labeling proteins with gold particles, several parameters should be considered: (1) the pI of the protein, (2) the pH of the adsorption process, and (3) the quantity of protein charged to the labeling reaction. It is generally believed that most proteins can be made to adsorb maximally at or near their isoelectric point (Norde, 1986). This is the pH of net electrical neutrality for a protein, wherein any electrically induced repulsive or attractive forces are balanced. For many proteins, especially antiserum-derived immunoglobulins, the average pI is a broad band encompassing a range of pH values. Thus, a polyclonal antibody preparation may possess an average pI much different than a particular purified monoclonal.

Geoghegan (1988) determined that as the pH of the adsorption reaction increased beyond the pI range, the percentage of IgG bound to gold particles decreased. However, for high-pI immunoglobulins, coupling at basic pH values increased the coupling yield. Geoghegan also noted that the more immunoglobulin that was charged to the adsorption process, the more ended up being coupled, although the percentage bound would decrease.

Thus, while definite standards for the ratio of protein to gold are not universally agreed upon, the efficiency of the process can be improved by following these general guidelines: (1) perform the adsorption reaction at a pH within the range of the pI of the protein being modified or at slightly higher pH; (2) charge an amount of protein to the gold particles that is slightly more (by about 10%) than necessary to maintain colloidal stability upon addition of NaCl; (3) avoid high overloads of protein, since this may promote subsequent leaching of bound material; (4) evaluate the degree of adsorption and the relative coagulation of the gold particles by measuring the absorbance of the solution at 580 nm; and (5) optimize each protein–gold conjugate as to colloidal stability and retention of activity.

An approximation of the correct amount of protein to be added to a gold sol to maintain stability of the colloid can be carried out using the following protocol (Slot and Geuze, 1984).

Protocol

1. Add 0.25 ml of the gold suspension to separate tubes containing 25 µl of different concentrations of the protein to be adsorbed. The amount of protein required to stabilize 1 ml of most gold sols is in the microgram range. The protein concentrations should be from about 10 µg/100 µl to about 150 µg/100 µl. Mix well.
2. After about 1 min, add 0.25 ml of 10% NaCl to the gold/protein suspension. Mix well.
3. Monitor the stability of the gold sol by its color or by the absorbance of the mixture at 580 nm. As long as the colloid continues to turn blue, and thus forms gold aggregates with addition of electrolyte, the amount of protein added is not sufficient to stabilize the suspension. This condition translates into a decrease in the absorbance at 580 nm. When the concentration of protein added is enough to stabilize the colloidal suspension, the solution no longer changes color (the absorbance at 580 nm no longer decreases).

4. The amount of protein added at the stabilization point plus 10% should be used to produce the final protein–gold conjugate.

The use of gold probes in detection systems has a number of advantages. The ability to label macromolecules with a range of gold particle sizes makes it possible to visualize the probe under a variety of microscopic conditions. Gold avoids all the disadvantages of radioactive labels, while being much more stable to quenching or fading than fluorescent probes or enzymatically developed substrate chromophores. A gold-labeled tissue, cell, or blot will maintain its record of staining on a permanent basis. Under sufficient magnification, an assessment of the degree of antigen labeling can be made simply by counting the number of gold particles present per unit area of cell or tissue mass. This cannot be done with other labeling systems, since chemical stains develop an amorphous quality that does not allow differentiation of individual molecules. Finally, gold probes are essentially non-toxic and relatively inexpensive to use.

A variety of biological molecules can be labeled with gold particles. Proteins are perhaps the most common gold probes; toxins, antibodies, immunoglobulin-binding proteins such as protein A, enzymes, lectins, avidin and streptavidin, lipoproteins, and glycoproteins have all been labeled with colloidal gold to form highly sensitive reagents. In addition, polymers, hormones, carbohydrates, and lipids have been gold-labeled for various applications. Small hapten molecules co-adsorbed with adjuvant peptides to gold particles make extraordinary immunogen complexes, producing polyclonal antibody responses having very high titers (Pow and Crook, 1993).

Very small gold particles can even be derivatized to contain specific chemical reactive groups for covalent coupling to macromolecules. For instance, an NHS ester-containing gold particle of 1.4 nm is manufactured by Nanoprobes (Stony Brook, NY). Presumably, such derivatives are formed by adsorption of chemically reactive polymers or by dative binding with a sulfhydryl-containing modification reagent.

The following sections discuss the preparation of colloidal gold suspensions of various particle sizes and their use in labeling proteins for detection purposes. Gold-labeled molecules and proteins are available from a number of manufacturers (Janssen, E-Y Labs, and Nanoprobes).

6.2. Preparation of Mono-Disperse Gold Suspensions for Protein Labeling

Mono-disperse colloidal gold suspensions useful for labeling macromolecules can be produced by a variety of chemical methods. Three main procedures have become common for making particles that fall into predictable particle-size ranges. All of them use reductive processes on chloroauric acid ($HAuCl_4$) to create the spheroidal gold particles. In general, the greater the power and concentration of the reducing agent, the smaller the resultant particles will be.

To create large-particle colloidal gold dispersions, chloroauric acid is normally treated with sodium citrate. The result is a particle range of about 15 to 150 nm, depending on the concentration of citrate utilized (Horisberger and Rosset, 1977; Horisberger, 1979; Pow and Morris, 1991). Medium-sized gold particles of between 6-nm and 15-nm diameter (average 12 nm) are formed by treatment with sodium ascorbate as the reductant (although some procedures use trisodium citrate at higher concentrations than the sodium citrate used for making large particles) (Horisberger and Tacchini-Vonlanthen, 1983; Albrecht, 1989). The smallest gold particles (<5 nm diameter) are created by reduction with either yellow or white phosphorus (Zsigmondy, 1905; Faulk and Taylor, 1971; Horisberger and Rosset, 1977; Pawley and Albrecht, 1988). Particles as small as 2 nm may be created by reduction with sodium borohydride (Bonnard *et al.*, 1984). Other more esoteric methods of reducing gold salts to form nanoparticles also have been developed, although their routine use is not yet established (Ryu *et al.*, 2011; Sharma *et al.*, 2012).

The following protocols for creating colloidal gold sols are adaptations from the above-cited articles. To obtain reproducible preparations, extreme care should be taken in making each batch to maintain the same reagent concentrations, temperatures, and times for the reactions. In each preparation, a color change is noted as the chloroauric acid is reduced from its initial state to the final gold sol. The initial color is typically a brown, purple–red, or dark blue, depending on the reductant used and other conditions. The final color of the monodisperse colloidal gold preparation is typically red.

Preparation of 2-nm Gold Particle Sols

1. Prepare 1 ml of a 4% $HAuCl_4$ solution in deionized water.
2. Add 375 µl of the chloroauric acid solution plus 500 µl of 0.2-*M* K_2CO_3 to 100 ml deionized water, cooled on ice to 4°C. Mix well.
3. Dissolve sodium borohydride ($NaBH_4$) in 5 ml of water at a concentration of 0.5 mg/ml. Prepare fresh.
4. Add 5 1-ml aliquots of the sodium borohydride solution to the chloroauric acid/carbonate suspension with rapid stirring. A color change from bluish-purple to reddish-orange will be noted as the additions take place.
5. Stir for 5 min on ice after the completion of sodium borohydride addition.

Preparation of 5-nm Gold Particle Sols

1. Prepare 7 ml of a 1% $HAuCl_4$ solution in deionized water.
2. Add 6.25 ml of the chloroauric acid solution plus 5.8 ml of 0.1-*M* K_2CO_3 to 500 ml deionized water. Mix well.
3. In a fume hood, prepare a saturated solution of white phosphorus in diethyl ether, then dilute 1 part of the saturated phosphorus solution with 4 parts of diethyl ether.
4. Add 4.16 ml of the diluted phosphorus solution to the chloroauric acid/carbonate solution with mixing.
5. React at room temperature for 15 min.
6. Bring the mixture to a boil and reflux until the color of the suspension turns from brownish to red. This should take no more than about 5 min.
7. Cool the sol to room temperature.
8. The pH of the suspension will be around 6. Adjustments to more alkaline conditions for adsorbing macromolecules of higher pI may be done by addition of 0.1-*M* K_2CO_3 with stirring. Monitor pH of the sol using a gel-filled electrode (Orion Research, No. 9115, Cambridge, MA) (Geoghegan *et al.*, 1980). After pH adjustment, the gold should be used immediately for complexing with a protein or other macromolecule.

Preparation of 12-nm Gold Particle Sols

1. Prepare 5 ml of a 1% $HAuCl_4$ solution in deionized water.
2. Add 4 ml of the chloroauric acid solution plus 4 ml of 0.1-*M* K_2CO_3 to 100 ml deionized water. Mix well and cool the solution on ice.
3. With rapid mixing of the chloroauric acid/carbonate solution, quickly add 1 ml of a 7% sodium ascorbate solution prepared in water. Maintain the solution cooling in an ice bath. Higher temperatures will create larger particle sizes. The color of the solution at this point will turn to a purple–red.
4. Adjust the volume of the reaction to 400 ml with deionized water.
5. Bring the mixture to a boil and reflux until the color of the suspension turns from purple–red to red.
6. Cool the sol to room temperature.
7. The pH of the suspension will be around 6. Adjustments to more alkaline conditions for adsorbing macromolecules of higher pI may be done by addition of 0.1-*M* K_2CO_3 with stirring. Monitor pH of the sol using a gel-filled electrode (Geoghegan *et al.*, 1980). After pH adjustment, the gold should be used immediately for complexing with a protein or other macromolecule.

Preparation of 30-nm Gold Particle Sols

1. Prepare 1 ml of a 4% $HAuCl_4$ solution in deionized water.
2. Add 0.5 ml of the chloroauric acid solution to 200 ml of deionized water and bring to a boil while mixing.
3. Add to the boiling, rapidly mixing solution of chloroauric acid 3 ml of a 1% sodium citrate solution.
4. Reflux for 30 min. The color of the suspension will change from dark blue to red as the mono-disperse colloidal gold particles are formed.
5. Cool to room temperature.

Any of the particle sols prepared above may be used to adsorb macromolecules to create gold probes. To concentrate the suspensions, the solutions may be filtered through a small-pore filter. Centrifugation also may be done. Each protein–gold complexation should be optimized for the proper amount of protein to add to maintain stability of the colloid. This can be done according to the method described in Section 1.

6.3. Preparation of Protein A–Gold Complexes

Protein A–gold probes (as well as other immunoglobulin-binding proteins adsorbed to gold) have been used to visualize antibody binding to antigenic sites in tissue sections, cells, and blots (Hearn, 1987; Jemmerson and Agre, 1987; Lethias *et al.*, 1987; Bendayan and Garzon, 1988; Yokota, 1988; Bendayan, 1989; Herbener, 1989; Roth *et al.*, 1989; Stump *et al.*, 1989; Hoefsmit *et al.*, 2011; Mannweiler *et al.*, 2011). Gold labeling of immunoglobulin-binding proteins provides "universal" probes for detection of any antibody–antigen interaction (Figure 14.27). Thus, only one gold-labeled reagent need be prepared to visualize many different immunochemical targeting procedures. This avoids having to make antibody–gold probes for each specific immunoglobulin used. The downside of this approach, however, is the potential nonspecificity of protein A in binding other antibodies that may be present within the sample.

Protocol

1. Determine the minimum amount of protein A required to stabilize the colloidal gold sol being used. The colloidal suspension should be adjusted, if needed, with 0.1-*M* K_2CO_3 to pH 6 to 7. Measure the pH of the sol using a gel-filled electrode. Determining the stabilization amount of protein A can be achieved according to the method described in Section 1.
2. Mix a stabilizing amount of protein A plus an additional 10% with the appropriate volume of colloidal gold. For example, Herbener (1989) mixed

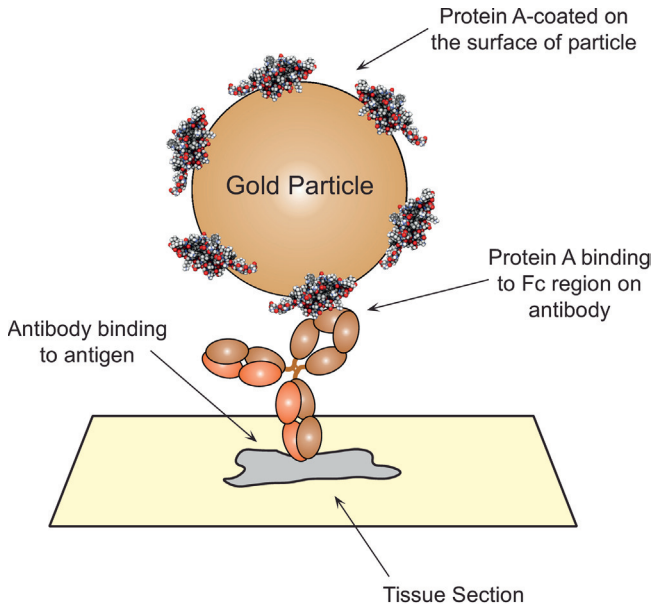

FIGURE 14.27 Antigens may be detected in cells or tissue sections through the use of protein A-coated gold particles. The binding of a specific primary antibody to its target antigen can be localized by the immunoglobulin binding capability of protein A, which occurs in the Fc region of the antibody.

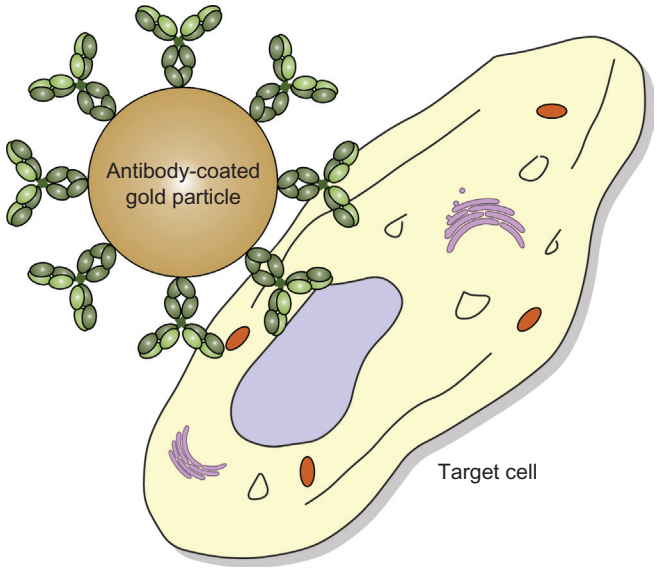

FIGURE 14.28 Antibodies coated on colloidal gold particles can be used to detect specific antigens in cells.

10 ml of a 14-nm gold particle sol at pH 6.9 with 0.3 mg of protein A dissolved in 0.2 ml water. Mix well.

3. After 1 min, add 250 µl of 1% polyethylene glycol (PEG; molecular weight 20,000) per 10 ml of gold sol used. The PEG helps to stabilize further the sol against aggregation.
4. Stir for an additional 5 min.
5. To remove excess protein A, centrifuge the preparation at a minimum of 50,000 *g* for 30 min to several hours (4°C), depending on the size of the particles and the amount of solution. Discard the supernatant, and resuspend the protein A–gold pellet in 0.01-*M* sodium phosphate, pH 7.4, containing 1% PEG.

6.4. Preparation of Antibody–Gold Complexes

Immunocytochemical staining with antibody–gold probes is a powerful way to detect, localize, and quantify antigen molecules in tissue sections and cells (Figure 14.28). Antibody–gold particles also have been used as chromogenic sensors in immunochromatographic strip tests (or lateral flow assays) (Preechakasedkit *et al.*, 2011). Metabolic processes can be followed, epitope mapping of the structural characteristics of macromolecules can be performed, and detection of pathogens or other foreign substances within cells can be accomplished using gold-labeled antibodies (Ellis *et al.*, 1988; Albrecht *et al.*, 1989; Cramer *et al.*, 1989; De Waele *et al.*, 1989; Nielsen *et al.*, 1989; Martinez-Ramon *et al.*, 1990; van den Brink *et al.*, 1990; Thiruppathiraja et al., 2011).

The optimal coupling pH for an antibody should be determined by measurement of the relative pI range of the immunoglobulin. Many antibodies, however, adsorb best at a pH of 8 to 9. The optimal level of protein addition to the gold sol to prevent aggregation should be determined according to the method of Section 6.1. In addition, bovine serum albumin (BSA) is often added instead of PEG (see the protein A coupling procedure, described previously) to further stabilize the antibody–gold suspension.

Protocol

1. Determine the minimum amount of antibody required to stabilize the colloidal gold sol being used. The colloidal suspension should be adjusted, if needed, with 0.1-*M* K_2CO_3 or NaOH to pH 8 to 9. Measure the pH of the sol using a gel-filled electrode. Determining the stabilization amount of antibody can be done according to the method described in Section 1.
2. Mix a stabilizing amount of antibody plus an additional 10% with the appropriate volume of colloidal gold. For example, Geoghegan (1988) found that an addition of 10 to 14 µg of antibody per milliliter of gold colloid resulted in stable preparations. Mix well after addition of antibody to the gold suspension.

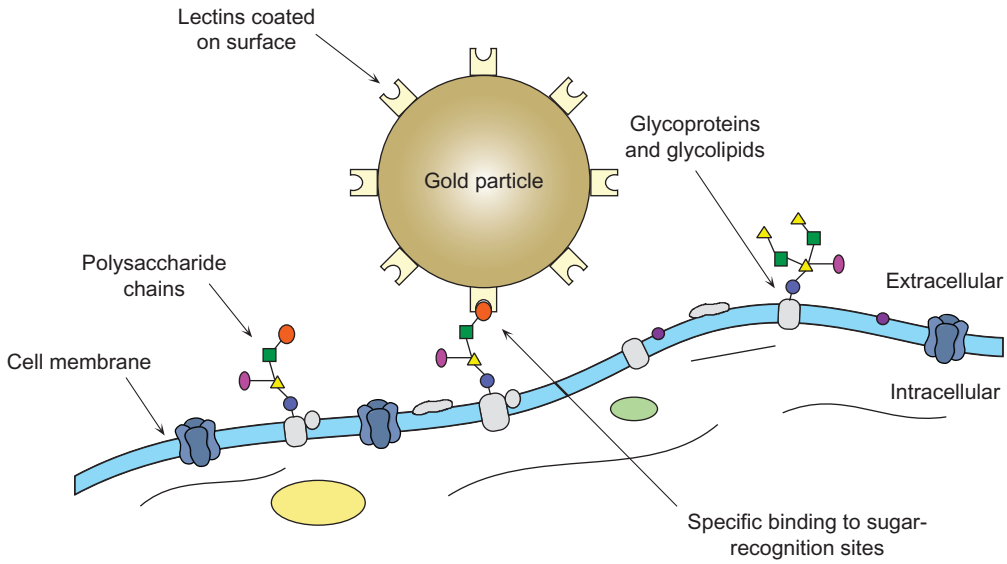

FIGURE 14.29 Lectins coated on gold particles can be used to detect specific carbohydrate sequences in cell surface glycoconjugates.

3. After 1 min, add a quantity of 10% BSA to bring the concentration to 0.25% in the antibody–gold suspension. The BSA helps to further stabilize the sol against aggregation and also blocks nonspecific binding sites. Alternatively, PEG may be added according to step 3 of Section 3.
4. Stir for an additional 5 min.
5. To remove excess IgG, centrifuge the preparation at a minimum of 50,000 *g* for 30 min to several hours (4°C), depending on the size of the particles and the amount of solution. Discard the supernatant, and resuspend the antibody–gold pellet in 0.01-*M* sodium phosphate, pH 7.4, containing 0.25% BSA (or 1% PEG, as desired).

6.5. Preparation of Lectin–Gold Complexes

Lectins, or proteins with specific binding sites for carbohydrates, can be used as targeting molecules to localize particular glycoconjugates such as glycoproteins or glycolipids on cell surfaces (Figure 14.29). Labeled with gold particles, lectins are important probes for detection of cell-surface components, intracellular receptors, and in immunological or biochemical assay procedures (Bog-Hansen *et al.*, 1978; Nicolson, 1978; Kimura *et al.*, 1979; Roth, 1983, 2011; Benhamou *et al.*, 1988; Nakajima *et al.*, 1988; Sánchez-Pomales *et al.*, 2012).

The following generalized protocol is an adaptation for the labeling of 15-nm gold particles with *Aplysia* gonad lectin, as described by Benhamou *et al.* (1988). Each lectin–gold preparation will have its own unique pH optimum and ratio of lectin-to-gold for the absorption process.

Protocol

1. Determine the minimum amount of lectin required to stabilize the colloidal gold sol being used. The colloidal suspension should be adjusted, if needed, with 0.1-*M* K_2CO_3 or NaOH to a pH equal to or slightly above the pI of the lectin being used. For *Aplysia* gonad lectin, the optimal pH for adsorption was determined to be 9.5. Nakajima *et al.* (1988) include pI conditions for a number of different lectins. Measure the pH of the sol using a gel-filled electrode. Determining the stabilization amount of lectin can be done according to the method described in Section 1.
2. Mix a stabilizing amount of lectin plus an additional 10% with the appropriate volume of colloidal gold. For example, Benhamou *et al.* (1988) found that an addition of 5 µg of lectin per milliliter of gold colloid resulted in stable preparations. However, in their final lectin–gold conjugate preparation a 5-fold increase in this ratio (25 µg lectin/ml gold) was used to fully stabilize the sol. Mix well after addition of lectin to the gold suspension.
3. After 1 min, add 250 µl of 1% polyethylene glycol (PEG; molecular weight 20,000) per 10 ml of gold sol used. The PEG helps to further stabilize the sol against aggregation.
4. Stir for an additional 5 min.
5. To remove excess lectin (particularly important if the 5-fold excess ratio is used), centrifuge the preparation at a minimum of 50,000 *g* for 30 min to several hours (4°C), depending on the size of the particles and the amount of solution. Discard the supernatant, and resuspend the lectin–gold pellet in 0.01-*M* sodium phosphate, pH 7.4, containing 1% PEG.

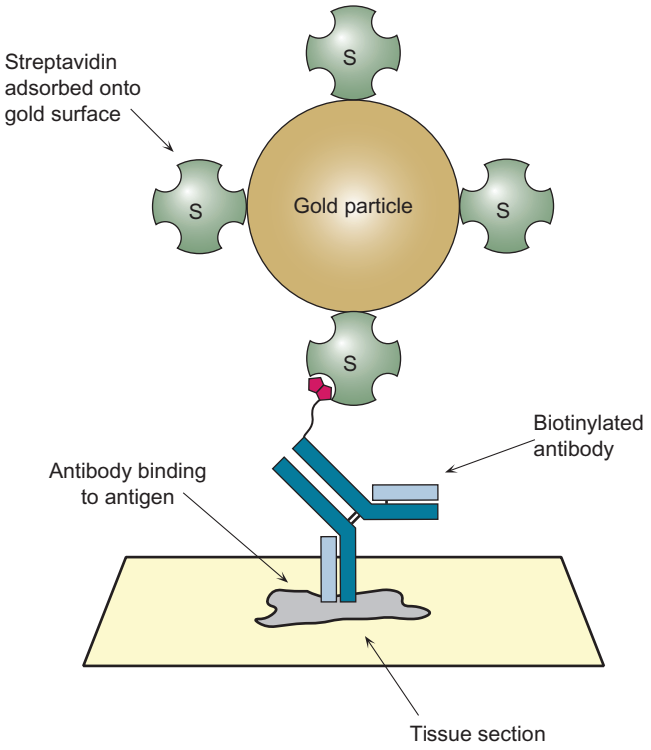

FIGURE 14.30 Streptavidin-coated gold particles can be used to detect biotinylated antibodies that are bound to specific antigenic determinants.

6.6. Preparation of (Strept)avidin–Gold Complexes

Avidin– or streptavidin–gold conjugates can be used to detect, localize, or quantify the binding of biotinylated molecules in cells, tissue sections, or blots (Bonnard *et al.*, 1984; Morris and Saelinger, 1984; Bronckers *et al.*, 1987; Gillitzer *et al.*, 1990; Ishida-Yamamoto *et al.*, 2012; Krager *et al.*, 2012) (Figure 14.30). These reagents are similar to the use of protein A–gold complexes in detecting immunoglobulins (Section 3) in that they are "universal" for detecting any biotin-labeled molecules. Thus, targeting molecules need not be directly modified with gold, only biotinylated so that they are able to interact with avidin– or streptavidin–gold conjugates. See Chapter 11 for additional information on (strept)avidin–biotin techniques, including conjugation and biotinylation protocols.

The following protocol is based on the method of Morris and Saelinger (1984) for the labeling of succinylated avidin with gold particles of 5.2 nm diameter. Succinylated avidin was used to reduce the pI of the protein, thus eliminating nonspecific binding due to the strong positive charge of the native tetramer. Alternatively, streptavidin or NeutrAvidin (Thermo Fisher) can be used in a similar immobilization protocol to coat gold particles without the need for using a succinylated derivative.

Protocol

1. Prepare a 200-ml gold sol by using white phosphorus reduction as described in Section 2.
2. Prepare 5 ml of a 1-mg/ml succinylated avidin solution by dissolving the protein in 50-m*M* sodium phosphate, pH 7.5.
3. With stirring, add the succinylated avidin solution to the colloidal gold suspension at room temperature.
4. React for 30 min with constant mixing.
5. Remove excess protein by centrifugation at a minimum of 50,000 *g* for several hours.
6. Suspend the succinylated avidin–gold pellet in 50-m*M* Tris, 0.15-*M* NaCl, pH 7.5, containing 0.5 mg/ml PEG (molecular weight 20,000).
7. Centrifuge again under the same conditions to ensure complete removal of non-adsorbed protein.
8. Resuspend the pellet in Tris buffer containing PEG and store at 4°C.

A similar protocol has been used by Bonnard *et al.* (1984) in the preparation of streptavidin–gold probes.

Protocol

1. Prepare 20 ml of a gold sol by the white phosphorus method described in Section 6.2.
2. Dissolve streptavidin in 0.1-*M* sodium phosphate buffer, pH 7.4, at a concentration of 1 mg/ml.
3. With stirring, add the streptavidin solution to the gold suspension. Immediately add 200 µl of 1-*M* sodium bicarbonate.
4. React for 10 min at room temperature.
5. To stabilize further the colloid, add 200 µl of 2% PEG 6000.
6. Centrifuge the streptavidin–gold suspension at a minimum of 50,000 *g* for several hours to remove excess protein solution.
7. Resuspend the pellet in 0.1-*M* sodium phosphate, 0.02% PEG, pH 7.4, and store at 4°C.

CHAPTER

15

Immobilization of Ligands on Chromatography Supports

Affinity chromatography has become one of the most powerful techniques available for the isolation of biological molecules. Since the beginnings of this technology in the late 1960s and early 1970s the application of affinity separations using immobilized affinity ligands has grown to affect nearly every aspect of life science research and has even been used in many other scientific disciplines. The basic concept of affinity chromatography involves the use of a biospecific or chemically specific interaction between an immobilized ligand and a desired target molecule to selectively bind and interact with the target even in complex solutions containing many other components. This specific affinity interaction is able to capture the target while removing contaminants or other molecules in a solution and in a single step enrich or purify the targeted molecule away from all other molecules that cannot bind the ligand (Figure 15.1).

Immobilized affinity ligands have been used for many purposes, including the isolation or purification of proteins and other biological molecules, in the capture and study of interacting proteins, for removal of contaminants from biological solutions, for enzymatic or chemical catalysis, and for analytical separations involving the assay of a targeted molecule (Calleri *et al.*, 2011; KumaraSwamy *et al.*, 2011; Sheshagirirao *et al.*, 2011; Zeng *et al.*, 2011; Cheung *et al.*, 2012; Vuignier *et al.*, 2012). Chapter 1, Sections 3.3 and 3.4, describe many of these application techniques in the general introduction to bioconjugation. In this chapter, the techniques of immobilization of affinity ligands will be described, including the matrices available for coupling, the activation chemistry used to form reactive groups on these supports, and the coupling chemistry commonly used to couple a wide variety of ligand types. Many of the methods are based upon those described in Hermanson *et al.* (1992), but they are significantly updated here to reflect the latest developments in chromatography support materials and coupling techniques.

The immobilization of affinity ligands onto insoluble support materials allows the creation of a specific affinity matrix that has binding specificity toward a desired target molecule. The insoluble support typically consists of a biocompatible material that can be modified to covalently link to the affinity ligand. The word "matrix" often is used to describe any material to which a biospecific ligand may be attached covalently. In most cases, the matrix is insoluble in a biological solution containing the target molecule. In some cases, however, the matrix may consist of a soluble polymer that can be modified to contain an affinity ligand.

The most common matrix type used for affinity chromatography consists of porous, beaded materials of generally spherical design that can accommodate biological macromolecules within their porous structure. This type of support material is typically used for chromatographic purposes in the purification of proteins and other biological molecules in volumes ranging from the bench-top research scale to the bioprocess scale. These materials often are referred to as affinity "supports," "resins," "beads," or "gels." Affinity chromatography supports of this type that are used in purification processes often have particle diameters ranging from about 50 to 150 µm and easily settle out of suspension when left standing without mixing. Matrices of this diameter can be used in packed columns or batch operations in scales ranging from microliters or milliliters for bench chromatography to literally hundreds or thousands of liters in size, which are exploited for many process chromatography applications in biotech and pharmaceutical companies.

In other applications, affinity supports can be prepared using nonporous beads consisting of particles at the low-end micron- or even nanometer-diameter range. Affinity supports prepared with such small

particles also can be used in packed columns for chromatography purposes, such as in HPLC or UPLC separations, but most often they are used to create insoluble affinity supports for use in batch separations or in analytical techniques. The immobilization of antibodies or other affinity ligands onto microspheres, for example, has been extensively used to develop heterogeneous immunoassays to measure the concentration of proteins or other target molecules in biological samples. Superparamagnetic microspheres can also be coupled with affinity ligands to form a separation system that can capture a target molecule and then be rapidly separated from solution through the application of a magnetic field. Such affinity supports are widely used in clinical diagnostic autoanalyzers to measure important analytes in patient samples. See Chapter 14 for a discussion on the coupling methods typically used with these very small particles to produce affinity supports.

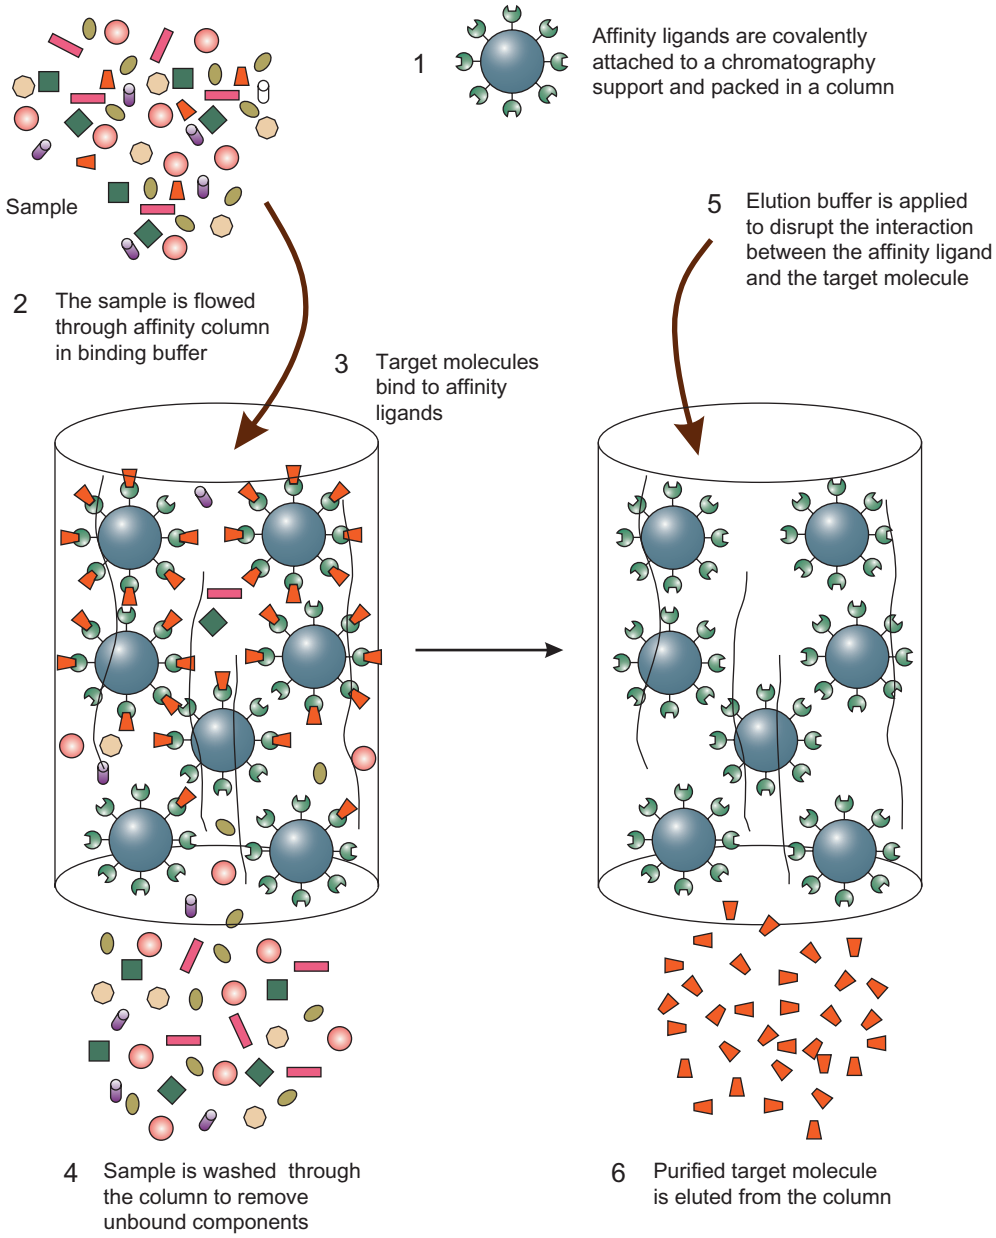

FIGURE 15.1 The principal of affinity chromatography in a column format is depicted in this illustration. An immobilized ligand is attached to an insoluble support material which is typically beaded in nature and the affinity resin is packed into a column. The column is equilibrated with binding buffer and a sample containing a target molecule which has affinity for the ligand is passed through the column. The target molecule binds to the immobilized ligands and is retained in the column while any not-bound material is washed off. An elution buffer is then added to the column, which disrupts the interaction between the ligand and the target molecule and allows the purified target to be isolated.

1. SUPPORT MATERIALS USED FOR AFFINITY CHROMATOGRAPHY

Affinity supports used for chromatography purposes can be highly diverse and have a wide range of properties. They can consist of natural polymers, synthetic organic supports, inorganic ceramic particles, naturally occurring constructs such as diatomaceous earth, membranes or surfaces, or composite constructions consisting of two or more of these materials. The most widely used matrix materials are greater than 10 μm in size and consist of natural polymers such as agarose or synthetic polymeric beads that are formed from hydrophilic monomers. Affinity supports of less than 10 μm in diameter commonly consist of copolymer derivatives or silica-based supports. Even extremely small nanoparticles made of metallic spheres or semiconductor alloys also are important substrates for the immobilization of affinity ligands; however, the coupling of ligands to nonporous particles of less than about 5 μm in size is described in Chapter 14, while this chapter exclusively focuses on the coupling reactions commonly used to make affinity chromatography supports on larger porous particles, membranes, and monolithic constructs.

For use with biological molecules, affinity supports must have a base matrix that is both hydrophilic and biocompatible so that the matrix itself does not bind nonspecifically to molecules in a sample. Therefore, to prepare a highly specific affinity chromatography support, the matrix must have two characteristics that are important to the performance of the final affinity complex: (1) it must be inherently low in nonspecific binding; and (2) it must contain reactive groups or functional groups that can be activated to couple the desired affinity ligand. The following sections summarize the major matrix types typically used for affinity chromatography and fulfill these criteria for biocompatibility and functionality.

1.1. Natural Product Chromatography Supports

Agarose Supports

One of the most common support materials is agarose, which is the naturally occurring major polysaccharide component found in agar, extracted from certain red seaweeds (class Rhodophyta, red algae). It consists of alternating residues of D-galactose and 3,6-anhydro-L-galactopyranose (Figure 15.2), with the occasional presence of repeating D-galactose side chains in α-1,4 linkages (initially linked to the C6 hydroxyl of D-galactose of the main chain). Some of the L-galactose residues are not in the anhydro form, thus the polymer may contain a quantity of alternating D-galactose and L-galactose residues. The C6 –OH group of the D-galactose units can be methylated in some preparations, as can the C2 –OH group of the L-galactose units on the main chains. The main polymer strands can be

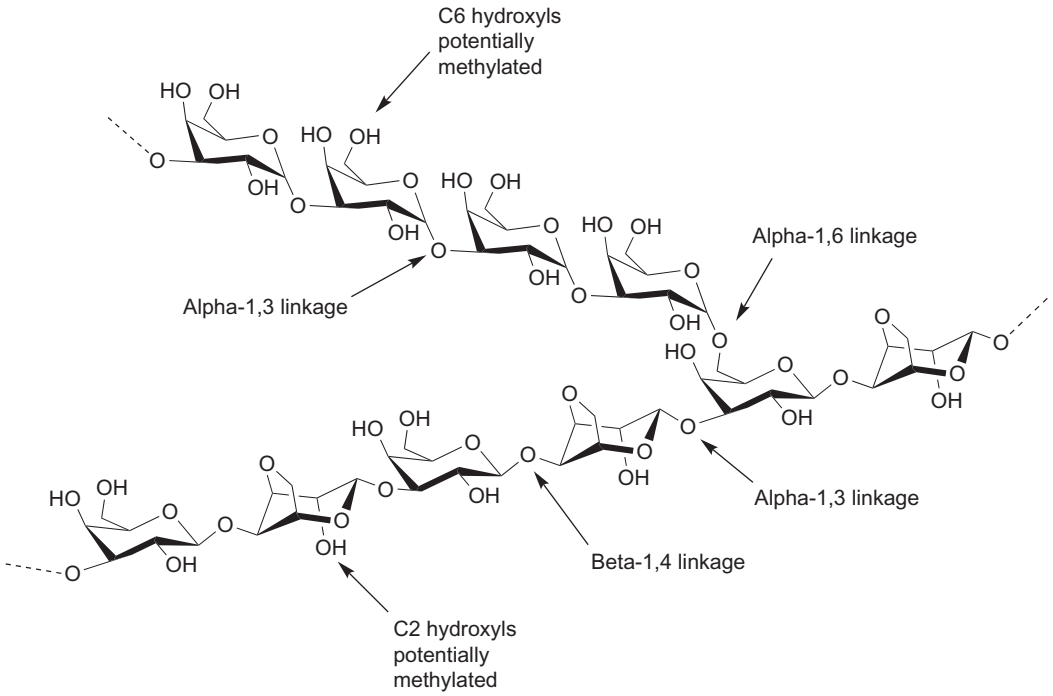

FIGURE 15.2 The repeating disaccharide structure of an agarose polymer is shown, which contains abundant hydroxyl groups that confer excellent hydrophilicity to chromatography supports made of this natural carbohydrate.

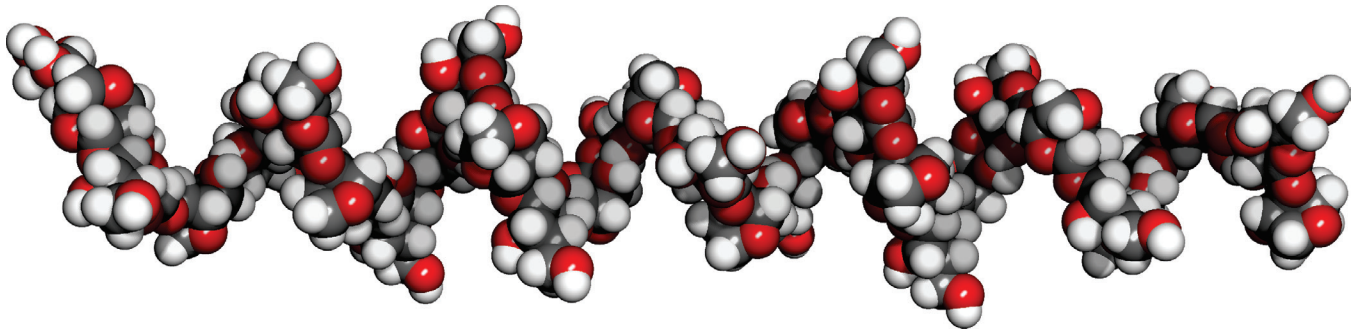

FIGURE 15.3 A space-filling, twisted helical structure of a single agarose polymer strand is illustrated in this figure. In agarose chromatography supports multiple double helices are often associated in super-helical structures which include triple helices. These polymer structures are naturally stabilized through numerous hydrogen-bonding sites along the polysaccharide chains. In crosslinked agarose, the structure is further stabilized by covalent attachments between the chains, which prevent disruption due to melting or denaturation.

further associated together in a left-handed, double-helical construction held together by hydrogen bonds, and these double helices can be further associated with two other double helices in a large wound complex. Two such complexes subsequently can be wrapped around each other into larger supermolecular helices, which are all stabilized by a huge network of hydrogen bonding between chains. Figure 15.3 illustrates the natural helical arrangement of a single agarose polymer strand. The double and higher order helical polymers arrange themselves together through a complex structure that is extraordinarily gelatinous in nature and when formed into beads. The agarose component takes up only about 2 to 6% of the particles by weight, while the remainder is water which hydrates and swells the aerogel structure. The agarose polymer strands weave throughout each particle to form a highly porous gelatinous bead that has a translucent appearance under a microscope and a spongy consistency. Since the large hydrodynamic volume of the support forms the bulk of each bead, the pore structure of agarose is huge compared to other chromatography supports. For this reason, agarose can have an exclusion limit for macromolecules well into the millions of Daltons.

In addition, the carbohydrate nature of an agarose support provides an uncharged, very hydrophilic environment for optimal use with biomolecules, which naturally has very low nonspecific binding character toward proteins. Commercial beaded agarose supports are typically crosslinked with small bifunctional reagents such as 2,3-dibromopropanol, epichlorohydrin, or divinyl sulfone to increase the stability of the matrix and prevent melting under elevated temperature or changing structure under denaturing conditions. Non-crosslinked agarose supports also can be used for chromatography, but the chemical, thermal, and mechanical stability of the crosslinked agarose supports is far superior for use in affinity separations.

The aerogel structure of agarose chromatography supports creates a large inner particle environment that accommodates even the very largest macromolecules; however, due to its gel-like construction and compressible nature agarose easily can be damaged. The most critical factors that may cause bead damage include mechanical disruption such as grinding particles against surfaces, using too high a flow rate during chromatography which may result in an excessive pressure drop which crushes the beads, the use of solvents that alter the internal structure of the beads by disrupting hydrogen bonding, or drying the particles without the use of an excipient. Agarose actually can be freeze dried and stabilized against particle damage through the addition of a sugar molecule such as lactose, which takes up the hydrogen bonding interactions upon loss of water. Some reactive agarose supports are stabilized for commercial purposes by freeze drying in the presence of 15% lactose and will rehydrate rapidly without difficulty or damage to the particles. Other nonreducing sugars may also be used for this purpose, as the multiple hydroxyl groups on the sugars effectively stabilize the agarose polymers and prevent large-scale collapse which could lead to irreversible shrinkage and disruption of the spherical nature of the beads.

Crosslinked agarose can be used with a large number of water-miscible solvents such as dimethyl formamide (DMF), dimethyl sulfoxide (DMSO), tetrahydrofuran (THF), dimethyl acetamide (DMAC), acetone, dioxane, methanol, ethanol, or pyridine, provided the exchange from water into the solvents is done slowly and sequentially with increasing concentrations of solvent. The recommended procedure for exchanging agarose into a solvent is to first wash with water, then with 30% of a solvent/water (v/v) solution, followed by a 70% solvent/water (v/v) solution, and finally washing the beads with 100% solvent. For complete removal of water from

within the porous structure of agarose the final wash with solvent should be extensive (at least 10 bed volumes of solvent). Many activation methods of agarose are performed in a nonaqueous environment using one of these solvents and it is essential that all water be removed to prevent hydrolysis of the activating agent or hydrolysis of the resulting reactive groups.

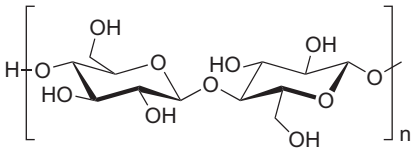
The handling of agarose chromatography supports during washing, activation, ligand coupling, and mixing procedures should be done carefully to avoid particle damage. Although crosslinked agarose is very robust and can be used with many different reactions, there are a number of caveats that should be considered to avoid gel damage. When filtering agarose to wash with water or solvents, care should be taken to avoid drying out the support during the filtration process. The use of a fritted glass filter funnel using vacuum filtration perhaps is the easiest process for filtration and washing, because the particles will not clog the filter and neither will they get lost around a piece of filter paper as they could if a Büchner funnel was used. As the aqueous or solvent solution is filtered through the beads a packed bed of agarose will form on the fritted funnel. As the solution filters through the support and reaches the top of the bed, the vacuum should be removed and the filtration stopped to avoid drying out the top of the agarose cake.

In addition, beaded agarose supports should never be used with a stirring bar, because during the mixing process the bar can grind the beads against the vessel and cause particle damage. For mixing during activation or coupling procedures, gentle end-over-end mixing or the use of an overhead paddle stirrer should be performed depending on the volume of gel being derivatized. Neither of these methods will cause mechanical damage to agarose particles.

The techniques involved with the immobilization of affinity ligands on agarose are very similar to bioconjugation reactions used for the attachment of one molecule to another. Typically, chromatography supports are handled in bulk using batch methods for washing, mixing, activation, or coupling procedures. However, once an affinity support is prepared on agarose by coupling a ligand, any subsequent affinity separations can be carried out using batch methods or by column chromatography while the support is packed in a column.

Agarose chromatography supports can be used with a wide range of activation and coupling reactions. The support mostly contains secondary hydroxyls that originate from the repeating disaccharide composition of the polymer strands along with hydroxyls that may have formed from the crosslinking process if it was done with epoxide-containing reagents. Epoxide crosslinking may also form some primary hydroxyls from unreacted epoxides, which subsequently underwent ring opening to form diols. In addition, the principal crosslinker used to form crosslinked agarose matrices, namely 2,3-dibromopropanol, will add a primary hydroxyl to each site of its reaction within the agarose polymers.

The hydroxyls on agarose may be activated in nonaqueous solution to form reactive electrophilic derivatives that are able to react with nucleophiles on affinity ligands to be coupled. Agarose may also be activated in aqueous solution using sodium periodate, which cleaves diols at the associated carbon–carbon bonds to form primary aldehydes. The primary linear chain of agarose only contains diols if some of the 3,6-anhydro-L-galactose are not in the anhydro form and instead exist as L-galactose residues. Since all of the commercial crosslinked agarose chromatography resins can be periodate oxidized to a considerable activation level, there must be large amounts of L-galactose present in all agarose preparations. Section 2 in this chapter describes many of these activation and coupling reactions along with examples for the immobilization of important affinity ligands.



Agarose chromatography supports are among the most popular beaded matrices for affinity separations. General Electric (formerly Pharmacia and Amersham) manufactures a broad range of basic crosslinked agarose beads suitable for separations ranging from bench scale to process chromatography. GE's agarose supports, sold under the Sepharose name, are the most widely used for biopharmaceutical production, including the manufacture of recombinant antibodies destined for therapeutic use. Other manufacturers, such as Sterogene and Agarose Bead Technologies (ABT), also supply the base gel in one or more forms for use in producing affinity chromatography supports. Many suppliers of affinity media use these base supports to activate and couple affinity ligands. Important commercial suppliers of activated agarose supports as well as the associated affinity ligand derivatives include GE, Thermo Fisher, Bio-Rad, Qiagen, and Sigma, among many other companies.

Cellulose Supports

Cellulose is a natural polysaccharide polymer containing hundreds or thousands of repeating units of D-glucose linked through β-1,4 glycosidic bonds (Figures 15.4 and 15.5) (Svec, 2002). It is derived from plants, being a primary component of the cell walls, and is commonly used in many consumer products, from biofuels to fiber in foods, paper, and insulation. Cellulose chromatography supports can consist of two main varieties, either an amorphous, fibrous, or crystalline particulate form with limited porosity or a spherical beaded form having a range of different porosities. Amorphous cellulose has long been used as a rather

crude chromatography support for separations of various organic molecules and occasionally of biological macromolecules. Its use for affinity chromatography applications has been limited by its poor flow characteristics and rather inadequate performance in protein-based separations due to its lack of porosity and capacity.

Cellulose chromatography media are also available in a spherical beaded form with porosities suitable for affinity separations dealing with proteins and other macromolecules. Natural cellulose supports such as the fibrous variety typically have tightly packed polysaccharide chains, which limit the maximal porosity that is achievable. The use of regenerated cellulose provides a more hydrated and less tightly packed form of cellulose and thus permits larger pore sizes to be formed when creating beads. Porous cellulose beads are typically made by preparing a solution of a cellulose derivative and dispersing it into another solvent system that is immiscible. Rapid stirring of this mixture forms small droplets that allow the cellulose to re-solidify into spherical beads the size of the droplets. Chisso Corporation (JNC) manufactures a wide range of regenerated cellulose beads under the Cellufine name having two different porosities for use in biomolecule separations. Some of these supports include a number of immobilized affinity ligands for the separation of proteins, and they are available in quantities suitable for research chromatography to process scale separations. One matrix in particular, the GCL-2000 gel filtration support, is an underivatized particle having a size exclusion limit of 2 million Daltons, which is eminently appropriate for protein separations. This base cellulose matrix may be used in many of the activation and coupling reactions that are described in this chapter for the immobilization of affinity ligands on hydroxylic supports.

Cellulose repeating disaccharide

FIGURE 15.4 The repeating saccharide structure of cellulose, which contains numerous glucose residues linked through at least two types of glycosidic bonds. Neighboring chains are held together through extensive hydrogen bonding networks to stabilize its macromolecular structure.

Another beaded cellulosic media available for affinity chromatography that includes particle sizes ranging from about 30 μm up to 0.5 mm in diameter is produced by Iontosorb in the Czech Republic and distributed under the trade name Perloza. These supports consist of regenerated cellulose with no crosslinks, but nonetheless they have excellent mechanical stability even with large pore structures, which can accommodate proteins and other macromolecules. Reactive derivatives of the Perloza support are available containing cyanuric chloride or tosyl groups for the immobilization of affinity ligands.

A different type of cellulose matrix that has been used for affinity chromatography separations is available in the form of membranes. Cellulose membranes typically have pore sizes in the low-micron range

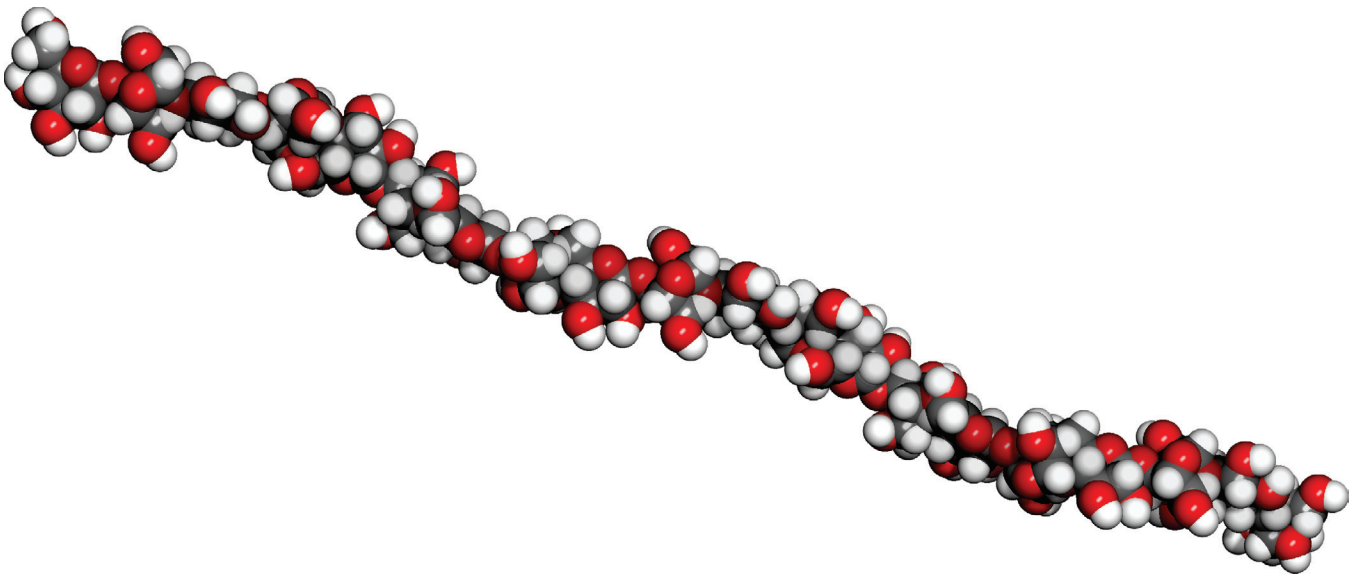


FIGURE 15.5 The three-dimensional structure of a single cellulose polymer is shown, demonstrating the abundant hydroxyl groups that provide hydrophilicity and functional groups for activation and coupling of affinity ligands.

(e.g., 0.45 μm) that easily accommodate proteins and are often used for filtration or clarification of biological solutions. Cellulosic membranes may be activated in a similar manner to cellulose beads and then covalently modified to contain affinity ligands for use in chromatographic separations. Hybrid cellulose membranes (containing other polymers) or pure cellulose membranes have both been used for the immobilization of ligands for affinity separations. For instance, a regenerated cellulose microporous membrane was activated and coupled with protein A to form an affinity support for the purification of antibodies (Boi *et al.*, 2008). The affinity membrane was found to have excellent capacity and could capture IgG from polyclonal human antibody solutions in good yield even at high flow rates. Membranes offer a monolithic alternative to bead-based resins for use in higher flow conditions and they require less maintenance to maintain a column for purification purposes. Although beaded resins still dominate the chromatography industry, membrane-based separations are definitely gaining more interest for their potential advantages in rapid affinity separations.

Inorganic Supports

Another support material often used for affinity separations consists of porous inorganic particles of extremely rigid construction and consisting of a variety of possible compositions. Some of the most common matrices in this category include porous glass, silica, alumina, ceramic supports, zeolites, and even the use of naturally occurring siliceous shells of unicellular organisms, called diatomaceous earth (or kieselgur; originating from aquatic plants called diatoms).

A commonly used support for affinity chromatography applications is controlled pore glass (CPG). CPG is typically made from borosilicate glass under high temperature resulting in the segregation of the silicate from the borate-rich portions. Subsequent rapid cooling and acidic etching of the particles causes the removal of the borate phase, which in turn results in the formation of craters and pore structures throughout the remaining silicate matrix. CPG supports having pore diameters in the range of ≥1000 Å (≥100 nm) are large enough to allow affinity chromatography for the separation of proteins and other macromolecules. CPG supports are extremely rigid and will hold up to high linear flow rates in packed column beds. However, the glass particles also are breakable, so that care should be taken in handling, mixing, and packing columns, as fines can form easily from particle-on-particle grinding. For this reason, avoid the use of magnetic stir bars or harsh mixing conditions. Paddle stirring under moderate mixing rates works well to preserve the integrity of the CPG particles, as does the use of a round-bottom flask in a rotary evaporator under slow rotational speeds.

Another stability issue with glass particles is the potential to dissolve under alkaline conditions. CPG supports are stable at acid or neutral pH, but will dissolve at pH values equal to or higher than pH 8.0. Buffered conditions containing 50- to 150-m*M* NaCl should be used for all aqueous conditions with CPG beads, because some degradation can occur even at neutral pH in unbuffered water. Conversely, CPG is capable of tolerating a wide range of nonaqueous solvent conditions without the shrinking and swelling effects of most polymeric supports. It also withstands high-temperature conditions for use with any derivatization reactions requiring elevated temperatures.

Naked glass particles have considerable potential for nonspecific binding of biomolecules, especially proteins and oligonucleotides, due to the preponderance of silicic acid groups (–Si–OH) on the surface. For this reason, the base CPG support first needs to be modified to create a layer that is not heavily charged with silicic acid functionalities, which will make it more appropriate for chromatography applications. Typically, this is achieved through silanization of the surface with a functional silane compound that contains uncharged groups and preferentially hydrophilic characteristics. Chapter 13 discusses the modification of particles and surfaces with functional silanes for all kinds of bioconjugation and immobilization applications. CPG beads may be modified with reactive or hydroxylic functionalities to block the silicic acid character and allow subsequent coupling of affinity ligands. Once blocked and functionalized, the degree of nonspecific binding toward proteins and oligonucleotides should drop to negligible.

A recommended first step in modifying CPG is to silanize the surface using an epoxy silane, which can be used directly to couple ligands, or alternatively the epoxide groups can be hydrolyzed to form hydrophilic diols (Figure 15.6). The following protocol is based on the methods of Weetal (1969) and Regnier *et al.* (1976). Similar protocols may be used to coat the particles with other functional silanes containing alternative reactive groups or functional groups for immobilization purposes. An important factor in the use of functional silanes to derivatize porous silica or glass particles is that the method must result in only a thin layer of silane coating or the pores will be clogged with silane polymer. In particular, if the reaction is performed in aqueous solution, which is often used for the silane modification of surfaces or nonporous particles, then the resultant high degree of silanol polymerization will quickly reduce porosity. Silylation reactions performed under nonaqueous conditions will limit the degree of modification to only a uniformly thin layer throughout the inner and outer surfaces of the CPG particles, thus preserving the pore structure of the support while efficiently coating the raw glass core.

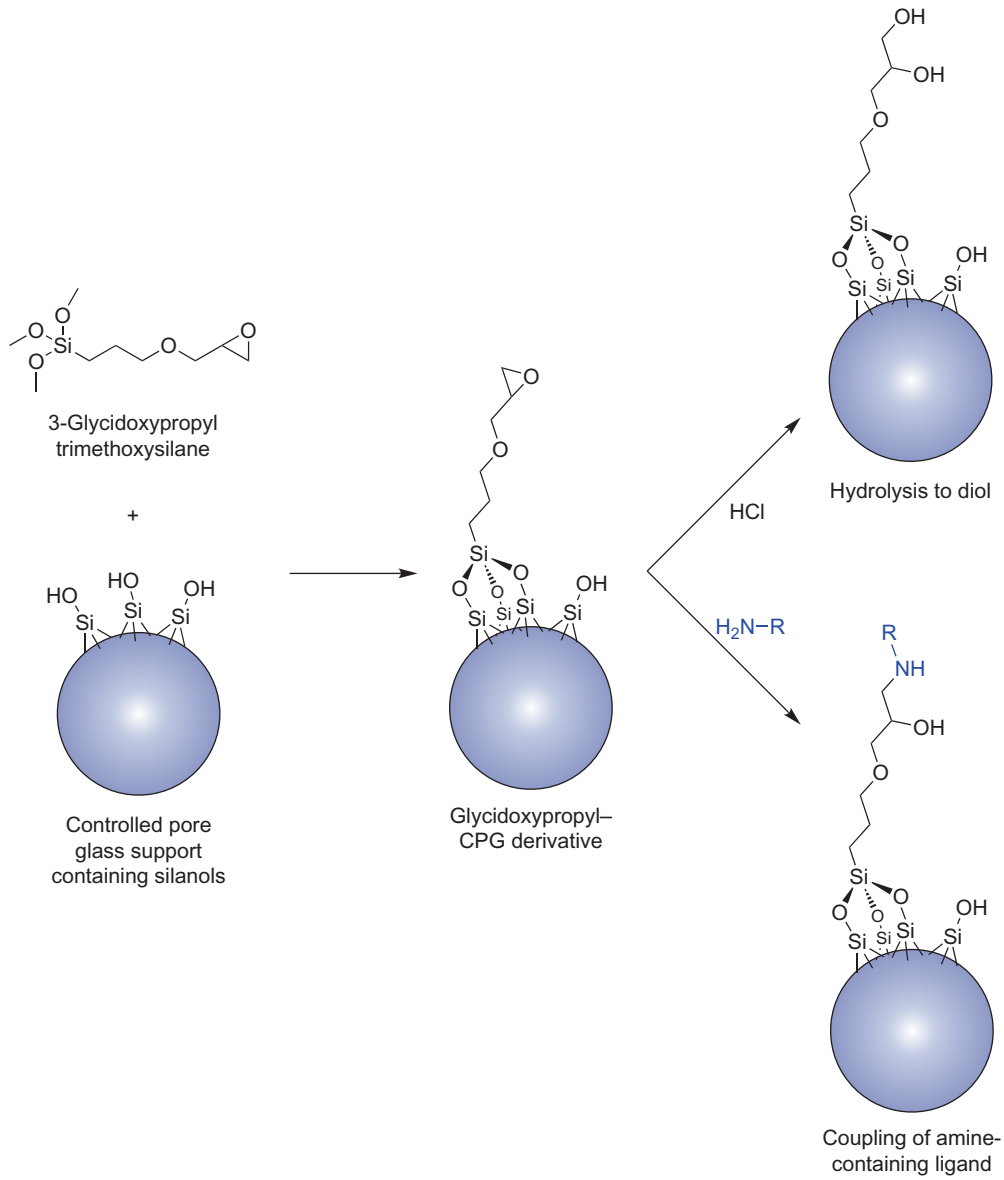

FIGURE 15.6 The reaction of 3-glycidoxypropyl trimethoxysilane with CPG and hydrolysis of the epoxide groups to yield diols or coupling of an amine-containing ligand to the epoxy groups to yield a secondary amine linkage.

Other silica or inorganic particles containing –OH groups may be modified using the following protocol. For the modification of particles less than about 30 µm, the filtration and washing process should be changed from vacuum filtration to centrifugation or tangential flow filtration to prevent clogging of filters or loss of particles through filter pads that are too coarse to prevent the particles from going through the pores.

Protocol

1. Add a quantity of CPG particles to a round-bottom, rotary evaporator flask and add a quantity of 50-m*M* HCl to cover the matrix and provide enough volume to suspend them during rotation. Place the flask in a rotary evaporator and slowly initiate rotation while placing the flask under vacuum. The HCl protonates the silicic acid groups and the vacuum removes entrapped air within the pores of the matrix. Mix for 1 h at room temperature, while intermittently breaking and reestablishing the vacuum.
2. Remove the particles from the flask and transfer them to a fritted glass filter funnel or a Buchner funnel containing a glass fiber filter pad. Drain the HCl solution and then wash the particles with 5 volumes of deionized water followed by washing into acetone using sequentially increasing concentrations of acetone in water. Filtration may be carried out by application of a vacuum to a filter

flask to increase the flow through the filter pad. Wash with at least 10 volumes of pure acetone to remove the last traces of water. Allow the particles to dry on the filter while applying a vacuum to aid in the removal of acetone by filtration and evaporation. Gently break up the filter cake using a plastic spatula to better disperse the particles and facilitate drying.

3. Transfer the particles to the round-bottom rotary evaporator flask and cover them in toluene. Again rotate the flask for an hour while pulling a vacuum to remove entrapped air. Next, heat the slurry in the rotary evaporator unit to 40 to 60°C while continuing the application of vacuum to begin distillation of the toluene. Continue the distillation process until water stops azeotropically distilling along with the toluene. If the last traces of water are not completely removed, the silylation process will result in hydrolysis of the trimethoxy groups and rapid polymerization of the functional silane, which will clog the pores of the CPG support. Cool the flask and remove excess toluene from the support by filtration.
4. Prepare a solution containing 10% (v/v) 3-glycidoxypropyl trimethoxysilane (Acros Organics) and a total volume equal to the volume of particles to be treated. Transfer the support back into the rotary evaporator flask and add the silane solution to the particles to resuspend them. React overnight at room temperature with rotation at slow speed.
5. Transfer the particles to the filter funnel and remove excess silane solution. Wash extensively with dry acetone to remove remaining traces of silane and toluene. Finally, filter off the acetone and dry the particles under vacuum. The coated, epoxy functional particles may be used directly for coupling an affinity ligand or may be treated as in step 6 to hydrolyze the epoxide group to a hydrophilic diol. Protocols for the coupling of amine-, thiol-, or hydroxyl-containing ligands to epoxide-reactive groups may be found elsewhere in this chapter.
6. Transfer the modified CPG support into a clean rotary evaporator flask and add a quantity of 50-m*M* HCl to cover the particles. Place under vacuum to remove entrapped air with slow rotation. Heat the flask to 50 to 60°C for 1 to 2 h to hydrolyze the epoxide groups into diols. The hydroxyl groups may be used in a number of different activation reactions to couple affinity ligands. For instance, the adjacent hydroxyl groups may be oxidized with sodium periodate to yield a reactive aldehyde group for coupling to amine-containing molecules.

Glass supports treated in this manner to yield a diol coating on the surface will have low nonspecific binding to proteins or other biomolecules. The silylation process coats the inner and outer surfaces of the particles and prevents biomolecule interactions with the silicic acid functionalities. However, it is known that silica- and glass-based chromatography supports give higher potential nonspecific binding character toward protein-containing samples than agarose supports, presumably due to some exposure of the silica backbone (Ghose *et al.*, 2007). Alternative silane treatments may also be carried out with CPG supports to create other functionalities for further derivatization. In particular, an aminopropyl silane may be used to add amine functionalities to a glass surface, which may be used for direct coupling of carboxylate-containing ligands or to build hydrophilic spacer arms prior to coupling an affinity molecule. In addition, other support materials such as silica and alumina may be treated in a similar manner to create functional matrices suitable for affinity chromatography. See Chapter 13 for further information regarding functional silane compounds and their reactions with substrates.

Commercial affinity supports prepared on glass particles include a high-capacity protein A or protein G matrix, which has a high density of immunoglobulin-binding proteins immobilized on its surface (Prosep-A or Prosep-G from Millipore or Trisopor-Protein A from BioCat). These supports can tolerate high flow rates during chromatographic purification of antibodies, because the base particle is extremely robust and incompressible. Binding capacities of over 45 mg/ml for antibodies are not unusual on this type of affinity support material.

Composite Gel–Ceramic Supports

Novel chromatographic support materials have also been created from the use of porous, inorganic particles that have been coated with a gelatinous natural polymer. The core ceramic particle provides an incompressible substrate that can take the rigors of large columns and rapid flow rates, while the gel coating creates a hydrophilic surface that is low in nonspecific binding character. This type of support was originally developed by BioSepra and commercialized under the trade name HyperD. BioSepra subsequently underwent a series of acquisitions and sales until the company was ultimately sold to Pall Corporation in 2004. U.S. patents 5,234,991 (1987) and 5,268,097 (1993) describe the preparation and use of these "gel-in-a-shell" supports, which consist of a base inorganic mineral oxide bead containing a hydrogel-filled pore structure (Figure 15.7). The type of core particle used for the HyperD supports is a porous silica bead called Spherosil, which was originally manufactured by Rhone-Poulenc but is now produced by Pall Corporation.

The hydrogel that is used to fill and coat the internal surfaces should ideally be a long linear polymer with a molecular weight of at least 10^4 Daltons. It also

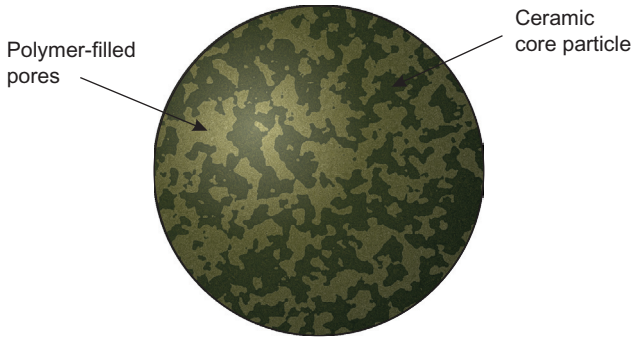

FIGURE 15.7 An illustration of a gel–ceramic composite support material. The ceramic core forms the structural spheroid shape of the support, and it has also very large pore structures to accommodate macromolecules. These pores are filled with polymeric gels, such as agarose, to create a hydrophilic porous resin, which combines the advantages of the polymer with the robust and rigid nature of the ceramic core to give a superior chromatographic support useful for process scale affinity chromatography.

should be hydrophilic to produce a biocompatible surface and be partially cationic in nature in order to stick to the core inorganic support material, which has a negative charge character. Most often the polysaccharide derivative is aminated to contain tertiary or quaternary amine derivatives along the length of the polymer. Examples of polymers that can be used in this fashion include DEAE–dextran and QAE–dextran derivatives, which contain multiple positively charged amines. It is believed that the positively charged polymer interacts with the negatively charged mineral oxide bead surface and forms multi-point, strong noncovalent interactions that are essentially irreversible. For instance, in the modification of CPG or silica supports, the negatively charged silicic acid groups likely interact with the cationic groups of the polymer, creating a large number of charge interactions along each polymer molecule. The polymer-coated surface also can be treated with a crosslinker such as a *bis*-epoxide or epichlorohydrin to further stabilize the hydrogel and provide a composite gel–ceramic particle, which is stable to strong acid or base without disrupting the polymer coating.

The use of aminated dextran, starch, or agarose as the gel layer for coating the particles can result in a poly-hydroxylic support material that can be activated to contain reactive groups capable of coupling affinity ligands. Methods to produce this type of composite gel–ceramic particle can be used successfully on such mineral oxide supports as glass, silica, alumina, titanium, and magnesium. The final "gel-in-a-shell" construction combines the benefits of the rigid ceramic core with the hydrophilicity and immobilization capacity of the biocompatible polymer (Xia *et al.*, 2011). The inorganic phase typically consists of particles with huge pore structures that allow for fast mobile-phase access that eliminates the diffusion limitations often seen with standard porous beaded supports. The large pores allow rapid sample distribution throughout the interior structures of the beads, thus overcoming the drop-off in capacity usually observed as flow rates through a column increase.

Activation and coupling methods for the immobilization of affinity ligands on these composite supports can involve any of the methods described in this chapter for the activation of hydroxylic functional groups. This includes the use of aqueous periodate oxidation to form aldehyde groups, which can then be used to couple amine-containing ligands such as proteins through the use of a reductive amination reaction process. This activation and coupling reaction process is described elsewhere in this chapter in the section entitled *Amine-Reactive Immobilization Methods*.

1.2. Synthetic Polymeric Chromatography Supports

Perhaps the most diverse category of affinity chromatography supports is represented by resins that consist of various types of synthetic polymers. Synthetic supports are produced from the controlled polymerization of various functional monomers and crosslinking monomers in a stirred solution that produces beaded particles having a porous structure. In some cases, polymeric supports may consist of a combination of natural polymers and synthetic polymers. For instance, an agarose–polyacrylamide composite support may be made that combines the hydrophilic functionality of a polysaccharide with the tight pore structure of a polyacrylamide particle, thus creating a matrix that can be easily derivatized to contain affinity ligands.

Synthetic polymeric supports can be designed to have a variety of different physical characteristics that are appropriate for chromatographic separations (Gokmen and Du Prez, 2012). As compared to natural supports, synthetic matrices may have superior physical and chemical stability, while still being able to withstand the high flow rates typically seen in process chromatographic separations. Polymeric supports also can withstand enzymatic degradation or microbial contamination better than some naturally occurring polymers, which may be ideal substrates for bacterial growth. Porous polymeric chromatography supports designed by using reactive or functional monomers can easily be coupled directly with affinity ligands or activated to contain a reactive group for immobilization. Many commercially available synthetic polymeric supports contain primary or secondary hydroxyls and are extremely hydrophilic and low in nonspecific binding. In addition, hydroxylic-containing supports can

be activated by a number of different immobilization chemistries and subsequently coupled with a wide variety of affinity molecules.

Polyacrylamide Supports

Polyacrylamide chromatography supports are typically made by the copolymerization of two monomers: acrylamide and *N*,*N*′-methylene bisacrylamide, first described by Hjerten and Mosbach (1962) (Figure 15.8). The support can have a variety of pore sizes depending on the degree of crosslinking monomers added to the polymerization reaction. The greater the amount of bisacrylamide present in polyacrylamide, the smaller the pore structure in the resultant beads. Bio-Rad offers a broad range of polyacrylamide resins that differ in the pore size and exclusion limit of the particles. These supports are classic gel filtration (size exclusion chromatography, or SEC) matrices that can separate proteins based on their molecular weight. However, they may also be used as supports to couple affinity ligands for purification of selected target molecules. For working with proteins, a size exclusion limit for the polyacrylamide beads should be chosen that will allow the protein molecules to enter the pores and interact with immobilized affinity molecules.

Polyacrylamide resins are typically supplied dry and must be hydrated in aqueous solution with gentle agitation prior to use. Weigh out an appropriate amount of dry beads and slowly add them with mixing to a quantity of aqueous buffer equal to about twice the anticipated volume of hydrated gel.

Polyacrylamide supports are characteristically soft in nature and gelatinous in appearance. They also display low nonspecific binding character toward biomolecules, rather good pH and buffer stability, and because they are totally synthetic, the supports are not able to support microbial growth. In addition, since polyacrylamide does not contain carbohydrate components, the support is ideal for use in the affinity purification of carbohydrate-binding proteins. For this reason, affinity supports prepared on polyacrylamide containing immobilized sugars, disaccharides, or small polysaccharides often have been used for the specific purification of lectins.

A major deficiency of polyacrylamide-type resins is their inability to support acceptable flow rates to permit larger-scale separations to take place in a reasonable time frame. Due to the compressibility of polyacrylamide, maximal linear flow rates are often limited to no more than 10 to 15 cm/h, which is far less than 10% of the flow rate that can be expected from agarose supports or other polymeric matrices. In addition, polyacrylamide beads have a tendency to shrink and swell with different solvents, buffers, and salt concentrations. Severe reduction in particle size can occur in organic solvents and

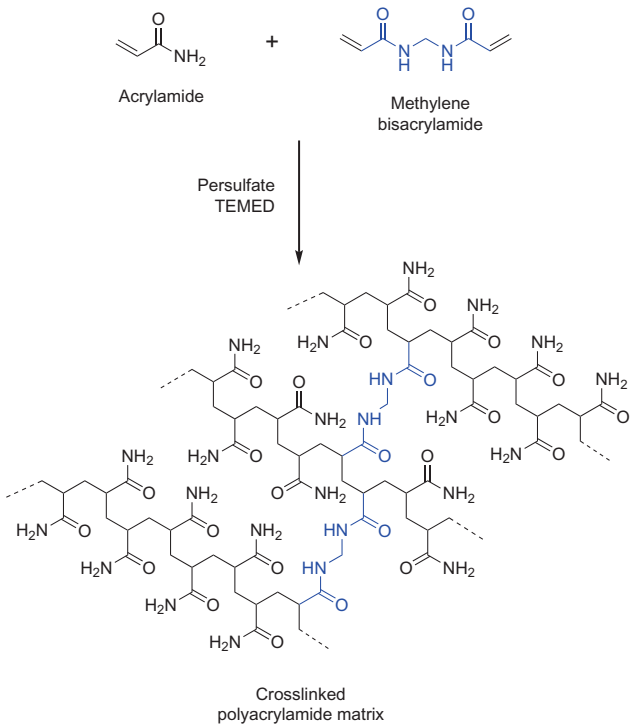

FIGURE 15.8 Polyacrylamide supports are made from the copolymerization of acrylamide and the crosslinking monomer *N*,*N*′-methylene bisacrylamide. The ratio of crosslinking monomer to acrylamide monomer controls the degree of porosity in the final support material.

this characteristic limits the range of chemical reactions that can be done to immobilize affinity ligands on them. Shrinkage of the particles also causes a collapse of the internal pore structures, which in this case may restrict coupling of ligands only to the outer surfaces.

Chromatography particles made of polyacrylamide do not naturally contain reactive groups or functional groups suitable for the immediate attachment of affinity ligands. Derivatives of polyacrylamide are typically made through partial hydrolysis of the amide bond linkages within the gel or through a process of transamidination carried out at elevated temperatures using amine-containing spacer arms or ligands. Using such strategies a number of methods have been developed to produce the requisite functional or reactive groups needed for immobilization of a wide range of affinity ligands.

Modification of polyacrylamide through transamidination involves the addition of a high concentration of an amine-containing ligand and heating while gently mixing. For instance, a diamine-containing spacer molecule may be reacted in large excess with the polyacrylamide support while mixing at 90°C and the amide bonds within the matrix will be broken and reformed with a linkage to the amine group on the

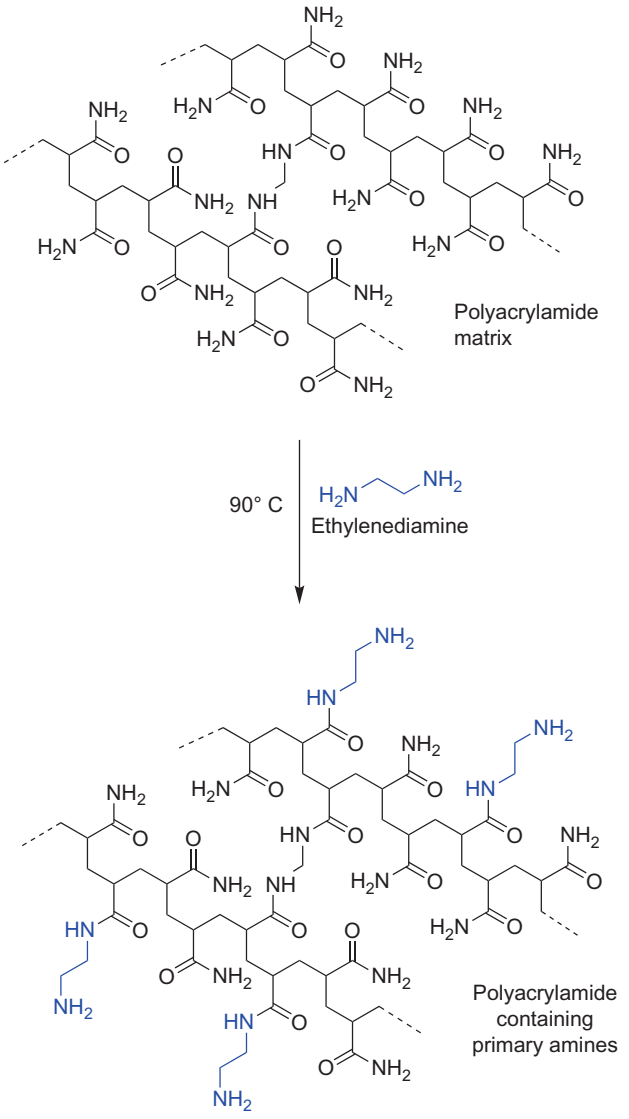

FIGURE 15.9 Polyacrylamide supports may be modified with ethylenediamine using a transamidination reaction at high temperature to produce amine groups on the support for further reactions.

spacer (Figure 15.9). A high density of such modifications may be obtained using a variety of amine- or diamine-containing molecules. In addition, hydrazide groups may be formed on the polyacrylamide support by reacting the gel at 50°C with an excess of hydrazine. (Note: Hydrazine is extremely toxic and explosive—use a fume hood and use proper personal protective equipment to handle safely.)

The following protocol describes the modification of polyacrylamide beads with ethylenediamine (EDA) using thermal transamidination, as disclosed by Inman and Dintzis (1969). A similar procedure may be used to create hydrazide groups using hydrazine substitution. All operations using EDA or hydrazine should be done in a fume hood using appropriate protective equipment.

PROTOCOL

1. Set up a three-necked, round-bottom flask in a fume hood with a heating mantle and paddle stirring rod and overhead stirring motor. Add 500 ml of EDA to the flask and stir the solution while heating to 90°C. Monitor the temperature using a thermometer inserted into one of the three necks in the flask.
2. Stir the EDA solution rapidly while slowly adding 25 g of dry polyacrylamide beads. The beads should be added in small amounts to avoid clumping of the particles. The beads will swell in the hot EDA solution as the reaction occurs.
3. Stir the solution for 5 h at 90°C.
4. Remove the heating mantle and allow the gel slurry to cool to room temperature with continued stirring. After cooling, add an equal volume of crushed ice made from deionized water to chill the slurry as it comes into contact with aqueous solution, because the EDA solution is highly basic and its dissolution into water is exothermic.
5. Transfer the gel slurry with the crushed ice to a fritted glass filter funnel or Büchner funnel containing a glass fiber filter pad and wash the matrix with 0.2-*M* NaCl in 1-m*M* HCl. Add additional crushed ice to prevent severe heating of the gel during the initial wash steps. Wash the gel until the excess EDA has been removed and the gel has decreased in pH to neutrality or acidic conditions. After the unreacted EDA has been washed out of the support, wash thoroughly with 0.2-*M* NaCl for at least 5 bed volumes. The TNBS test for amines may be used to check for the presence of EDA in the washings and to check a small volume of derivatized gel for successful coupling (Chapter 2, Section 4.3). An orange color is indicative of the presence of amines.

Trisacryl Supports

Another polymeric support made for chromatographic operations is Trisacryl, a matrix that was originally produced by IBF Biotechnics but is now available from Pall Corporation as a result of several acquisitions. The polymeric support gets its name from the fact that a key monomer used in the copolymerization process is made from the amide derivative of acrylic acid with Tris buffer (tris(hydroxymethyl)aminomethane), the actual chemical name for which is *N*-acryloyl-2-amino-2-hydroxymethyl-1,3-propanediol. This acrylamide derivative is reacted along with the crosslinking dimer *N*,*N*′-diallyltartradiamide or another crosslinking dimer, *N*,*N*′-methylene bisacrylamide, to give the final beaded, porous polymer known as Trisacryl (Figure 15.10). The Tris component of the polymeric mixture provides strong hydrophilicity due to the three

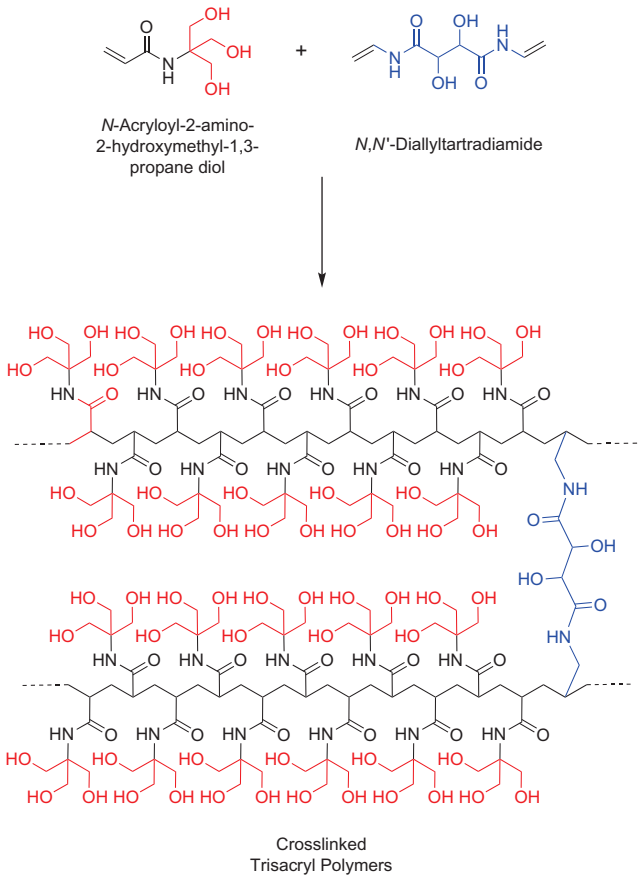

FIGURE 15.10 Trisacryl supports are made by the copolymerization of a vinyl monomer containing a tris-hydroxymethyl group and the crosslinking monomer *N,N'*-diallyltartradiamide. The support contains a high density of hydrophilic hydroxyl groups, which can be used for activation and immobilization reactions to couple affinity ligands.

hydroxyl groups present on each monomer unit, while the crosslinking monomer is added in an optimized ratio to control the final porosity and mechanical strength of the particles (Batista-Viera *et al.*, 2011). The main Trisacryl polymers are highly dense structures three-dimensionally with an outer presentation of hydroxyl groups completely surrounding each linear chain and periodic crosslinking monomers bridging the chains to create a stable matrix (Figure 15.11).

The primary hydroxyls within Trisacryl create abundant functional groups for activation and coupling of affinity ligands. They also help to prevent nonspecific binding to biological molecules, thus making affinity supports made on Trisacryl have the potential to be highly specific without secondary "matrix effects." Limiting the degree of crosslinking within the matrix can produce a support with large pores having an exclusion limit exceeding 10 million Daltons, which makes it imminently fitting for protein separations. This type of beaded support, called Trisacryl GF-2000,

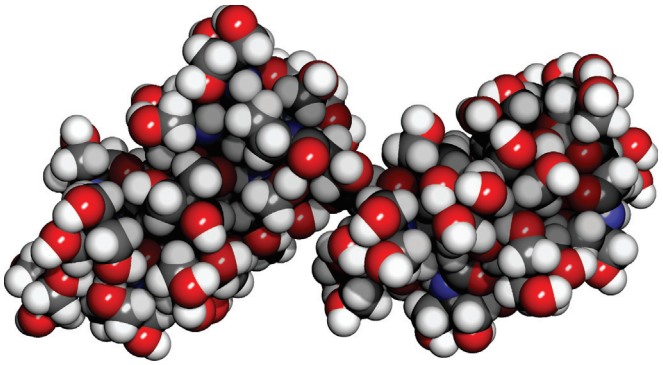

FIGURE 15.11 The three-dimensional, space-filling molecular model of a portion of the Trisacryl polymeric structure showing a single crosslink.

is available in two particle size ranges that can be chosen to reflect the needs of the affinity chromatography application. The smaller particle size range, 40 to 80 µm, can be used for analytical to medium-scale separations wherein tighter peak shapes are desired from packed columns used along with bench-scale liquid chromatography systems, for instance FPLC-type instruments. Alternatively, a larger particle size range is available, 80 to 160 µm, that can be used for process scale separations where faster flow rates are necessary for greater efficiencies in the isolation of biomolecules. Both supports have identical porosities, so the ultimate choice of particle size should be made based upon the intended application needs.

Unlike plain polyacrylamide resins described previously, Trisacryl supports have much greater rigidity and are not as gelatinous in nature. For this reason, columns packed with Trisacryl have better stability to changes in mechanical pressure and flow rates used during chromatography; therefore affinity resins made using this support can be used without difficulty to produce large quantities of proteins or other biomolecules in process separation procedures. The chemical stability of Trisacryl also is excellent, as it can be used in pH environments from pH 1 to 11 without breakdown due to hydrolysis. At highly basic pH values, however, the support material may hydrolyze by cleavage of the polymer amide bonds; therefore, only brief exposure to NaOH (0.2 *N*) for sanitization and regeneration should be done to prevent matrix damage.

The abundant hydroxyl groups within Trisacryl can be used for activation and immobilization of affinity ligands. The activation reactions typically form intermediate electrophilic reactive groups that can be used to couple with affinity ligands containing nucleophilic groups, such as amines, thiols, and other hydroxyls. Examples of activation reagents that can be used with Trisacryl include cyanogen bromide (CNBr), carbonyl

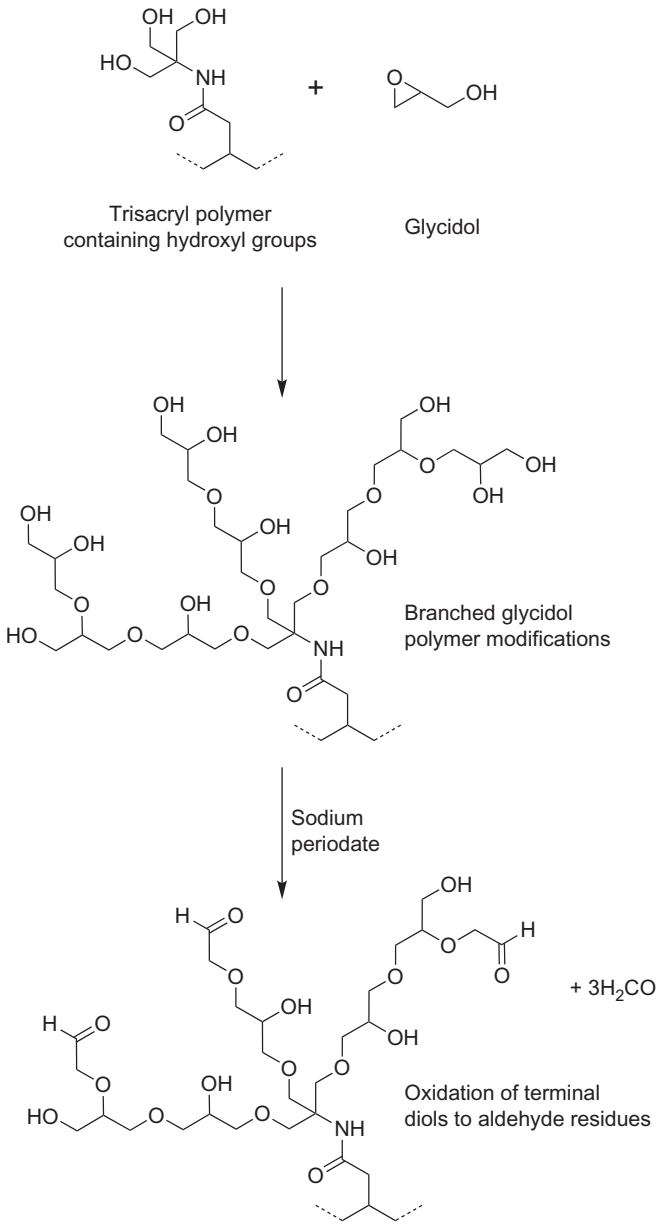

FIGURE 15.12 Glycidol modification of Trisacryl supports followed by periodate oxidation to form aldehydes useful for coupling amine-containing affinity ligands. The glycidol polymers formed within the porous structure of the support can be controlled as to their density and size by modulating the mole excess of glycidol added to the reaction.

diimidazole (CDI), tresyl chloride, tosyl chloride, divinyl sulfone, and *bis*-epoxides such as 1,4-butanediol diglycidyl ether (see corresponding sections later in this chapter). The only caveat to keep in mind with regard to the activation of Trisacryl is that sodium periodate treatment to form aldehydes, which is a common route to form reactive groups on polysaccharide-containing supports, cannot be used successfully. This is due to the fact that the hydroxyls on Trisacryl come from the Tris groups along the polymer strands and are not on adjacent carbon atoms, so there are no periodate-oxidizable groups present within the matrix. One alternative strategy to create aldehyde groups that has been found to be effective is to first react the matrix with glycidol (a monofunctional epoxide–alcohol; Figure 15.12), and then periodate-oxidize the resultant gel, which now contains diols, to form reactive aldehydes (see corresponding section, this chapter).

Sephacryl Supports

Sephacryl supports were originally developed by Pharmacia and are now sold by GE Healthcare Life Sciences as a result of a series of company acquisitions and mergers. This support is actually a composite of a naturally occurring polysaccharide derivative and a synthetic polymer. The porous, beaded support is made from the copolymerization of allyl dextran and *N*,*N*′-methylene bisacrylamide wherein the dextran carbohydrate is crosslinked by the bisacrylamide, which forms a strong hydrophilic matrix consisting of a multitude of glucose residues (Figure 15.13). The relative porosity of the matrix can be controlled by the amount of the components, especially the crosslinking monomer, added to the polymerization reaction. Sephacryl is available in a range of different molecular weight exclusion limits, and the largest of these, Sephacryl S-300 or S-400 with exclusion limits of 1500 and 8000 kDa, respectively, are appropriate for use as affinity supports as they can accommodate interacting proteins within their pore structure without difficulty.

Some Sephacryl supports have particle sizes that are rather small for use in gravity columns or for process-scale separations, because the matrix was originally designed to be a gel filtration or size exclusion type of support, which provides high resolution on FPLC- or HPLC-based applications. However, the Sephacryl HR series of supports has a particle size distribution that is larger than the Sephacryl SF series and this allows it to be used for moderate-scale affinity separations (25- to 75-μm diameter particles).

Sephacryl supports are supplied pre-swollen as an aqueous suspension containing a preservative. The gel is relatively stable to mechanical stresses during handling, so it can be mixed and washed using standard filter funnels to exchange the matrix into the appropriate solvent or buffer for activation and coupling. Stirring should be performed using a paddle stirrer or by rotation, however, and not using a stir bar to avoid grinding and breakdown of the support. Also avoid drying the support to prevent collapse of the particle, which may be irreversible without the presence of an excipient such as lactose in high concentration.

Immobilization reactions performed on dextran-based gels like Sephacryl can take advantage of the

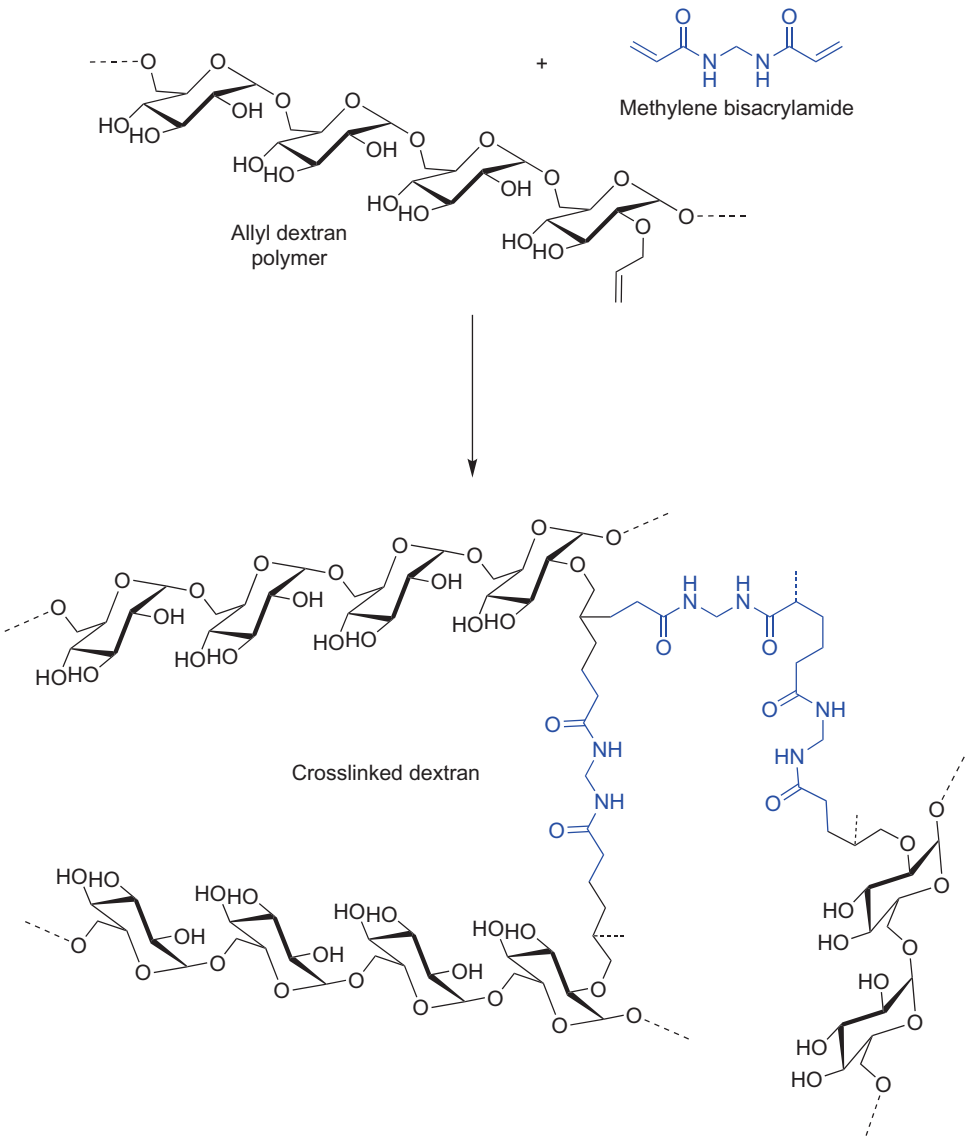

FIGURE 15.13 The chemical nature of Sephacryl supports, which are formed from the copolymerization of *N,N′*-methylene bisacrylamide and allyl dextran to create a crosslinked dextran matrix having good physical stability.

abundant quantity of hydroxyl groups on the glucose residues within the matrix. Since the bisacrylamide crosslinks provide increased physical stability, the support will tolerate washing into environments including 100% organic solvents, which are often used for activation reactions prior to coupling an affinity ligand. In this regard, activation reactions using CDI, tresyl chloride, and tosyl chloride can be carried out to create intermediate reactive groups that then can be used in organic solvent or transferred back into aqueous buffers for coupling to amine-containing ligands. In addition, aqueous-phase activation methods also can be used with Sephacryl, including periodate oxidation of the diols on glucose to form aldehydes, activation with divinyl sulfone, or activation with *bis*-epoxide-based compounds such as 1,4-butanediol diglycidyl ether. See the corresponding sections in this chapter for the experimental protocols related to activation and coupling using these methods.

Ultrogel AcA Supports

Originally, Ultrogel supports were produced by IBF but as a result of acquisitions they are now sold by Pall Corporation. The supports consist of agarose that is copolymerized with acrylamide monomers to produce a particle that has the biocompatible advantage of agarose and the size exclusion and controlled porosity capability of polyacrylamide-based supports (Figure 15.14). The result is a range of size exclusion matrices that are superior to standard polyacrylamide

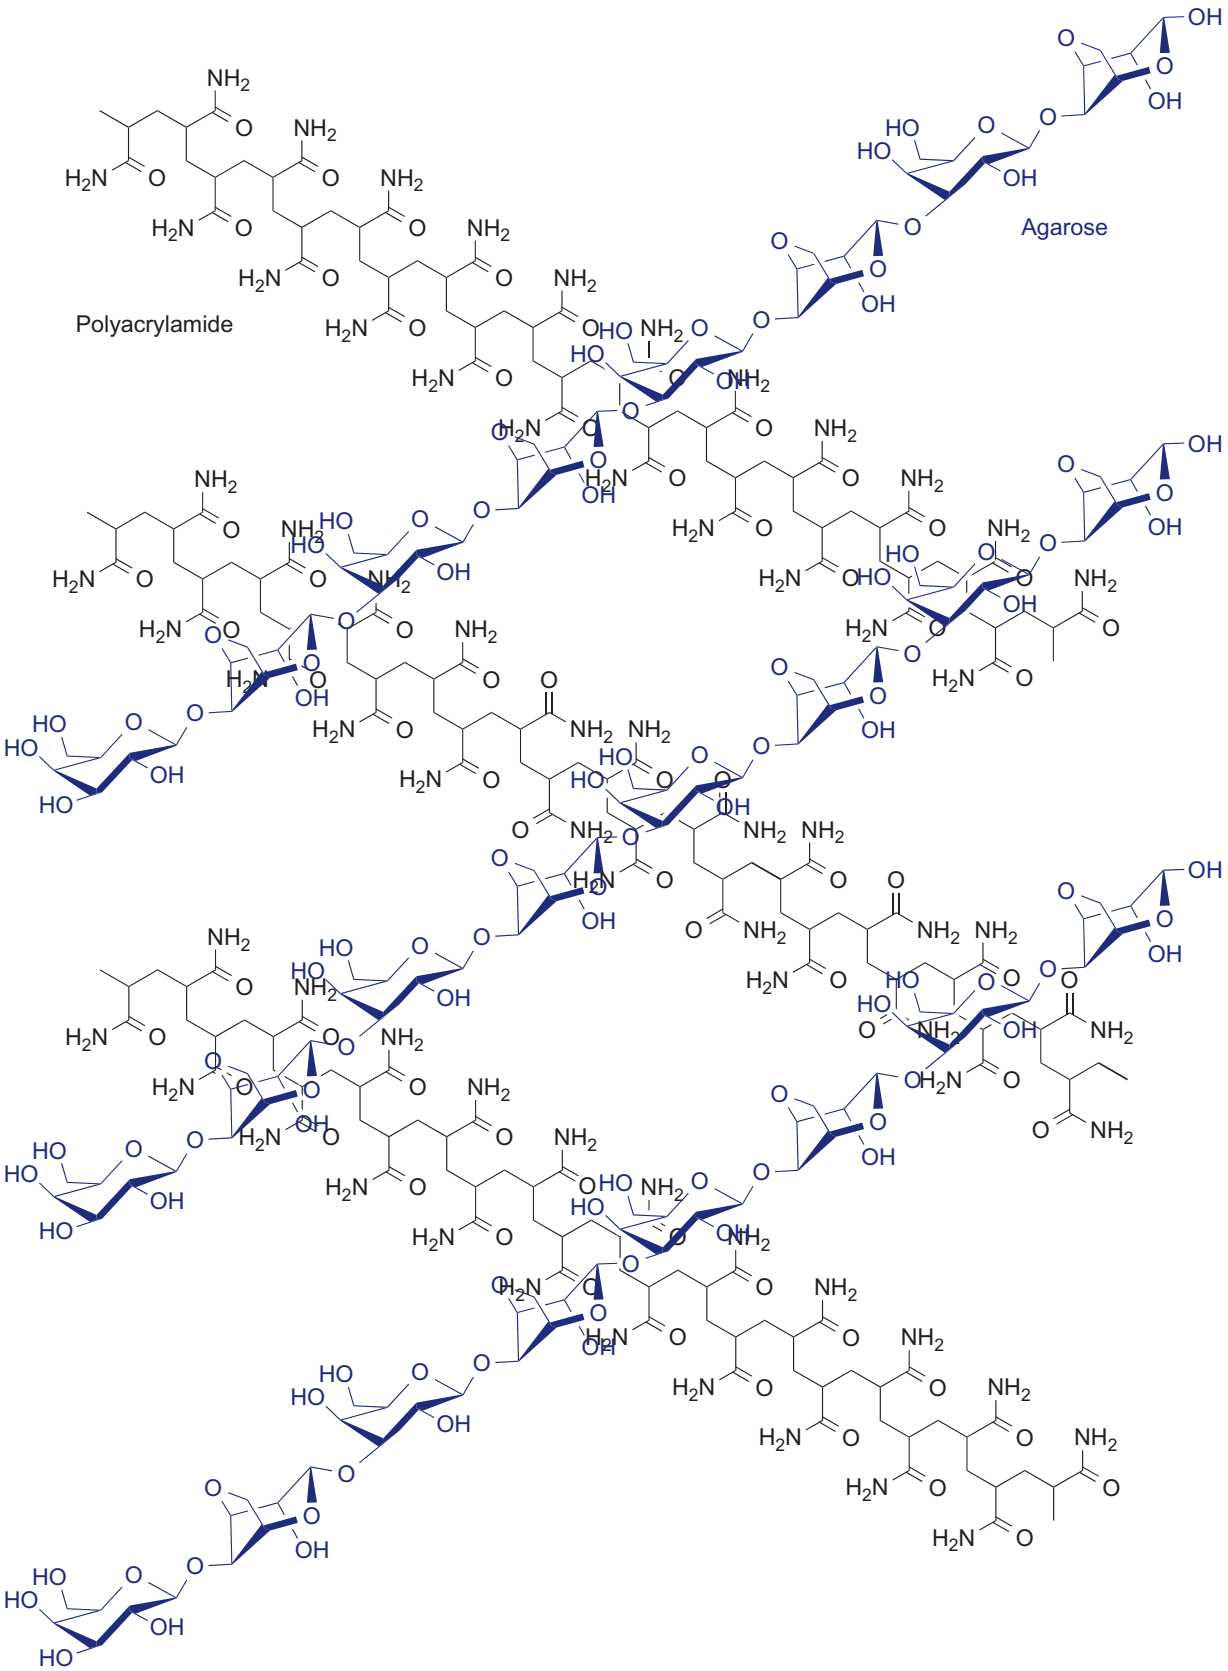

FIGURE 15.14 Ultrogel supports contain a combination of agarose polymers and polyacrylamide to create a complex network within the particles.

supports, but have smaller pore structures than supports made of agarose alone. In the preparation of the beads, the percentage of polyacrylamide in the support governs the final porosity, with a higher percentage of agarose providing a higher exclusion limit of the final support. A particular Ultrogel support containing 2% agarose and 2% polyacrylamide provides an exclusion limit of about 3000 kDa, which is sufficient for most affinity chromatography applications involving proteins. Unfortunately, Ultrogel supports do not utilize crosslinked agarose in the preparation and thus they may have some solvent sensitivity in addition to the potential to be damaged by high concentrations of denaturants or extremes of pH.

Ultrogel is also available as a paramagnetic particle in which iron oxide (Fe_3O_4) has been incorporated into the core of the polymer. The resultant bead can be used in magnetic separations wherein the particles can be removed from solution by the application of a magnetic field. The porosity of this particle is not as great as that of the chromatographic support in that it only has an exclusion limit of 200 kDa, which will likely reduce the overall capacity of the matrix for binding proteins. However, it will likely have superior binding capacity compared to the use of nonporous magnetic particles, which are often used in small-scale affinity separations.

Ultrogel supports should not be used with activation methods that require nonaqueous conditions, as solvents will damage the support. However, the matrix may be activated in aqueous conditions using CNBr, divinyl sulfone, or epoxide activation methods with success. It is anticipated that activation with *bis*-epoxides will create internal crosslinks and help to stabilize the support as compared to the base support. See the appropriate sections in this chapter that describe these activation protocols.

UltraLink Azlactone Supports

The UltraLink resins that are available from Thermo Fisher Scientific (Pierce) were originally developed at 3M in the mid-1990s and commercialized under the Emphaze name. This support material consists of the copolymerization of vinyldimethyl azlactone (oxazolone) with the crosslinking monomer, *N*,*N*′-methylene bisacrylamide (Figure 15.15). The azlactone monomer creates a particle containing reactive groups that is immediately useful in the coupling of amine-containing ligands, such as proteins. Therefore, the base support is unusual in that it comes already activated for the immobilization of affinity ligands, which is a feature designed into the matrix from the start. The amount of azlactone-reactive groups can be controlled simply by altering the ratio of the reactive monomer to the crosslinking monomer. Beads have been synthesized that contain from 100 µmoles/ml gel to 300 µmoles/ml of azlactone functionality. The typical azlactone reactivity in UltraLink resin is sufficient for the immobilization of over 30 mg/ml of protein A or over 20 mg/ml of human IgG, which is in excess of the levels usually required for protein-based affinity ligands.

The UltraLink support in its active form comes as a dry powder that, upon addition to an aqueous buffer, swells to become fully hydrated beads with a particle size of about 50 to 80 µm and a spherical appearance under a microscope. The beads typically hydrate in aqueous solution to yield a support having a total swollen volume of about 10 ml/g of particles. The fully swollen particles have pore structures of at least 500 Å with a total surface area of about 250 m^2/g. The porous internal structure of the beads is large enough to accommodate interacting proteins, including antibodies, thus making the support very appropriate for affinity chromatography applications dealing with proteins. Once the particle is hydrated, the azlactone-reactive groups are susceptible to hydrolysis and so they should be added directly to a ligand solution for coupling to avoid losing reactivity. Although the azlactone groups will hydrolyze with ring opening to terminal carboxylates (Figure 15.16), the rate of hydrolysis is relatively slow compared to other electrophilic groups commonly used for immobilization. The rate of coupling to an amine-containing ligand takes place with maximal yield usually within 1 to 2 h at room temperature.

Azlactone groups are reactive toward nucleophiles (e.g., $–NH_2$, –SH, –OH), but with the greatest coupling potential being with amines at basic pH values. The reaction proceeds with nucleophilic attack on the azlactone carbonyl group causing ring opening and rearrangement to an amide bond linkage with the amine-containing ligand and forming a short spacer arm to the matrix (Figure 15.17). Small amine-containing ligands may be coupled in aqueous or organic solution, provided that the organic solvent chosen allows the beads to fully swell upon addition to the ligand solution, so that the internal pore structures may be accessed during the immobilization reaction (see Table 15.1).

The UltraLink polymeric support has excellent mechanical properties for rapid chromatographic separations, being able to tolerate high linear flow rates while still maintaining high binding capacities. The support will tolerate flow rates several times higher than highly crosslinked agarose supports, thus making it useable in large columns under rapid flow without collapse of the particles. The particle structure permits high-pressure chromatography, with typical maximal pressure drops across the column exceeding 1000 psi before bead damage is observed. In practice, such extreme pressure conditions are never required, because very high flow rates can be realized under

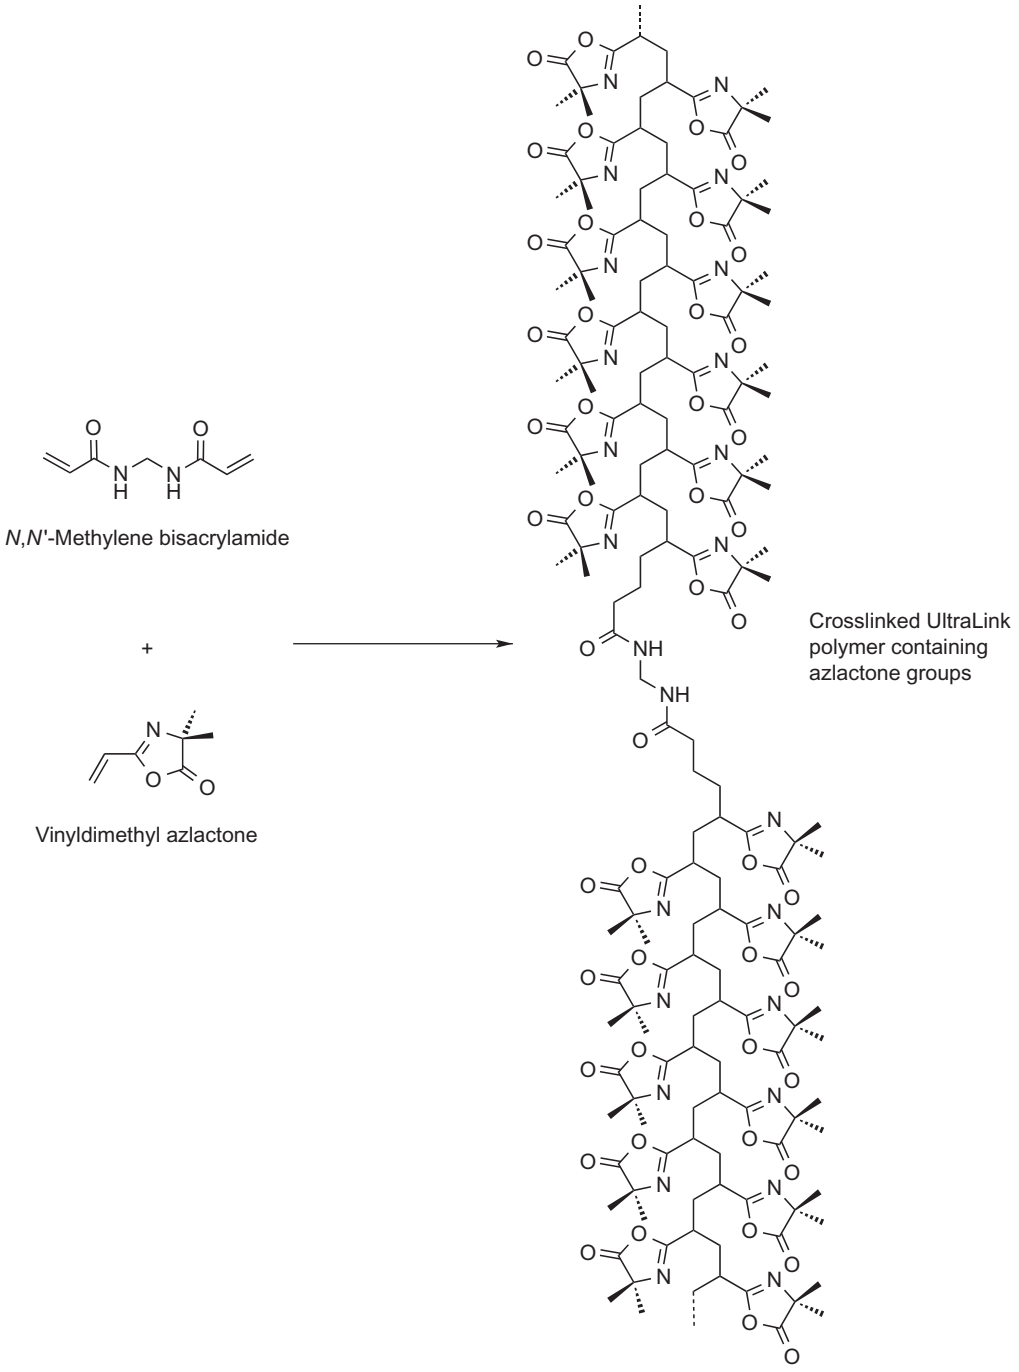

FIGURE 15.15 Ultralink resins are prepared by the copolymerization of *N*,*N*′-methylene bisacrylamide and the reactive monomer vinyldimethyl azlactone. The ratio of these two monomers used in the polymerization process controls the crosslinking and the degree of azlactone functionality in the final support.

pressures of far less than 100 psi. In addition, studies performed with derivatized UltraLink supports have demonstrated the excellent chemical stability of the base copolymer construction as well as the stability of the covalent bond formed with amine-containing ligands. The polymeric matrix is stable to degradation in extremes of pH (1–14) and heat, as well as being resistant to harm in highly denaturing conditions or high salt or buffer conditions.

For use of UltraLink azlactone-activated supports in the coupling of affinity ligands, the dry matrix should be accurately weighed to result in a known volume of hydrated gel in the coupling buffer. Approximately 0.1 g of beads will be hydrated to a volume of 1 ml of gel,

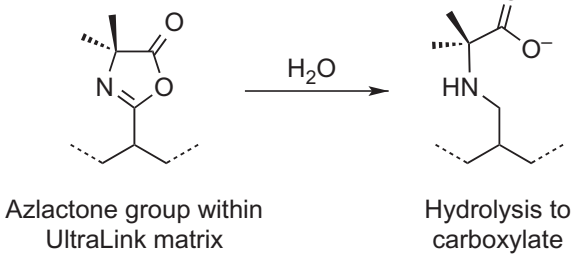

FIGURE 15.16 Azlactone groups can hydrolyze in aqueous solution, which results in ring opening and the formation of a carboxylate group at the end of a short spacer.

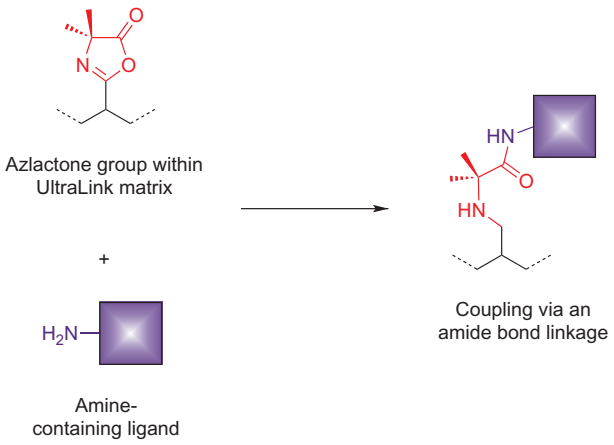

FIGURE 15.17 An amine-containing ligand can react with an azlactone group by attack at the electrophilic carbon atom of the carbonyl to result in ring opening and formation of an amide bond linkage with the ligand.

TABLE 15.1 **UltraLink Swelling Properties in Various Solvents**

	Solvent	Solubility Parameter (cal/ml)	Volume (ml/gm)	Relative Swelling[2] (%)
Dry particles	–	–	4.5	0
Aqueous Solvents	Water	23.4	8.10	100
	1-*N* HCl	–	8.08	99.4

[2]*Relative percent swelling equals the amount of swelling in a solvent from dry beads relative to the amount of swelling in water = ([ml in solvent] – [ml of dry particles]) × 100/([ml in water] – [ml of dry particles]) = ([ml in solvent] – 4.5 ml) × 100/3.6 ml.*

but the exact swelling factor is production-lot dependent, so the user should consult the lot-specific information before use. The amount of coupling reaction solution to use with a given amount of dried particles should be equal to at least twice the amount of the hydrated volume of beads that is anticipated after swelling. This is due to the fact that an equal amount of solution to the hydrated bead volume will be completely taken up within the pore volume of particles during the hydration process and a proportion of at least 50% slurry of gel in the reaction solution is needed to allow proper mixing during the reaction.

The dried UltraLink particles are supplied with a small amount of Triton X-100 coating within the particles to facilitate rapid uptake of water into the pore structures without entrapment of air. For this reason, there will be an inherent absorbance at 280 nm to the reaction medium due to the release of detergent from the support. Unfortunately, this interference will prevent the determination of the amount of protein coupled during the reaction simply by measuring the difference in absorbance at 280 nm of the solution before and after coupling, as can be done with many other coupling methods. Protein coupling can, however, be determined using the BCA protein assay reagent (Thermo Fisher) to measure the amount of immobilized protein directly on the surface of the beads after immobilization.

The handling of UltraLink supports can be performed using spatulas for manipulation, paddle stirrers or rotators for mixing, and standard filter funnels with membranes or fritted glass filters for washing. The matrix is very robust and is not easily damaged in use. The methods used for the immobilization of proteins or other affinity ligands onto azlactone-activated supports are described in subsequent sections within this chapter.

Toyopearl HW Supports

Toyopearl supports are comprised of a synthetic polymeric matrix that is commercially available from Tosoh Bioscience. The matrix is made from the copolymerization of glycidyl methacrylate, polyethylene glycol (PEG), and pentaerythritol dimethacrylate to form a complex structure that is hydrophilic and rich in hydroxyl groups for activation and coupling of affinity ligands (Figure 15.18). The polymerization of the two acrylate-containing monomers is combined with the covalent linkage of the PEG–OH groups to the glycidyl epoxides, thus forming pentaerythritol and PEG crosslinks within the porous polymer network making up the bead internal topography. The PEG chains are very hydrophilic and certainly contribute heavily to the biocompatible nature of the support, while the pentaerythritol dimethacrylate crosslinks add rigidity by locking the polymer strands together.

Toyopearl-type supports have moderate mechanical stability and are able to tolerate pressures of at least 45 psi (3 bar) without bead collapse. This makes possible reasonable linear flow rates and large column configurations for process-scale separations or automated separations using an FPLC or HPLC system for smaller scale operations. A type of Toyopearl support containing a higher degree of crosslinking, and thus greater rigidity for higher pressure resistance, is available under the designation "PW," but this matrix has lower capacity than the HW resins for protein purification applications. The larger-particle-size versions of the support will be able to achieve higher linear flow rates at lower pressure drops across a column bed and thus be capable of reach higher flow rates than the smaller particle grades. The matrix is also quite robust to handling, mixing, and chemical reactions carried out during activation and coupling procedures. Toyopearl supports are able to withstand extremes in pH (2–12), high salt or buffer concentrations, the presence of denaturants, and a solvent exchange into nonaqueous conditions without suffering damage to the particles.

The wide variety of Toyopearl supports available commercially come pre-swollen as thick slurries in aqueous solution. A wide selection of different particles sizes and porosities is available for different applications, depending on the resolution of separation desired and the size of the column being used. Typically, smaller particles will be more appropriate for analytical separations, while larger particle diameters are more suitable for bench-scale to process-scale separations. The different exclusion limits available reflect the fact that the matrix was originally developed for gel filtration or size exclusion chromatography and is still used for these applications. Small particle sizes of the support can be obtained that consist of 20 to 40-μm spherical beads and are designated "S" grade (for "superfine"), while medium particles are in the range of 40 to 90 μm ("M" grade), larger particles that have diameters of about 90 to 120 μm (designated "C" grade for "coarse"), and very large particles of diameters ranging from 100 to 300 μm (designated "EC" grade for "extra coarse"). The particle size distribution generally gets broader as the particle grade and diameter increase, thus giving the smaller-particle-sized supports the potential to provide greater peak resolution in gel filtration chromatographic separations. In general, the larger particles provide less back pressure for a given flow rate and are more amenable to large-scale chromatography, while the smaller particles provide greater resolution and are more appropriate for analytical separations where peak resolution is important.

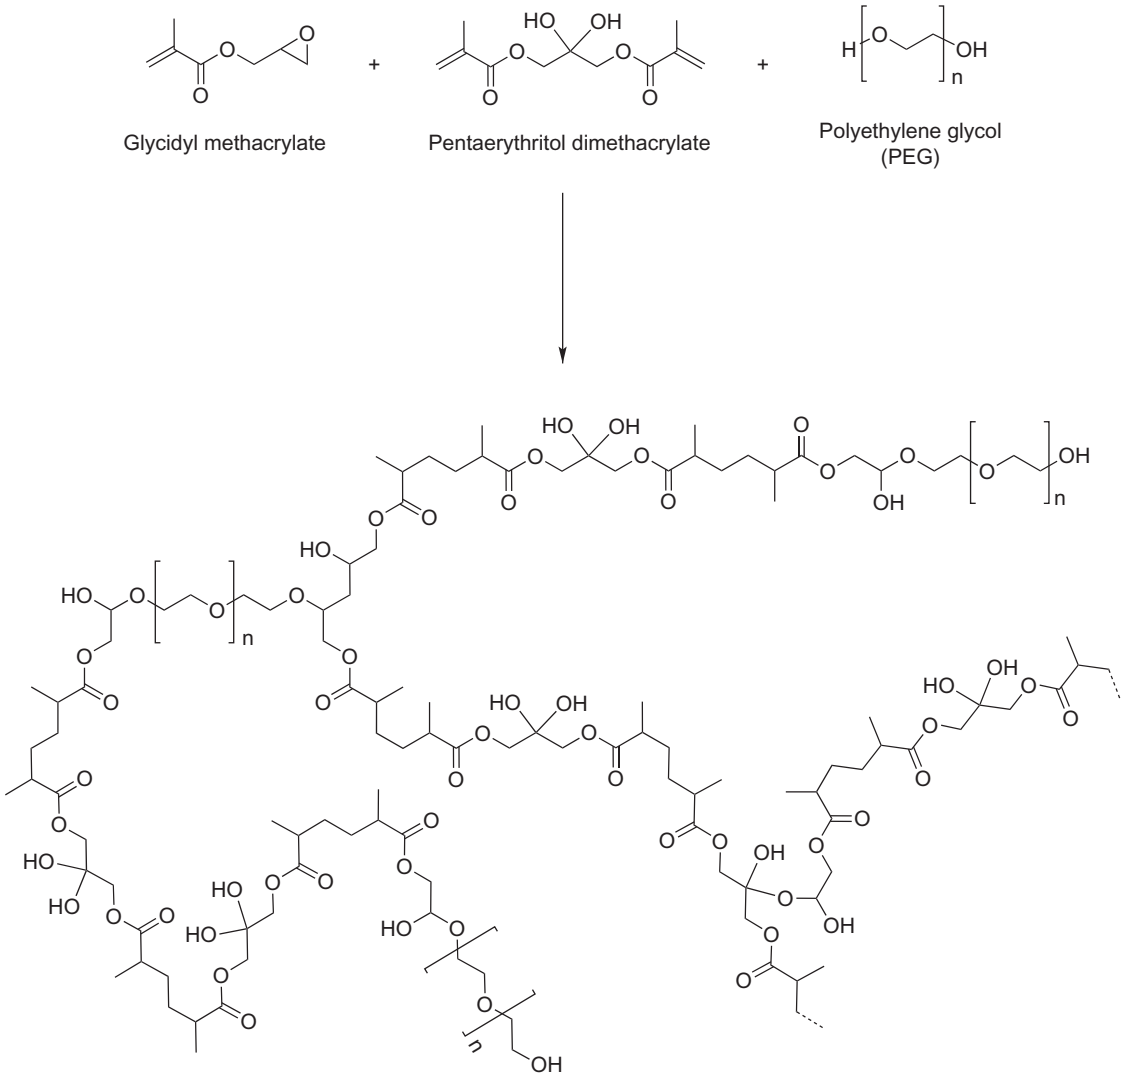

FIGURE 15.18 Toyopearl supports are constructed from the copolymerization of glycidyl methacrylate, the crosslinking monomer pentaerythritol dimethacrylate, and polyethylene glycol (PEG). The epoxy monomer is also able to provide crosslinks within the support with neighboring hydroxyl groups and also incorporate PEG chains within the structure by reacting with the epoxides, which provides significant hydrophilicity. The support also contains an abundance of primary and secondary hydroxyl groups that can be used to couple affinity ligands.

For affinity chromatography use, the Toyopearl support having an appropriate exclusion limit (correlating to its maximal pore size) may be chosen to best accommodate the molecules being separated. For protein separations, typically the supports having the larger exclusion limits will provide the best opportunity for protein–ligand interactions in affinity separations, especially when two large proteins have to interact within the pores. For routine affinity purifications, the Toyopearl HW-65 or HW-75 resins will provide the best performance, as the exclusion limit of these gels are up to 5000 kDa, with a fractionation range for size exclusion chromatography listed as approximately 50 to 5000 kDa. Pores of this size will allow even the largest macromolecules to interact within the matrix, including use in applications involving the capture of interacting proteins using co-immunoprecipitation procedures.

Toyopearl supports contain mainly secondary hydroxyl groups within its structure due to the presence of the pentaerythritol crosslinks as well as resulting from the creation of secondary hydroxyls upon epoxide group coupling with another hydroxyl within the web

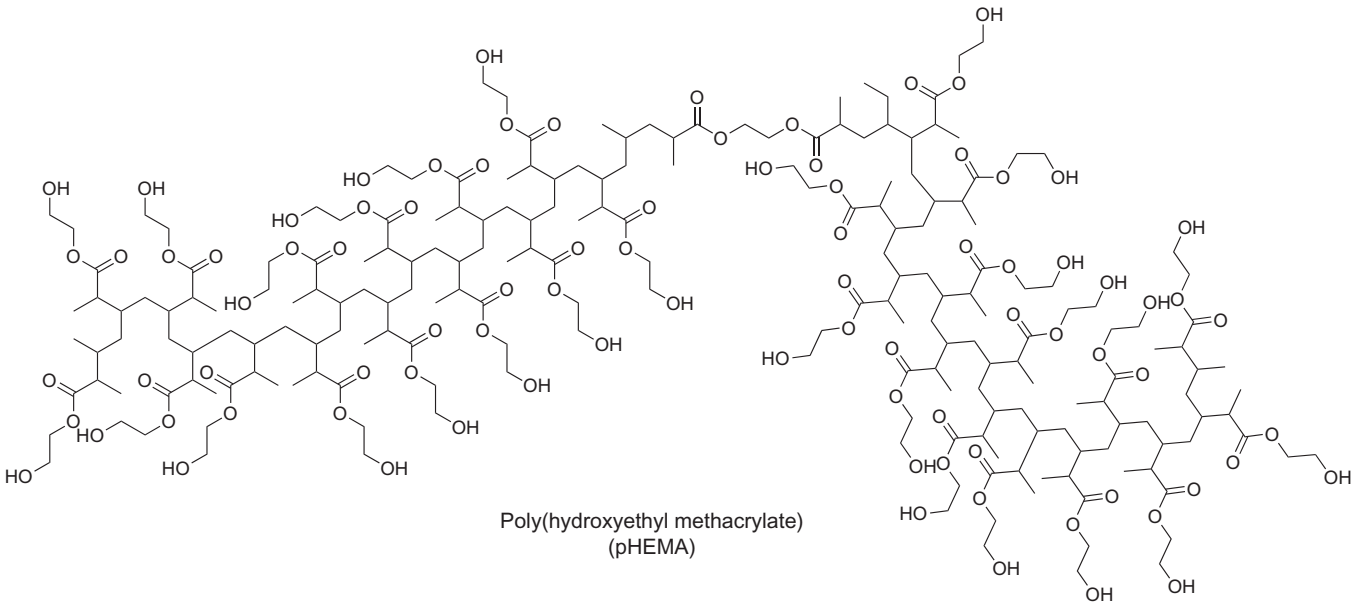

FIGURE 15.19 Poly(hydroxyethyl methacrylate) (pHEMA) supports can be made from the copolymerization of 2-hydroxyethyl methacrylate (HEMA) and the crosslinking monomer ethylene dimethacrylate. The result is a support that is very hydrophilic and contains numerous primary hydroxyl groups, which can be activated for the coupling of affinity ligands.

of polymers. There is also some potential for primary hydroxyls being present if epoxide hydrolysis occurred without coupling to another hydroxyl group or some of the PEG–OH groups remained uncoupled at one end within the gel. Using any of these hydroxyls, the support can be activated through any of the activation reactions designed to create an electrophilic reactive group. This includes the use of such common activation reagents as CNBr, CDI, tresyl chloride, tosyl chloride, *bis*-epoxide, and divinylsulfone. However, the support cannot be directly oxidized with sodium periodate to give aldehydes, as in the case of agarose-containing matrices; nevertheless, an intermediate modification with glycidol can be carried out to create polymer grafts on every hydroxyl within the gel that terminate in diols, which afterward can be oxidized to provide abundant aldehydes for immobilization through reductive amination (similar to the procedure previously mentioned for Trisacryl supports). The initial glycidol derivatization process results in the small epoxide coupling to internal hydroxyls on the support and forming a terminal diol as the epoxide ring opens. Additional glycidol molecules then can react with these newly formed hydroxyls, thereby creating polymer grafts. Subsequent oxidation with periodate then creates an aldehyde at the end of each glycidol chain with simultaneous loss of one molecule of formaldehyde. Coupling of amine-containing ligands on this derivative can be achieved through Schiff base formation followed by reductive amination to form a secondary amine linkage (see Section 2.1).

Separon HEMA Supports

Copolymer particles made of 2-hydroxyethyl methacrylate have been used to create highly hydrophilic chromatography supports that have abundant primary hydroxyls, which can be used for activation and coupling of affinity ligands. This synthetic support made from the copolymerization of HEMA and ethylene glycol dimethacrylate was developed decades ago in Czechoslovakia and commercialized by Tessek, Ltd., under the name Separon HEMA (Figure 15.19). The dimethacrylate crosslinking monomer adds rigidity to the HEMA polymer, and the ratio of crosslinker to HEMA in the final matrix controls the relative porosity of the support as well. A molecular model of a portion of the crosslinked HEMA polymer is shown in Figure 15.20, which illustrates the abundant hydroxyl groups present within the matrix. The particles are spherical and are available in sizes of 10-µm and 60-µm average particle diameters. HEMA supports also come in a range of porosities from 40 to 2000 kDa that provide abundant choices of porosity for size exclusion chromatography applications, and the degree of porosity can be chosen based upon the size of the molecules being separated. Particles having the largest pore size should be selected for general affinity chromatography separations using macromolecules, because the interior of the particles is able to better accommodate interactions between large biomolecules.

The high density of primary hydroxyl groups on the HEMA support allows convenient derivatization with

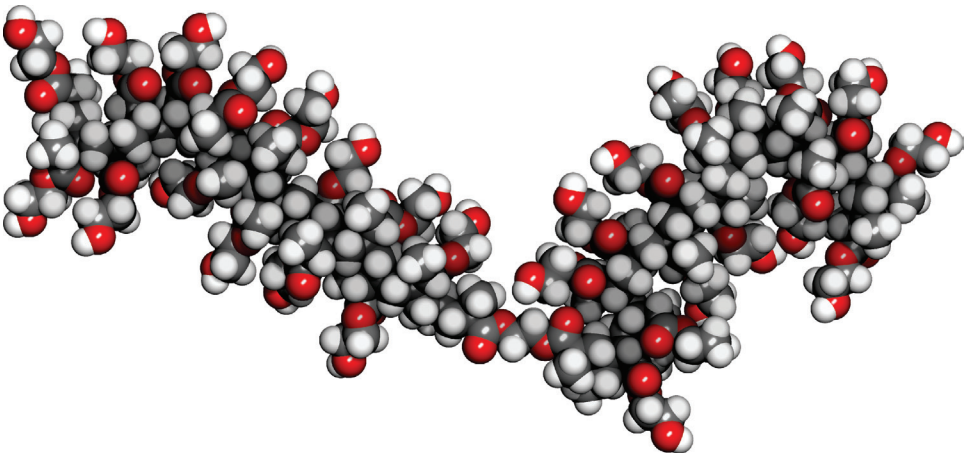

FIGURE 15.20 The three-dimensional, space-filling molecular model of a portion of a pHEMA support showing the numerous hydroxyethyl groups and a crosslink made from ethylene dimethacrylate.

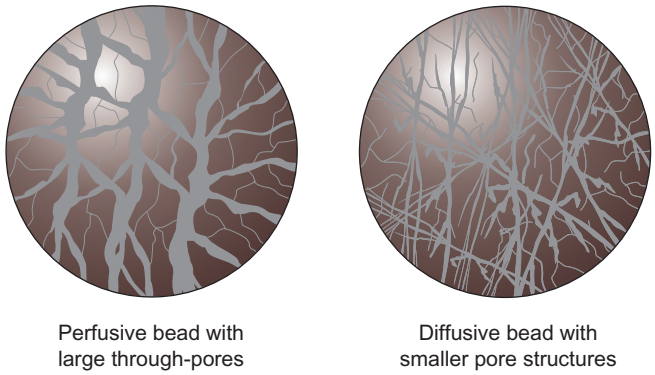

FIGURE 15.21 An illustration of the difference between a perfusive chromatography support containing large through-pores and a typical diffusive chromatography support which contains mainly diffusion-limited access to the inner pore structure of each bead.

typical activation reagents to form reactive, electrophilic intermediates capable of coupling affinity ligands. All of the common activation methods for hydroxyls described in this chapter may be used with HEMA, except for the use of periodate activation, which requires diols to form aldehydes, and this support does not contain any periodate-oxidizable hydroxyls.

Although HEMA-based supports contain esters from each hydroxyethyl group linked to the methacrylate monomers, the ester bonds are extremely stable due to the configuration containing a tertiary alpha-carbonyl ester. It does not easily hydrolyze nor does it react with nucleophiles such as amines. The base support is stable to extremes of pH (2–12) and will tolerate NaOH sanitization procedures without breakdown of the polymeric structure. Two activated versions of the HEMA support are available from Tessek for the immobilization of affinity ligands: epoxy and vinyl sulfone. However, other activation methods may be designed from the base support for custom coupling purposes. In particular, glycidol modification may be carried out to create grafted polymers within the matrix that contain terminal diols on each chain. As described previously in the section on Toyopearl supports, these diols can be periodate oxidized to form terminal aldehydes for use in reductive amination immobilization procedures (see the corresponding section under activation methods in this chapter).

UNOsphere Supports

Another innovative polymeric chromatography support is produced by Bio-Rad under the name UNOsphere. The base matrix construction is unique in that the beads are said to contain "through-pores" that are a minimum of 0.5 μm in diameter with virtually no pores of less than 0.1 μm. This is reminiscent of Perceptive Biosystems' HPLC supports that were developed during the 1980s, which also are claimed to have larger through-pores, which make faster flow rates possible for analytical separations (Jungbauer, 1996; Gallant, 2004). The through-pores allow the mobile phase to enter into the internal spaces of the bead structure by convective flow rather than just by diffusion. In theory, this permits faster on and off rates for interactions with immobilized ligands than is normally possible using supports that only have convective flow around the beads (Figure 15.21). The majority of chromatography resins restrict internal bead access by diffusional processes originating from outside the particles. In perfusion supports, the larger through-pores inside the particles allow convective fluid flow to reach sites deep within each bead, thus increasing the effective volume of the support that can be used for affinity interactions during rapid chromatographic operations. The theory of intraparticle flow through perfusive supports and monoliths has been studied in great detail (Hamaker and Ladisch, 1996).

The UNOsphere polymeric resin is made from the copolymerization of functional and nonfunctional monomers in addition to a portion consisting of crosslinking monomer to form the final matrix. The resultant

beaded support has a particle size range of about 45 to 90 μm with a mean diameter of 60 μm. The spherical particles form a chromatography support that is analogous in its internal pore structure to some of the monolithic-type supports that are formed by polymerization of monomers directly within a column to produce a single continuous cylindrical matrix. It is also similar to the use of affinity membranes that contain a torturous pore structure with large and small pores where both convective flow and diffusion take place simultaneously throughout the matrix.

The large cavernous structures of through-pores within UNOsphere resins are constructed by careful selection of polymerization conditions, as described in U.S. patent 6,423,666 by Liao and Hjerten (2002). Just like most other polymeric supports, the particles are formed by suspension polymerization using a monofunctional monomer that may contain functional groups or reactive groups. For instance, the proper choice of monomer can yield a beaded chromatography resin containing ion-exchange functionalities, hydrophobic groups, or reactive derivatives able to spontaneously couple affinity ligands. One key to forming the large pore structure is controlled use of a crosslinking monomer during the polymerization reaction. Particularly, it has been found to be important to keep the concentration of crosslinker to a mole fraction of about 0.3 to 0.4 relative to the total monomer mixture. The construction of the through-pores is accomplished by the addition of some hydrophobic character to the monomers as well as the use of additives that modify the polarity of the aqueous medium during polymerization. Additives such as sulfate or other lyotropic agents can be used in addition to the potential use of hydrophilic polymers such as PEG, dextran, or methyl cellulose.

The base support can be used in process purification applications that involve large column sizes or high linear flow rates (up to 600 cm/h) without particle collapse or encountering severe back pressures. The polymeric support also can be sanitized using 0.1-*N* NaOH or regenerated after use with denaturants such as 6-*M* guanidine. A study of IgG purification on a UNOsphere support containing immobilized protein A was published by Perez-Almodovar and Carta (2009).

A reactive derivative of the UNOsphere support is available that contains epoxide groups, which can be used to immobilize affinity ligands containing amines, thiols, or hydroxyl groups (see the section on activation and coupling reactions, this chapter). It is supplied dry to ensure stability of the reactive group upon storage. The support contains approximately 50 to 132 μmoles/g of reactive epoxy groups, and upon addition to an aqueous solution hydration will cause the matrix to swell to approximately 5.5 to 8.0 ml/g of dry resin. The dry, activated support can be added directly to a ligand solution for coupling. The optimal pH range for coupling is 9 to 13 in a buffered solution containing at least 10-m*M* buffer salts to prevent pH changes during the reaction. Thiols can be coupled to the support at the lower pH, amines can be coupled in the middle of this range, and hydroxyl-containing ligands require pH 13 for efficient coupling. UNOsphere supports are not available in a hydroxylic form that could be used for custom activation and coupling of affinity ligands.

Eupergit Supports

Certain polymeric supports have found use for the immobilization of enzymes, which are often used as immobilized reactors in the manufacture of foods, antibiotics, and other organic compounds. Many of these supports are used in ton quantities annually for large-scale production processes. One such support that has found more use as an immobilized reactor than in affinity chromatography is Eupergit. These porous beads are made of methacrylate derivatives and were originally manufactured by Rohm Pharma Polymers, which was a unit within the Specialty Acrylics division of Degussa, AG in Darmstadt, Germany, but since 2007 this technology became a part of Evonik Industries. Eupergit is made by a copolymerization of glycidyl methacrylate, allyl glycidyl ether, methacrylamide, and the crosslinking agent *N*,*N*′-methylene *bis*-methacrylamide. The Eupergit C support that contains reactive epoxide groups has become very common for use in the preparation of immobilized reactors (Boller *et al.*, 2002; Berrio *et al.*, 2007) (see Chapter 1, Section 3.4, for a discussion of immobilized reactor applications). Unfortunately, after Rohm Pharma's merger with Evonik Industries, the Eupergit support was discontinued; however, some distributors still sell small quantities of it for research purposes (Sigma Aldrich).

Sepabeads, ReliZyme, and ReliSorb Supports

Although Eupergit is no longer manufactured commercially (see previous section), other polymeric supports continue to be used to prepare immobilized reactors for production purposes. One such material is called Sepabeads and is produced by Resindion, which is a subsidiary of Mitsubishi Chemical. This support material consists of a porous polymer made entirely of polymethacrylate which is formed into spherical white opaque beads. Sepabeads is available in a number of different formats including two different preactivated supports containing epoxide groups ready to couple ligands, two amino functionalized supports containing different length spacer arms, a diol derivative that can be periodate oxidized to create aldehydes for coupling amine-containing ligands, and two derivatives especially designed for hydrophobic interaction

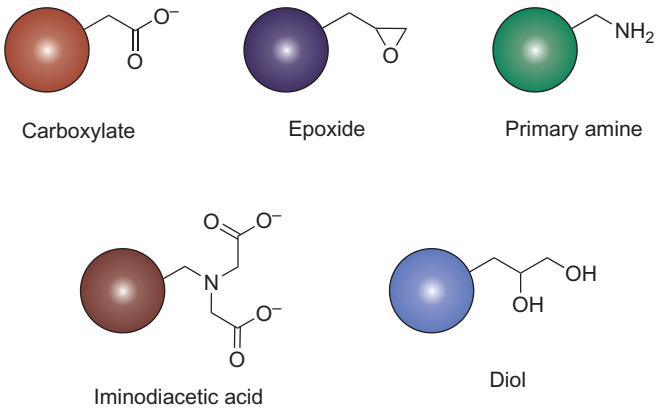

FIGURE 15.22 The derivatives of Resindion chromatography supports that are available commercially.

chromatography: a C_4 butyl and a C_{18} (Figure 15.22). The particle size of Sepabeads is available in two different size ranges: an "S" grade with a particle size distribution of 100 to 300 µm and an "M" grade having a particle size distribution of 200 to 500 µm.

The polymethacrylate Sepabeads support has an average pore diameter of approximately 10 to 20 nm, which is rather small for typical affinity chromatography resins. The average IgG antibody is about 11 nm in diameter, so large proteins may not be accessible to the smaller pore openings. However, a more recent iteration of the Sepabeads-type polymer was introduced under the name ReliZyme, and this material contains average pore sizes in the range of 40 to 60 nm, which are more amenable to protein chromatography applications. All of the derivatives available for the Sepabeads products also are available in the larger particle ReliZyme beads.

Resindion's Sepabeads and ReliZyme particles, however, were developed with a view toward their use as immobilized reactors rather than for applications in affinity chromatography. Most enzyme reactors are prepared through adsorption or covalent immobilization of enzymes onto solid-phase supports, and their subsequent use is to act as catalysts in the transformation of substrates into desired products. According to the company, an enzyme can be immobilized onto the Sepabeads or ReliZyme supports using one of four different approaches: (1) passive adsorption, (2) ionic interaction, (3) crosslinking, and (4) covalent coupling with a reactive group on the particles. Enzyme reactors have been prepared successfully using all of these strategies, although the most robust materials are formed using covalent coupling, which provides low leaching potential and a high degree of reusability.

A third resin material developed by Resindion is also potentially suitable for affinity chromatography applications. The ReliSorb supports are polymethacrylate spherical particles available in three different particle size ranges: 50–150 µm, 75–200 µm, and 200–500 µm, with corresponding mean diameters of 90 µm, 120 µm, and 300 µm. The larger average particle size of the ReliSorb resins permits high-flow chromatography over a wide range of linear flow rates. The spherical particles are extremely rigid with low swelling characteristics when hydrated in aqueous solvent. In addition, the pore structure of this support is in the range of 40 to 50 nm, thus making it useable for affinity chromatography separations using proteins and other biological macromolecules. The linear velocity of the largest particle size support can exceed 10 m/h with a pressure drop of only 0.5 bar/m of column bed height.

The ReliSorb particles also can be used in an expanded bed chromatography application, because the high specific gravity of the particles (>1.1 g/ml) permits controlled bed expansion when used in a reverse-flow mode. A packed bed of resin will expand from 100% to 200% over the linear flow rate of 200 cm/h to 300 cm/h, when used in an expanded bed separation system. This important characteristic allows crude samples to be separated on a bed of ReliSorb matrix without clogging the column. These properties are similar to the Streamline support materials from GE Healthcare.

The ReliSorb supports are available in a number of different derivatives including epoxide-activated, an iminodiacetic acid form for immobilized metal chelate chromatography, a diol derivative that can be periodate oxidized to form aldehyde groups, two amine functionalized resins, three different supports for hydrophobic interaction chromatography including a phenyl, butyl, and a C18 support material, as well as a number of derivatives for ion-exchange chromatography. The epoxide- and amine-containing supports may be used for custom immobilization of affinity ligands containing amines, thiols, hydroxyls, and carboxylates. The diol-containing support may also be activated using a number of different reaction strategies described later in this chapter (Section 2.1), which permits further customization of the support for particular applications.

Poly(Vinyl Alcohol) Supports

Crosslinked poly(vinyl alcohol) supports have been used as resins in column-based separations, particularly involving high-performance liquid chromatography (HPLC) (Battinelli *et al.*, 1996) (Figure 15.23). Poly(vinyl alcohol) (PVA) copolymers are typically made from the polymerization of poly(vinyl acetate) followed by the removal of the acetate ester by hydrolysis to create the PVA derivative. Itagaki *et al.* (1989) described the production of porous PVA particles for use in chromatography applications. The beads are formed by dissolving the linear PVA polymer in an aqueous

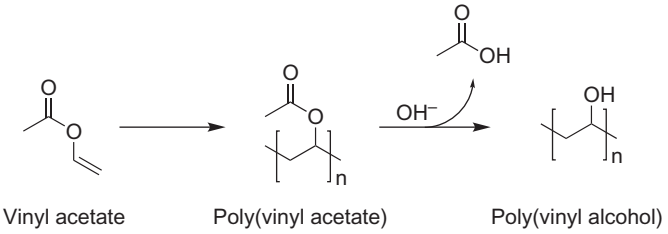

FIGURE 15.23 The reactions involved in the synthesis of a poly(vinyl alcohol) (PVA) support, which contains a huge density of hydroxyl groups throughout its structure.

solution containing a salt and dispersing the solution into a non-miscible organic solvent with stirring. The gelatinous polymer beads that form within the aqueous phase are stabilized through crosslinking with a bifunctional crosslinker, such as glutaraldehyde. One popular form of PVA copolymer is the Carbowax supports that are typically made from a combination of polyethylene glycol (PEG), polydimethylsiloxane, and PVA (note that Carbowax is a trade mark of Dow Chemical, which refers to their line of products incorporating PEG compounds). These resins are often used for separating compounds in analytical gas chromatography or HPLC through differential interactions *via* hydrogen bond formation with the ether oxygens and hydroxyls making up the beaded matrix. Supports made of PVA are extremely hydrophilic due to the abundant –OH groups. Derivatives of these supports have been prepared through esterification or by activation of the hydroxyl followed by covalent linkage of affinity ligands. For instance, a reverse-phase HPLC support was prepared by esterification of dodecanoic acid onto the hydroxyl groups to form a C18 column able to separate compounds based on hydrophobic interactions (Battinelli *et al.*, 1996).

Composite chromatography supports containing an inner core of a hydrophobic matrix and an outer shell of PVA have been created to make a biocompatible hydrogel for protein separations (Leonard *et al.*, 1995). A core particle made from porous polystyrene/divinyl benzene copolymer as modified through adsorption of PVA followed by stabilization by crosslinking. The resultant resin retained its ability to be used for size exclusion chromatography while the PVA outer layer provided hydrophilicity and decreased nonspecific binding toward proteins.

PVA polymers have also been used as carriers in the formation of drug conjugates. Kakinoki *et al.* (2008) created a paclitaxel–PVA conjugate to a linear 80-kDa PVA water soluble synthetic polymer to deliver therapeutic doses of the drug to tumor cells *in vivo*. The aqueous solubility of paclitaxel was dramatically enhanced through conjugation to the extremely hydrophilic PVA.

Membrane Supports

The use of porous membranes for the separation of proteins and other biological materials has existed for decades and remains an important component for purification, concentration, diafiltration, and removal of particulates including viruses and bacteria contaminants. Membranes are used routinely in processes ranging from small research-scale operations to huge bioprocess-scale production procedures in the pharmaceutical, biotechnology, and food industries. Synthetic and inorganic membrane supports are available with a broad range of porosity characteristics and structural compositions. Membranes may be constructed with large pores that permit macromolecules to freely pass through without being retarded or they may be made with smaller pore characteristics for selected filtration of molecules above a certain molecular size (e.g., ultrafiltration membranes). The internal pore structure of polymeric membranes is formed by the torturous entanglement of molecular strands, which leaves gaps and winding pathways through its three dimensional structure.

At a microscopic scale, the internal structure of a membrane is similar to that of a macroscopic sponge. The inner pores can absorb an aqueous solution within its open spaces and allow flow of a mobile phase directly through them at much faster linear flow rates than is possible using beaded chromatography supports. A packed volume of porous particles typically allows the mobile phase to freely move through it only by traveling around the beads, whereas the interior porous structure of the particles is accessed by diffusion. The process of diffusion is slower than perfusive flow and delays the interaction of molecules traveling in the mobile phase with the internal structure of the porous beads by the time needed for molecules within the mobile phase to diffuse into and out of the particles. By contrast, most of a membrane's internal pore structure is directly accessible by a flowing mobile phase with minimal need for diffusion to reach inner structures. The dominance of convective flow through membranes with minimal dependence on diffusional mass transfer is a key advantage of membranes over packed-bed chromatography methods. In principle, this allows for much faster affinity interactions between the mobile phase and a ligand attached to the membrane's surface than is possible using columns of porous particles.

However, membranes often have lower functional density than beaded supports, which can lead to a lower capacity for an affinity molecule to bind with a desired target. To overcome this potential deficiency, composite constructions of particles embedded within membranes have been made to combine the higher capacity of beaded chromatography supports with the faster flow rates possible with membrane supports.

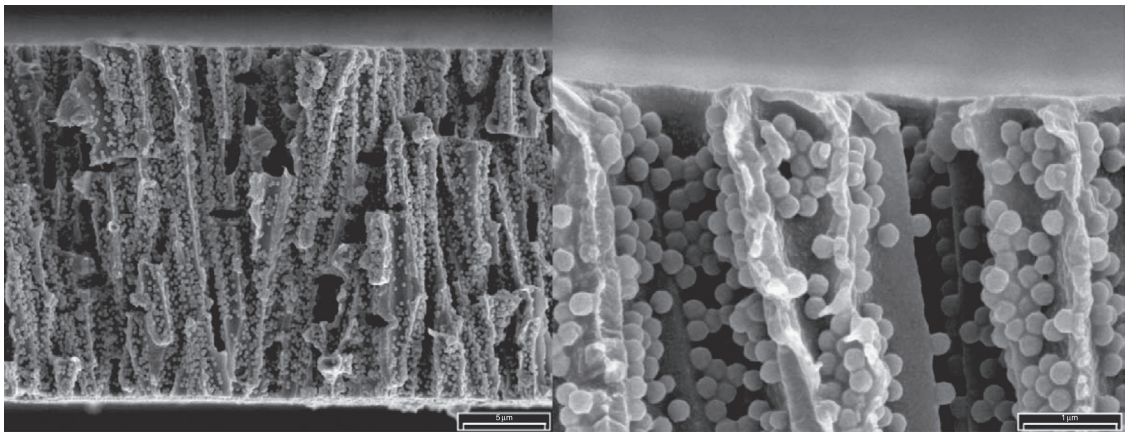

FIGURE 15.24 An SEM picture of the internal structure of a porous PET membrane-particle composite construction. The nanoparticles are covalently attached to the membrane inner pore structure and provide increased capacity for affinity separations or enzyme reactor applications. Reprinted with permission from Ulbricht, M. (2006) Advanced functional polymer membranes. *Polymer* 47(2006): 2217–2262; copyright © 2006 Elsevier.

Figure 15.24 shows the inner pore structure of a track-etched PET membrane (polyethylene terephthalate) containing large 1-μm pores and having nanoparticles covalently attached to the surfaces within it (Ulbricht, 2006). The particles provide significantly increased capacity for coupling enzymes used as reactors for chemical transformations, which occur in the mobile phase as it passes through the membrane.

Membranes are available having a broad selection of porosities ranging from those designed for ultrafiltration of biomolecules to ones more appropriate for filtration of particulates or microbial contamination. Ultrafiltration membranes can be selected to have pore sizes that can allow the passage of molecules below a particular molecular weight range while generally excluding molecules above that point. The molecular weight cutoff value of membranes actually is an approximate figure, not an exact exclusion limit, but it provides useful information about what biomolecules potentially can access the interior porous structure of the support and pass through. To use membranes for affinity separations, the selection of molecular weight cutoff must be one that is high enough to accommodate the intended molecules being targeted so they can bind an immobilized affinity ligand attached within the membrane's structure. Thus, most membrane-based affinity supports utilize membranes having large pore sizes in the micron range that allow proteins to pass through, for instance >0.2 μm. This cutoff range is essential to provide internal space for protein–protein interactions to occur within the internal membrane structures while also allowing for rapid mobile phase flow.

Commercial polymeric membranes are available in a wide range of chemical compositions, including hydrophobic or hydrophilic polymers, having functional groups on the matrix available for chemical modification, containing anionic or cationic groups for ion-exchange separations, or having affinity ligands for capture of specific target molecules. Similar to beaded chromatography supports, polymer membranes can be made from naturally occurring polysaccharides or synthetic polymers. Some of the more popular polymeric compositions consist of cellulose (regenerated), nitrocellulose, cellulose acetate, polyamide (e.g., nylon), polyimide, polyester, polyvinylidene difluoride (PVDF), polyacrylonitrile, polysulfone, polyethylene, polypropylene, poly(vinyl alcohol) (PVA, crosslinked), pHEMA (crosslinked), and a number of copolymers or composites of these polymers (Ulbricht, 2006) (Figure 15.25).

Nitrocellulose and PVDF have long been popular for use with proteins, especially in western blotting procedures in which electrophoretically separated proteins are non-covalently transferred and adsorbed onto the membranes and probed immunochemically using antibody conjugates. These membrane supports also can be used in affinity separations using non-covalently adsorbed proteins as capture ligands to selectively purify target molecules. However, to prepare more stable covalent attachment of affinity ligands it is necessary to have a functional group available on the membrane that can be activated and used to couple a protein or other affinity molecule. In this regard, membranes containing amines, carboxylates, or hydroxyl groups provide the greatest flexibility in the selection of activation and coupling chemistries available to immobilize affinity ligands. Hydroxyl-containing membranes are particularly desirable for use in affinity separations. Unmodified cellulose (including regenerated cellulose) membranes in addition to PVA and pHEMA membranes or composites provide excellent hydrophilicity

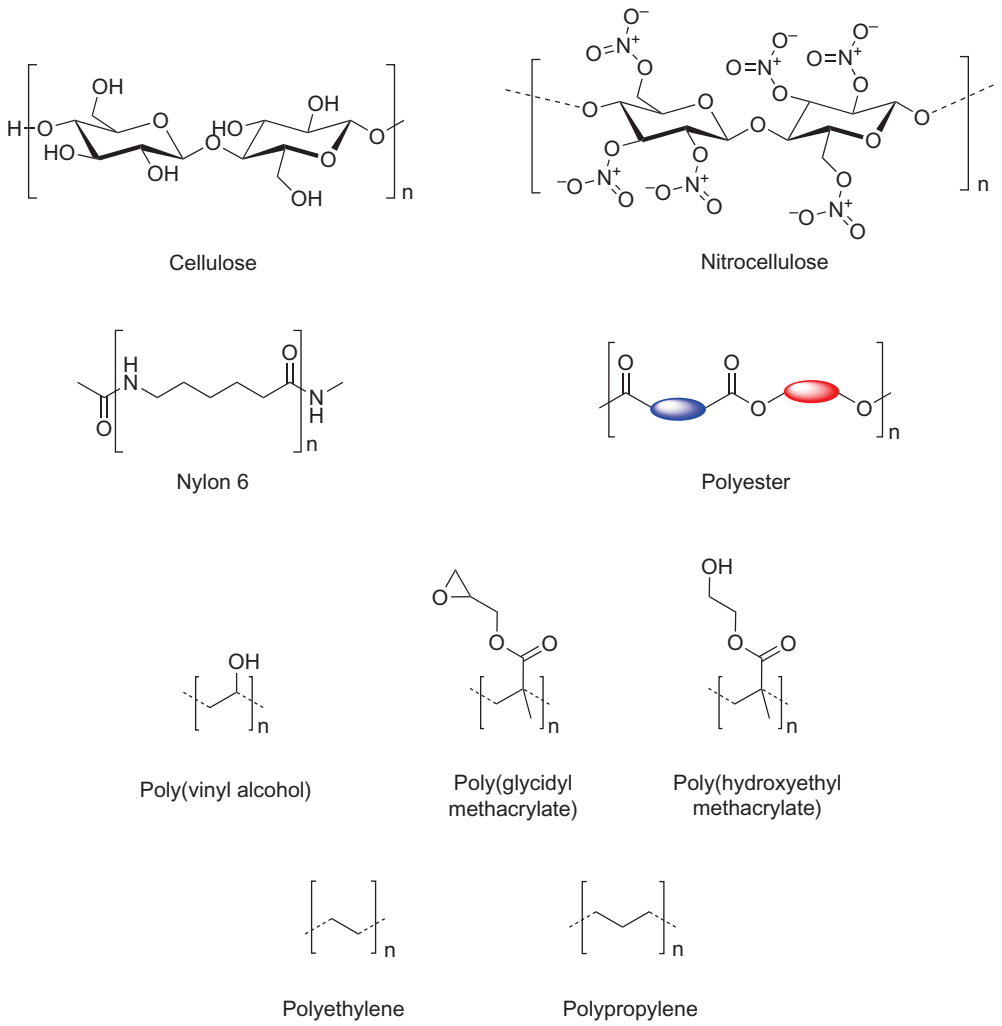

FIGURE 15.25 The polymer structures of common membrane compositions.

and low nonspecific binding with abundant hydroxyls for coupling ligands. Composites containing naturally occurring hydroxylic polymers such as chitosan or dextran also provide abundant functionalities for activation and coupling ligands. Another benefit of hydroxylic membranes is that they do not generate residual charge character from the remaining functional groups after coupling an affinity ligand, as may be the case with amine-containing or carboxylate-containing membranes, which could create considerable positive or negative charges, respectively.

An important monomer type that has been used to prepare affinity membranes is glycidyl methacrylate, which contains an epoxide group that can be used to immobilize affinity ligands through available thiols, amines, or hydroxyl groups. Copolymers of glycidyl methacrylate can be prepared with other hydrophilic monomers to provide the membrane composition of choice. The terminal epoxy groups on poly(glycidyl methacrylate) membranes also can be hydrolyzed by acid treatment to create terminal diols, which then can be periodate-modified to form aldehydes. The aldehydes can subsequently be used for coupling amine-containing ligands by reductive amination (see the corresponding section in this chapter on reductive amination and also Chapter 3, Section 5, and Chapter 4, Section 4). For instance, Akgöl *et al.* (2002) prepared a membrane consisting of poly(hydroxyethyl methacrylate-co-glycidyl methacrylate) that contained hydroxyl groups from the pHEMA component and epoxy groups from the polymerized glycidyl monomers (Figure 15.26). This membrane was used to couple the enzyme cholesterol oxidase for use as an immobilized reactor. In addition, Teke and Baysal (2007) used a base membrane consisting of nylon-6 (polyamide) and then grafted glycidyl methacrylate onto it using benzophenone as an initiator to create a reactive epoxide-containing membrane, which was used for coupling urease.

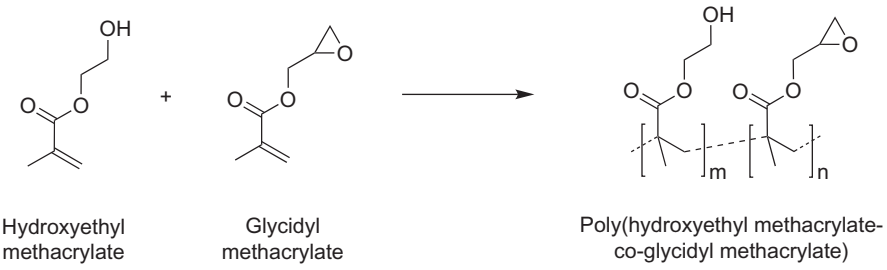

FIGURE 15.26 The structure of a poly(hydroxyethyl methacrylate-co-glycidyl methacrylate) membrane.

Polymer grafting onto existing substrates has been an important route to the creation of reactive groups or functional groups on the surface of a non-functionalized membrane. Grafting onto a block copolymer substrate can introduce novel characteristics into a membrane that normally could not be created through the original membrane synthesis (Koguma *et al.*, 2000). The process of grafting can create new polymer arms or tentacles coming off of the original membrane surface (Figure 15.27). For instance, the grafting of new polymer strands onto the internal structure of porous membranes has been used to increase the coupling capacity of membranes for immobilizing affinity ligands (Muller, 1990; van Reis and Zydney, 2007). Covalent grafting can be done *via* solution-phase polymerization of vinyl monomers in the presence of a membrane substrate and an initiator. Many routes to initiating this type of grafting reaction have been described and some of them can be used to graft synthetic polymers onto natural polymer surfaces (Jenkins and Hudson, 2001). Once the polymerization reaction is initiated, a new graft copolymer will be formed within the solution and can be attached to the existing membrane through any remaining vinyl groups left over from its initial synthesis. Most often, however, linking groups have to be created on the original block polymer surface to facilitate covalent attachment of the new polymer. Covalent graft copolymer modification of membranes and surfaces may use irradiation (i.e., using electron beam or Co^{60}) to form radicals on the existing substrate, which can provide initiation sites for graft polymer growth (Gürsel *et al.*, 2008). New polymer grafts may also be created by linking a polymer tentacle to a membrane using traditional conjugation chemistry. Gacal *et al.* (2006) used the Diels–Alder chemoselective ligation reaction (Chapter 17) to covalently attach PEG or poly(methyl methacrylate) polymers to a polystyrene substrate, thus creating novel surfaces with completely different properties from that of the original polymer. Noncovalent grafting also can be performed through the adsorptive interaction of a functional polymer with the existing membrane substrate, which instead of forming polymer arms, forms a layer

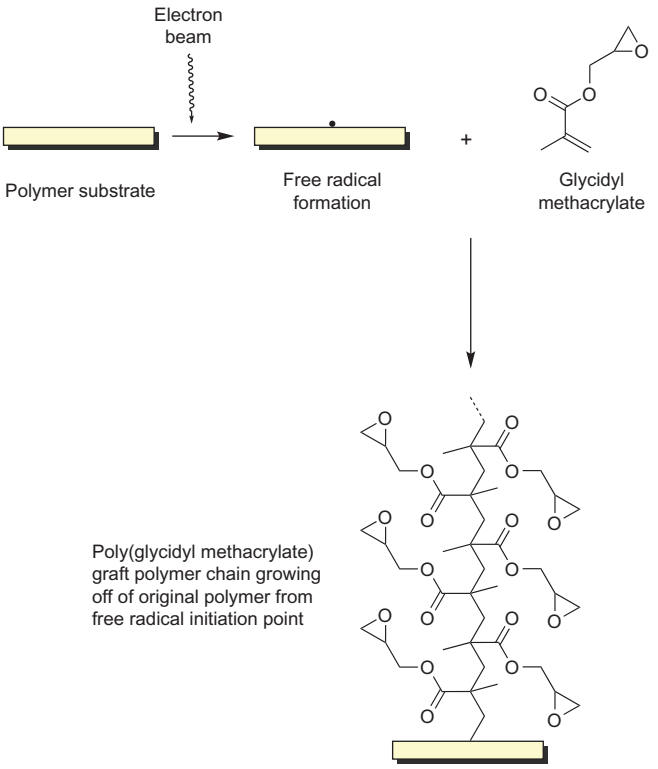

FIGURE 15.27 General illustration of grafting onto an existing polymer substrate. Many different polymer types can be grafted onto substrates to create new properties or add functional groups for coupling affinity ligands.

of the new polymer onto the initial membrane, in some cases filling the inner pores (Yang *et al.*, 2011). This type of composite membrane is similar in construction to the "gel-in-a-shell" structure of agarose-filled ceramic particles (described previously in this chapter).

Membrane-affinity supports have also been formed by the combination of porous beaded chromatography particles, which have been entrapped or grafted within the tangled polymer strands of a membrane (Borneman, 2006). This composite construction of porous beads within a membrane scaffold creates a chromatography support having the high potential convective flow rates characteristic of polymeric membranes plus the high

capacity and increased surface area present within the internal pores of particles. Particle-loaded nonwoven fibrous membranes were developed by 3M (Markell *et al.*, 1994) and commercialized under the trade name Empore. These membranes contain either derivatized polystyrene particles or silica particles within an inert 10% polytetrafluoroethylene (PTFE) matrix and are used primarily for solid-phase extraction (SPE). Another fibrillated membrane/particle construct was made by incorporating 3M Emphaze beads (UltraLink, see previous section, this chapter) into a PTFE membrane, which provides azlactone-reactive groups for coupling affinity ligands (Haddad *et al.*, 2010). A similar membrane-entrapped particulate technology was developed by Millipore and used to produce chromatography supports in pipette tips (Zip Tips) (Kopaciewicz *et al.*, 2000). In addition, particle-embedded membranes have been used for the immobilization of enzymes to use as reactors, forming supports of high activity due to the capacity enhancement made possible by the entrapped particles (Ulbricht, 2006). An SEM picture of a nanoparticle-embedded membrane was shown previously in Figure 15.24 of this chapter. All of these constructs provide the ease of use and stability that are typical of membranes with the higher capacity of packed bed chromatography supports. Unlike packed beds, however, the particle-loaded membranes maintain better matrix stability by holding the particles in place and not being susceptible to bed disruption, which can lead to non-uniform flow characteristics.

Particle-loaded membranes have been used in affinity separations by immobilizing ligands on the embedded chromatography particles. Virtually any affinity separations that can be performed using beaded supports can be accomplished using particle/membrane composites. For instance, immunoaffinity applications using immobilized antibodies have been used successfully in SPE techniques to target and capture small antigens out of complex solutions, such as drugs in serum samples (Dombrowski *et al.*, 1998; Delaunay *et al.*, 2000).

Inorganic membranes also can be used for affinity separations. Membranes made of porous inorganic materials have been prepared from the same base compositions as beaded chromatography supports, including porous glass, silica, alumina, and ceramic materials. Many of these membranes are more rigid than those made from polymeric materials and can be molded during construction to fit the shape of a desired flow path or device. An exception to the usual rigidity of most inorganic membranes is glass fiber materials, which often are used in filtration applications and come in flexible disks of all sizes. Inorganic membranes may be surface modified to contain functional groups or reactive sites for coupling affinity ligands. The methods used to introduce sites for covalent coupling on inorganic substrates often make use of functional silanes to form a polymeric network containing side chains, which terminate in the functional group or reactive group of choice. These reagents and their uses are described in Chapter 13.

Monolithic Supports

Chromatographic monolithic supports are similar in construction to membranes, but rather than polymerizing monomers into a thin membranous sheet, the polymerization process forms a single continuous matrix that is contained within a three-dimensional shape, which acts as a mold. The final monolith thus can be constructed within a column shaped like a cylinder for standard chromatography purposes or formed within another type of mold that would result in a custom matrix shape. Early pseudo monoliths were constructed from stacked membrane sheets or from rolls of membranes, which formed larger beds of a discontinuous matrix. True monolithic supports, however, are constructed of a homogeneous porous matrix that takes on a desired shape dependent upon the mold in which it is contained. One of the first references to the name *monolith* with regard to a chromatography support was by Noel *et al.* (1993), who they prepared a continuous matrix of cellulose that took on the consistency of a sponge-like material.

However, explorations into the use of a continuous-phase matrix for chromatography separations occurred as early as the late 1960s and early 1970s, wherein uniform separation media were prepared from such materials as pHEMA, poly(ethyleneglycol methacrylate), foamed polyurethane, and other polymers for potential use in separations (Kubin *et al.*, 1967; Ross and Jefferson, 1970; Hileman *et al.*, 1973). Since that time, a wide variety of molded polymers have been used to form monolithic porous polymers useful for all types of separations, including immobilized affinity ligand applications (Svec and Fréchet, 1999; Svec *et al.*, 2003; Neff and Jungbauer, 2011; Shin *et al.*, 2011; Arrua *et al.*, 2012).

An example of a commercial monolith support is made by BIA Separations (Austria). The "Convective Interaction Media" produced by BIA is made in the form of disks and cylinders (Champagne *et al.*, 2007). The composition of the polymer monolith consists of a homogeneous unit made of polymethacrylate derivatives (Jungbauer *et al.*, 2008). The polymerization process produces large through-pores of 1.5-μm diameter with interconnecting pores throughout the support, which permits interactions between even the largest proteins or biological macromolecules within the media (Zmak *et al.*, 2003; Etzel and Bund, 2011; Neff and Jungbauer, 2011). The BIA monolith supports are available in popular affinity derivatives, including protein A,

protein G, and metal chelate. In addition, an epoxy-activated version is offered for direct immobilization of amine-containing affinity ligands as well as a carboxy and an amino form for coupling of custom affinity molecules.

Protista International AB also commercialized a monolithic chromatography matrix that contains unusually large pore structures. This "supermacroporous" support was produced by the polymerization of monomers in aqueous solution within a column at temperatures that cause frozen sections to develop within the forming polymer (Arvidsson *et al.*, 2002, 2003). The freezing of the aqueous regions causes very large pores to form consisting of cavernous spaces of 10- to 200-μm diameter throughout the "cryogel" monolith, thus creating a series of connected through-pores for rapid convective flow within the support (Arvidsson *et al.*, 2002, 2003) (Figure 15.28). A variety of monomers can be used to create the monolith, including derivatives containing ion-exchange groups, functional groups for modification, or reactive groups for immobilization of affinity ligands. A hydrophilic hydroxylic monolith was created using 2-hydroxyethyl methacrylate to form a cryogel containing abundant hydroxyl groups for subsequent activation and coupling (Savina *et al.*, 2007). Other cryogel compositions have also been formed using other acrylamide or methacrylate monomers (Persson *et al.*, 2004; Savina *et al.*, 2006; Plieva *et al.*, 2008).

The porous structure of the cryogel monolith even allows cell separations to be performed directly within the monolithic support using immobilized affinity ligands specific for certain cell types. For instance, Dainiak *et al.* (2005) used an IMAC support to separate different microbial cells by their ability to bind to the metal chelate ligands. Similarly, Kumar *et al.* (2003) used immobilized protein A to capture lymphocytes within a monolithic cryogel support, and Arvidsson *et al.* (2002) used immunoaffinity and anion-exchange monolith supports to capture microbial cells (Figure 15.29).

Polymeric monolithic supports are chemically similar to the corresponding membranes or spherical beads made from the same polymers—only the shape and size of the support are different. Therefore, the techniques used to activate and immobilize affinity ligands on a monolith's polymer surface are nearly identical to those used for other support materials of equivalent chemical composition. For an illustration of the polymeric structures of typical monolithic supports, see the previous overview of beaded chromatography supports in this chapter. The major difference between a monolith and a beaded support in the methods of ligand coupling is how the matrix is handled and washed during the activation and coupling reactions. Particulate supports can be manipulated as suspensions and washed after each reaction step using filtration devices, but a monolithic support is usually handled directly within the column or mold in which it was formed. For instance, if a column containing a porous monolith consisting of a pHEMA matrix is to be coupled with a protein affinity ligand, then each step in the immobilization process would be carried out by pumping the reagents through the column in a chromatography mode involving a series of sequential additions, incubations, and washing steps. This chromatographic reaction scheme must be carried out carefully to ensure that all parts of the monolith are treated equally and end up with the same density of reactive groups and immobilized ligands. This is not a trivial point, because reactants are added in the mobile phase and are pumped through from one end of the column and out the other end. As the reactions occur, the concentration of the reactants change as the solution passes through the matrix. This is true even in radial flow chromatography operations where the mobile phase travels from the center of a cylindrical shaped monolith through the side walls. In general, as reactions take place within the monolithic support, the

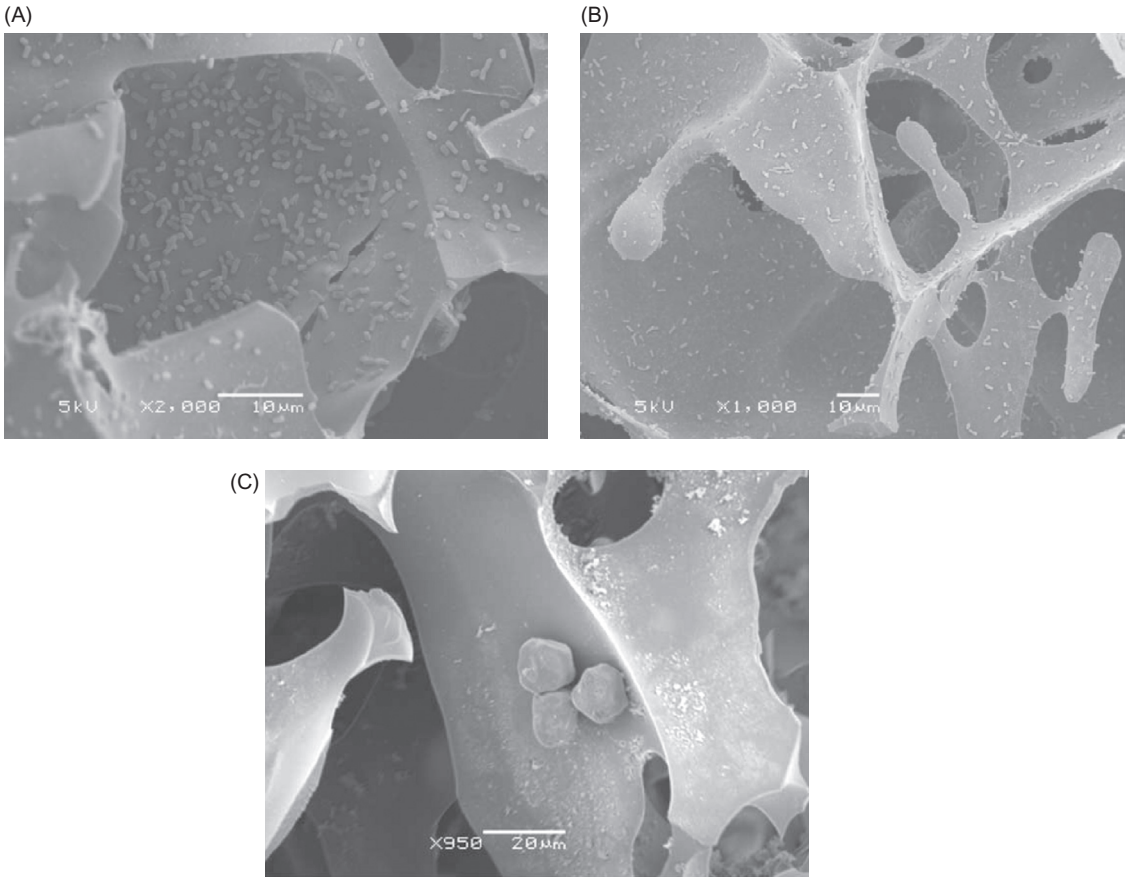

FIGURE 15.29 SEM images of supermacroporous monolith supports capturing *E. coli* cells using an anion-exchange group on the matrix (A and B) and lymphocytes from blood samples using immobilized protein A (C). (2002) Chromatography of microbial cells using continuous supermacroporous affinity and ion-exchange columns. *J. Chromatogr*. 977: 27–38, copyright © 2002 Elsevier; and Kumar, A., Plieva, F.M., Galaev, I.Y., and Mattiasson, B. (2003) Affinity fractionation of lymphocytes using a monolithic cryogel. *J. Immunol. Meth*. 283: 185–194, copyright © 2003 Elsevier.

reactant concentration in the mobile phase will decrease as flow travels through the support and any byproducts of the reactions that are released into the solution will increase as the reagent front passes through.

Thus, the rates and yields of the activation and coupling reactions will decrease as the mobile phase flows through the monolith polymer. This could potentially result in dramatic differences in the amount of activation and ligand coupling that occurs from the top of the monolithic column bed to the bottom, if consideration of this effect was not taken into account. To overcome this phenomenon, enough reactant solution must be passed through the matrix at each step in the activation and coupling process to fully saturate the monolithic support from top to bottom. One method of accomplishing this is to prepare a large excess of reagent solution and continually recirculate the solution through the column until the reaction period is complete. Alternatively, an excess of reactant solution may be passed through the monolith and then the support allowed to incubate in the solution of the reactant for an extended time to fully drive the reaction to completion. This process also can be used when coupling affinity ligands to an activated monolith, in which the support is gently mixed in the ligand coupling solution after an initial amount of ligand has been passed through the column to saturate all the internal pore structures. This is the general strategy recommended by BIA Separations for immobilizing ligands on an epoxy-activated monolith made from poly(glycidyl methacrylate).

2. ACTIVATION AND COUPLING OF AFFINITY LIGANDS TO CHROMATOGRAPHY SUPPORTS

The matrix and activation choices available for the preparation of immobilized affinity ligands are two of the most important considerations for creating an

optimal affinity support. The selection of an affinity ligand is obviously equally important, but for this discussion it is assumed that the target molecule to be captured and the affinity ligand to be immobilized have already been identified by the user. Matching an affinity ligand with the best possible matrix material as well as choosing the optimal coupling strategy for immobilizing the ligand are both critically important factors for ensuring high specificity and low nonspecific binding in the final chromatography support.

One of the first criteria in choosing an appropriate immobilization strategy is that the method used to activate and couple a ligand to a given support must be compatible with both the ligand and the matrix. In one regard, this means that the chemistry of activation must be chosen to be compatible in its reactivity with the type of functional groups present on the support material. For example, if the support is a polymer that contains abundant hydroxyl groups, which is a common characteristic for many matrices (see previous section), then an activation method should be chosen that will yield an activated intermediate based upon the presence of an initial hydroxyl. In addition, the reactive intermediate created from activating the support must be appropriate for coupling to the available functional groups on the ligand to be immobilized. For instance, an electrophilic reactive group that spontaneously couples to an amine may be an optimal choice for matrix activation when immobilizing an amine-containing affinity ligand, such as a protein.

Another important consideration is the reaction medium that is used to activate the chromatography support. Some activation methods require nonaqueous conditions in pure organic solvents, which potentially may harm a support material by causing collapse or shrinkage of particles with consequential changes to internal pore structures. Determining if a desired support can be exchanged from an aqueous environment into 100% solvent and back again without severe shrinkage or damage often is a prerequisite to deciding on an optimal activation strategy. For instance, a crosslinked agarose support can be washed into anhydrous acetone (or other water-miscible solvents) for activation and taken back into aqueous coupling buffer for immobilization of a protein without irreversible damage occurring to the particles. However, a beaded polyacrylamide matrix that was initially swollen in water will collapse by being exchanged into acetone, which will so severely constrict the pores within each particle that activation and coupling cannot occur efficiently throughout the internal regions of the support.

When choosing an activation method, consideration also should be made to residual functional groups left over after activation and coupling of an affinity ligand. Most activation chemistries alter the initial characteristics of a matrix to form the intermediate reactive groups. If this activated intermediate successfully couples with a ligand, then the desired covalent bond will form, which often replaces part of the reactive group with the coupled ligand. However, if ligand coupling does not occur at every reactive site on the support, then there will likely be reactive groups or hydrolysis products remaining after the reaction. The presence of such residual groups, if they are active, will still have coupling potential toward molecules in a sample when the affinity support is put to use. If any reactive groups remain after immobilizing an affinity ligand, the potential exists to covalently couple molecules that are not desired to be bound to the support and thus create sites for nonspecific interactions. Additionally, if hydrolysis of reactive groups occurs at the same time as ligand coupling, then another functional group may be formed in the process which represents the hydrolysis product. In some cases, this may generate charge characteristics, such as negatively charged carboxylates being left over after a reaction. Residual charged groups may cause nonspecific interactions with sample molecules independent of the desired affinity interactions. For these reasons, there is typically a blocking step associated with the ligand-coupling process that eliminates any residual reactive groups or blocks potential sites of nonspecific binding by capping them with a nonrelevant molecule. In some instances, the blocking of residual charged groups may not be possible after ligand coupling, because the ligand itself may have similar groups present and therefore would be modified in the process. In the end, the most important factor is to consider all of the reactions involved with support activation and ligand coupling to decide the best combination of reactions to produce an optimal affinity support.

Other important things to consider when choosing an activation method include the hazardous nature of the reagents required (personal safety and waste disposal issues), the reaction rate and yield when coupling a ligand, whether the reaction is reproducible and controllable under the chosen conditions, and if the process can be scaled up and performed in large batch sizes with similar efficiency to bench-scale experiments. Some activation and coupling methods work well in small scale, but are difficult to handle and control in process-scale operations. For instance, cyanogen bromide activation, despite its hazardous nature, is relatively simple to perform in a fume hood using milliliter quantities of a support; however, attempts to scale up this process to activate many liters of a support can result in significant problems related to environmental hazards and the difficulties in rapidly activating, washing, and using the activated resin. Therefore, each prospective activation strategy should be carefully

considered as to its relative ease of use and scalability in production before deciding upon a method of choice for coupling a desired affinity ligand.

In addition, the quantity of the support to use in the activation and coupling reactions is dependent on how much target molecule ultimately needs to be captured when using the affinity support in a chromatographic separation. The amount of support to use is also governed by how much affinity ligand is available for coupling. For abundant affinity ligands, an excess of affinity support can be prepared without significant cost considerations; however, for expensive ligands such as some primary antibodies or recombinant proteins, the ligand cost and availability may be the governing factors in deciding how much of an affinity support to prepare. Most of the protocols in this section involve the activation of from 1 ml to 100 ml of a support material. The amount of material actually used to produce a desired immobilized ligand may be varied from the given protocols simply by proportionally adjusting the reagents used in the reactions.

If a protein is to be immobilized onto a matrix, ideally it should be dissolved in the coupling buffer at concentrations of at least in the low mg/ml levels. Many proteins to be used as affinity ligands perform well if the immobilization reaction is performed at concentrations of about 3 to 6 mg/ml. In some cases, when maximal binding capacity is desired for the affinity support to capture a target molecule, a protein ligand may be coupled at concentrations much higher than this range, even >10 mg/ml. Most coupling reactions usually provide high yields of protein immobilization when using concentrations of up to about 20 mg/ml during the immobilization reaction. Immunoglobulin-binding proteins such as protein A are typically coupled to chromatography supports at the high end of this concentration range (>6 mg/ml) to maximize the binding capacity of the resultant affinity support for purifying antibodies.

However, regardless of the type of affinity support being prepared, it is recommended that experimental optimization be done for the coupling ligand concentration and the reaction conditions to provide the best possible affinity support performance for binding a desired target molecule. If some proteins are immobilized at too high a density on the support, then nonspecific binding may occur toward other molecules in a sample, or alternatively it may result in difficulty in eluting a bound target molecule due to extremely high affinity or avidity effects. Conversely, if too low a quantity of protein ligand is immobilized, the capacity and efficiency of binding to the desired target molecule may be unacceptably low. Of course, if only a small amount of a ligand is available for coupling, then using reaction concentrations down to the µg/ml levels may be carried out with success, but along with the realization that the resultant binding capacity of the support will be lower as well.

If a small amine-containing ligand is to be immobilized on the support, its concentration in the coupling buffer should be at least three times greater than the level of active groups on the matrix to obtain decent yields. Many activated supports may contain about 20 to 40 µmoles/ml gel of reactive groups; therefore a small amine-containing ligand might be reacted at a level of 60 to 120 µmoles/ml gel. Higher concentrations will result in higher yields of coupling, but optimization of the resultant ligand density should be carried out to obtain the best performance of the affinity support in its intended application.

A slightly different situation results if a diamine spacer molecule is to be coupled to an activated support to result in a free terminal amine. To avoid the reaction of the support with both ends of the linker the molecule should be dissolved in the coupling buffer at very high concentration. For instance, a 1.0- to 1.5-*M* concentration of ethylene diamine will maximize coupling yield while preventing both ends of the compound from coupling to the support.

It is interesting to note that when coupling small amine-containing ligands or larger proteins to microparticles or nanoparticles (see Chapter 14) the most frequently used immobilization technique involves activation of carboxylates on the particle surface using the carbodiimide EDC (with or without the addition of NHS or sulfo-NHS), which is then immediately used to react with the ligand. However, for larger particles used in chromatographic separations, the carbodiimide reaction is typically applied only when immobilizing small amine-containing molecules or diamine spacers, and then only in cases in which the molecules do not also contain carboxylates and thus have no potential for polymerization during the reaction. Most coupling methods involving chromatographic supports make use of a much wider variety of activation and coupling reactions to facilitate the immobilization of affinity ligands than those typically used with microparticles or nanoparticles. This statement does not mean that the methods described in this chapter cannot be applied to small particles—indeed they can with the appropriate changes to accommodate the differences in handling and washing, which typically involve centrifugation or magnetic separations as opposed to simple bulk filtration as can be done with chromatography supports. The reactions discussed in this chapter can be applied successfully to any immobilization requirement, whether the solid phase is a planar surface, a microparticle, a nanoparticle, a membrane, or a larger porous bead.

This section describes the activation methods commonly used to create reactive groups on

chromatography support materials. All of these reactions have been used successfully for many years and have abundant publications that describe the coupling of specific affinity ligands of all types. This section also contains suggested ligand coupling protocols following each activation procedure. All of these reactions should be performed with caution. Care should be taken to use the appropriate personal protective equipment to guard against exposure to potentially toxic compounds or flammable solvents. Most activation methods should be carried out in a fume hood wearing gloves and a lab coat as a minimum. Occasionally, a full-face shield or an organic mask also should be used to prevent chemical exposure to hazardous compounds.

2.1. Amine-Reactive Immobilization Methods

Periodate Oxidation and Reductive Amination

One of the most popular methods of immobilizing affinity ligands on chromatography supports involves the formation of aldehyde groups on the matrix followed by a reductive amination coupling reaction to covalently link amine-containing molecules. Sodium *meta*-periodate is an oxidizing agent that can be used to create aldehydes on chromatography supports that contain diols. Hydroxyl groups present on adjacent carbon atoms are a common feature in many resins made from polysaccharides, such as beaded agarose, cellulose supports, or cellulosic membranes. Diols may also be formed on synthetic polymeric support materials by careful choice of the monomers used during manufacture or from the selected chemical modification of a support after production. For instance, glycidyl methacrylate monomers can be used to prepare chromatography matrices that will yield epoxide groups in the final beaded support or membrane. Hydrolysis of the epoxides under acidic conditions will generate terminal diols on the carbon atoms that originally made up the epoxide rings. In addition, the crosslinking of some support materials with epoxide-containing agents, such as the use of epichlorohydrin or 1,4-butanediol diglycidyl ether to stabilize and strengthen beaded agarose supports, may create additional periodate-oxidizable diols from leftover, hydrolyzed epoxide groups (Figure 15.30).

Diols can even be formed on support materials containing non-periodate-oxidizable hydroxyl groups through modification with the small epoxide-containing compound glycidol (Hoyer and Shainoff, 1980; Shainoff, 1980; Guisán, 1988; Guisán *et al.*, 1997). The epoxy group of this compound reacts with hydroxyl groups under alkaline conditions to form an ether bond with the associated formation of a terminal diol (Figure 15.31). Reaction of glycidol in excess with hydroxylic supports results in the polymerization of the compound within the matrix through continued reaction with the hydroxyls produced as the epoxide couples. This may form branched polyglycerol chains in which each branch terminates in a diol, the formation of which dramatically increases the hydrophilicity of the matrix while forming the requisite periodate oxidizable components to create aldehydes for coupling affinity ligands. The amount of glycidol used in this process determines the ultimate size of the polymers formed and the potential affect on the internal porosity of the support, which can be significantly reduced even in highly porous gels (Eriksson, 1987). Glycidol modification has been used to immobilize and stabilize enzymes through multipoint attachment to the matrix, and the level of modification and subsequent activation to aldehydes can be controlled to produce between about 7 and 70 μmoles of reactive groups/ml gel (Suh *et al.*, 2003; Tardioli *et al.*, 2011; Nwagu *et al.*, 2012).

Periodate oxidation of diols proceeds by cleavage of the associated carbon–carbon bond with concomitant oxidation of the hydroxyl groups to aldehydes. If the diol consists of secondary hydroxyls present within the sugar rings of a polysaccharide polymer, it will result in two aldehydes being formed per oxidation event along with scission of the ring; however, if the diols are terminal—in other words, containing one primary hydroxyl group adjacent to a secondary hydroxyl, such as those created from epoxide hydrolysis or glycidol modification—an oxidation reaction would yield one molecule of formaldehyde (released) and one aldehyde remaining on the support at every diol site. In addition, if a series of three hydroxyls occur on neighboring carbons, such as in glucose-containing polymers like dextran, then treatment with periodate would result in the formation of one molecule of formaldehyde (from oxidation and loss of the central carbon atom) and two aldehydes generated from oxidation and cleavage of the glucose ring (Figure 15.32). The oxidation of polysaccharide polymers can be highly complex and has been studied extensively (Rinaudo, 2010). Periodate-oxidized supports prepared in this manner can be washed free of excess periodate (and formaldehyde) and stored for long periods without loss of aldehyde functionality.

Aldehydes (or ketones) can react with amine groups in aqueous solution to create reversible Schiff base linkages, the formation of which is enhanced at alkaline pH values. Schiff base formation is a dehydration reaction that can reversibly undergo hydrolysis in aqueous solution to reform the carbonyl group and the amine. However, Schiff bases can be stabilized and made essentially permanent by reduction to a secondary amine bond (Figure 15.33). Reducing agents that are suitable for this process include sodium cyanoborohydride and certain borane compounds (Borch *et al.*, 1971;

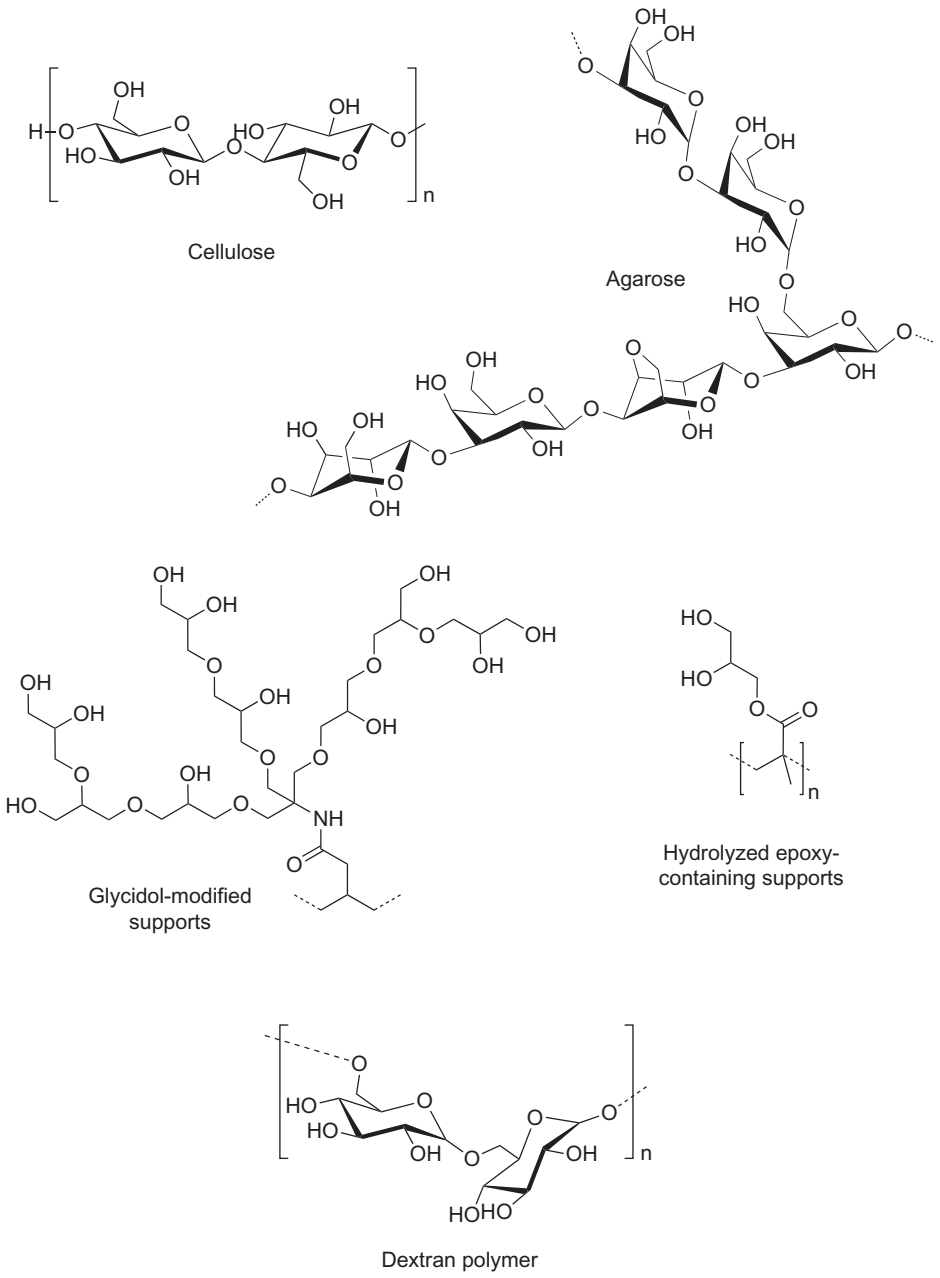

FIGURE 15.30 Polymeric supports and modified supports that contain hydroxyl groups suitable for activation and coupling of affinity ligands.

Jentoft and Dearborn, 1979; Baxter and Reitz, 2002). Stults *et al.* (1989) showed that up to 50 mg of BSA could be immobilized per gram of a crosslinked agarose-beaded support using pyridine borane as the reducing agent. Sodium borohydride may also be used to reduce a Schiff base, but it is about 5-fold stronger as a reducing agent than cyanoborohydride, and thus it could also reduce the aldehyde reactive groups used to create the initial Schiff base and it could reduce and cleave disulfides within protein molecules (Peng *et al.*, 1987). Cyanoborohydride will not normally appreciably reduce carbonyls, except under acidic conditions at pH 3 to 4 (Lane, 1972). Therefore, under slightly more alkaline conditions (pH 6–8), cyanoborohydride can be used to help drive the immobilization reaction to completion—reducing the Schiff base interactions as they form—whereas stronger reductants may also reduce one of the starting reactants, thus potentially reducing yields.

It has been shown that the coupling efficiency and the resultant stability of the reductive amination process for immobilizing proteins on agarose supports

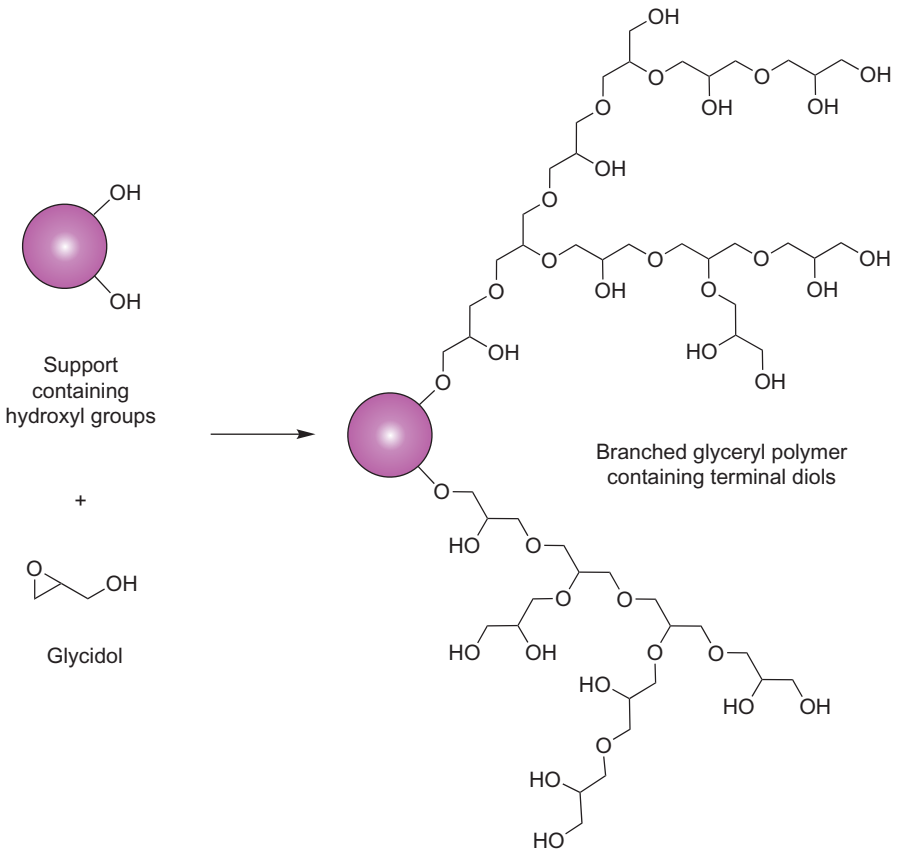

FIGURE 15.31 Glycidol reacts with hydroxyl-containing supports in a ring-opening process to create ether linkages, which in turn create additional hydroxyl groups. Glycidol can polymerize within the matrix to form branched polymers wherein each branch terminates in a diol, which may be periodate oxidized to form aldehyde groups.

are both excellent (Domen *et al.*, 1990). Proteins having abundant amino groups for immobilization typically have high coupling yields, which can exceed 95%. Yields can be enhanced by forming the initial Schiff base in a reaction medium having a more alkaline pH of 9 to 10 and then reducing the pH toward neutrality for subsequent reduction of the iminium double bond (Hornsey *et al.*, 1986). In addition, Ruzicka *et al.* (2006) showed that reductive amination reactions can be complete in just several minutes instead of the typical recommended reaction times of hours. They also contended that the reduction step with cyanoborohydride is unnecessary, as protein ligands immobilized *via* Schiff base formation at high pH appeared to have little ligand leakage even when treated with 0.1-*M* HCl. Despite these results on microliter quantities of support materials, care should be taken when coupling using much larger volumes of supports to determine the optimal reaction time for each step in the coupling process. Mixing and diffusion rates within bead slurries of quantities from hundreds of milliliters to multiple liters of gel can be quite different from reactions carried out in a micro flow cell with microliter amounts of gel. In addition, while Schiff base interactions can be more secure due to increased stability gained from multipoint attachment with proteins—given that the probability of all the associated Schiff base linkages hydrolyzing at once and releasing a protein molecule is low—it is still highly recommended that stabilization of these linkages be done through reduction to prevent the possibility of hydrolytic leakage of ligand over time. In particular, if an affinity ligand is immobilized through only a single amine to form an iminium Schiff base group, then failure to reduce that bond will result in significant ligand leakage over time by hydrolysis.

The following protocols involve various strategies to form the reactive aldehyde groups on support materials as well as the suggested coupling reactions for immobilizing amine-containing ligands. Note: The use of sodium cyanoborohydride is potentially toxic and dangerous. All operations should be performed in a fume hood while wearing appropriate personal protective equipment.

Periodate Activation Protocol

This protocol is designed to create aldehyde groups on diol-containing chromatography supports through

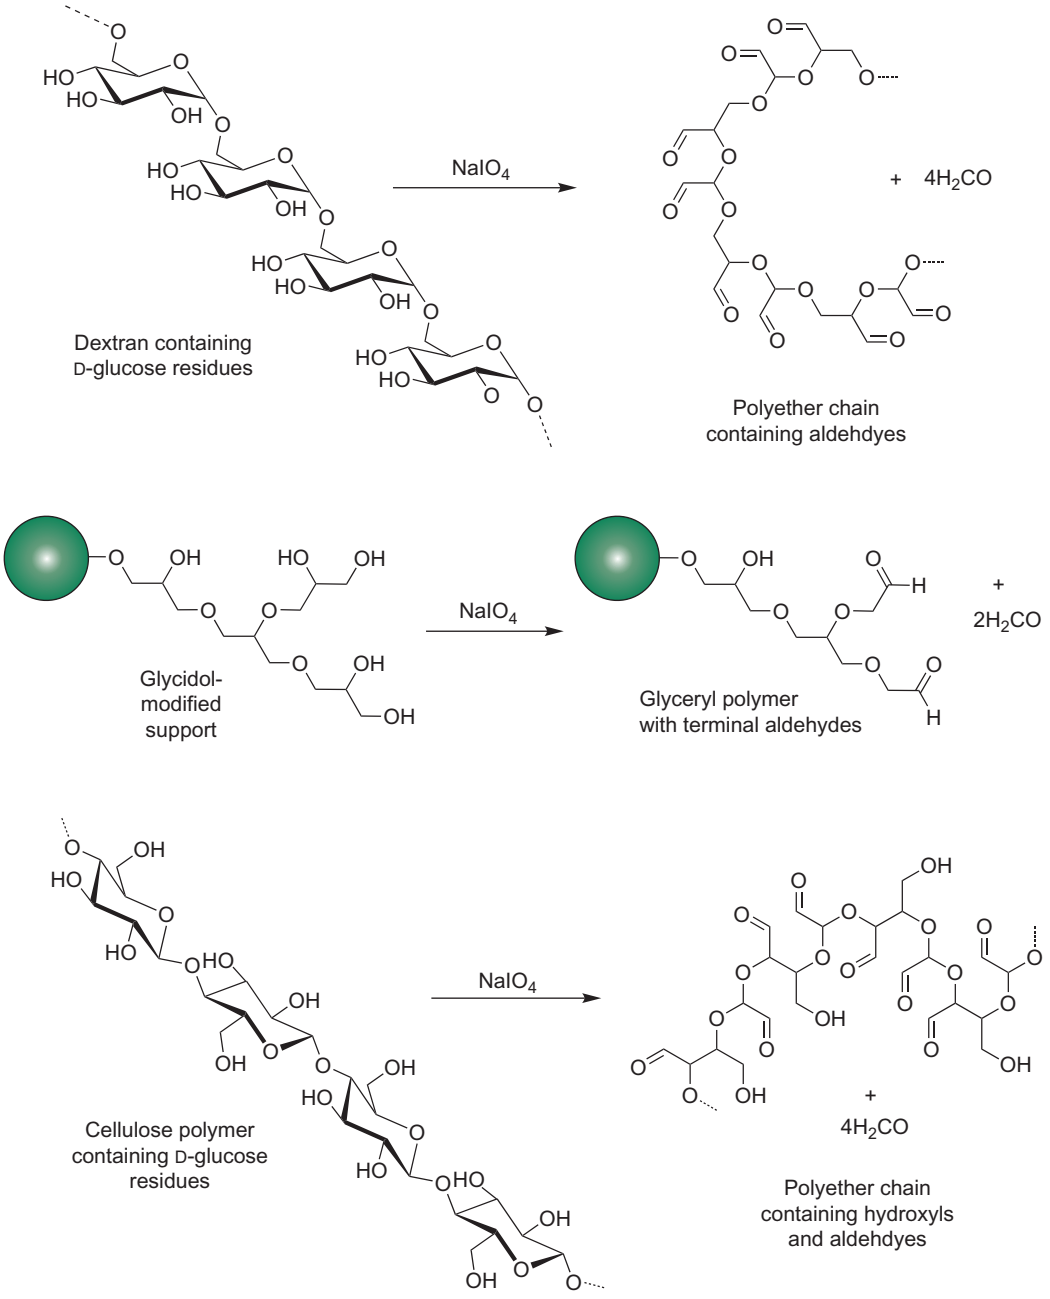

FIGURE 15.32 Diol groups in support materials may be oxidized with sodium periodate to form aldehydes, which can be used to immobilize amine-containing ligands by reductive amination. Saccharide residues containing diols, such as within dextran or cellulose polymers, will undergo ring cleavage and opening along with the formation of two aldehyde groups per sugar. Glycidol modified supports will undergo oxidation with the formation of a single aldehyde at the end of each branched-chain polymer.

oxidation with sodium periodate. This is useful for the activation of crosslinked agarose supports, cellulose- or dextran-containing beaded supports or membranes, and matrices that have been modified with glycidol or contain a hydrolyzed epoxide to create diol groups. Changes to the quantity of support material used from that described here may be done with corresponding proportional changes to the amounts of other reagents used.

1. Wash thoroughly 100 ml of a diol-containing chromatography support material (i.e., crosslinked agarose, dextran, cellulose, or a glycidol-modified support material) with at least several bed volumes of deionized water to remove any preservatives or other contaminants. The use of a sintered glass filter funnel works well for this purpose. Drain the support to a wet cake.

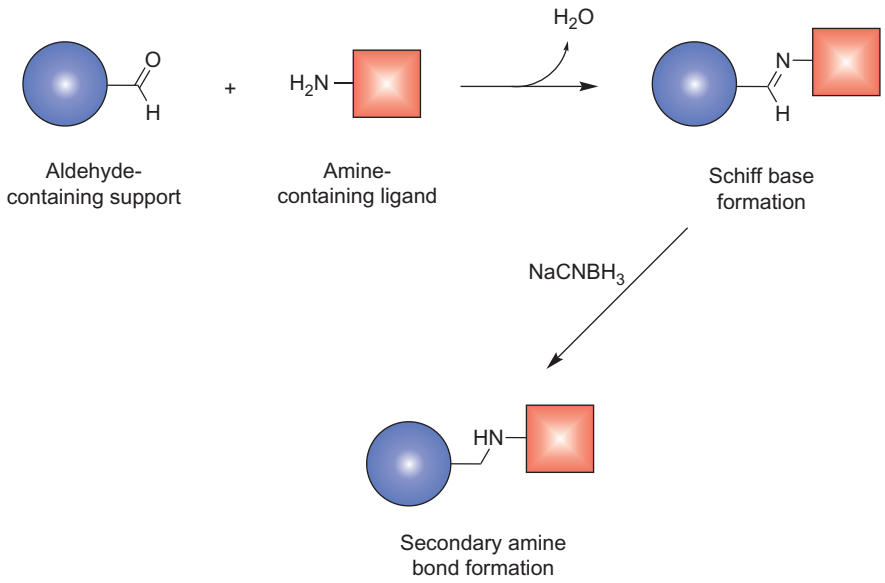

FIGURE 15.33 Aldehyde-containing supports can be reacted with amine-containing ligands in the presence of a reducing agent such as sodium cyanoborohydride to couple the ligand through a secondary amine bond.

2. Dissolve 4.28 g of sodium periodate ($NaIO_4$; MW = 213.89 g/mol) in 100 ml of water to prepare a 0.2-*M* solution. Mix the washed gel cake into the periodate solution to create a uniform suspension of the particles. Notes: At this level of periodate addition, the method will create a maximal level of aldehyde groups within the support as the internal diols are oxidized. If lower levels of aldehyde production are desired, then the amount of periodate addition can be controlled to provide this result. For instance, Guisán *et al.* (1997) determined that to create a support containing about 5 µmoles aldehydes/ml gel from a glycidol modified crosslinked agarose support (see the protocols which follow for glycidol modification), one could add a more dilute concentration of periodate to the modified support. To achieve similar moderated activation levels in this protocol, instead of using the recommended levels of periodate in step 2, dilute 5 ml of 0.1-*M* sodium periodate solution with 995 ml of water and then add this solution to the 100 ml of wet gel cake prepared in step 1. Conversely, to form about 75 µmoles aldehydes/ml gel on a glycidol modified agarose support, add 175 ml of 0.1-*M* sodium periodate to 825 ml of water and then add this solution to the wet gel cake. Stir these solutions for 60 min (for low-level activation) or 90 min (for higher activation) at room temperature to oxidize the supports to the desired level of activation, and then wash as in step 4. Another strategy that may control the level of aldehydes formed on a support is to regulate the initial glycidol modification reaction to control the amount of diols formed (Guisán, 1988).
3. Continue the reaction for 90 min at room temperature with constant mixing using an overhead paddle stirrer or a rotating mixer. Do not use a magnetic stir bar, as this will damage beaded supports. If oxidizing a membrane, the support material should be gently agitated throughout the reaction in a bath of the periodate solution. Periodate oxidation takes place rapidly to form aldehydes within the matrix, and such reactions on a small scale may be complete in as little as 10 to 15 min. For larger quantities of gel, longer reaction times may be appropriate to ensure complete mixing of the oxidant throughout the support. For some resins, such as non-crosslinked agarose or cellulose, extended oxidation may cause damage to the structure of the particles or may actually dissolve them. For such supports, a very brief 5- to 10-min exposure to periodate may aid in maintaining the matrix structure while still forming sufficient aldehyde groups for immobilization of ligands. For extremely sensitive supports, scale back both the concentration of periodate and the time of reaction.
4. Wash the oxidized support with at least 10 bed volumes of deionized water to stop the reaction and remove excess periodate and any formaldehyde that may have been formed during the reaction. The aldehyde groups created on the support by this process are stable in aqueous solution indefinitely if a preservative is added to the slurry to prevent microbial growth. Store the activated gel until use at 4°C as a 50% (v/v) slurry containing a preservative.

Use of Glycidol to Form Periodate-Oxidizable Diols

The following protocols can be used to modify primary or secondary hydroxyl groups on support materials to create diols susceptible to periodate oxidation. They can be used to modify supports that do not natively contain periodate-oxidizable diols, which are necessary to form aldehydes using oxidation. Polymeric support materials that can be used with success in this process include Trisacryl resins (containing primary hydroxyls from Tris-containing monomers) and Toyopearl resins (containing hydroxyls from pentaerythritol-containing monomers). In addition, other primary or secondary hydroxyl-containing supports such as those made from HEMA, PVA, and ethylene glycol methacrylate (EGMA) are candidates for modification with glycidol to create periodate oxidizable diols. Glycidol may also be used to modify amine-containing supports in a similar manner. The benefits of using hydrophilic modifications with glycidol to form polyglycerin spacers within a matrix for the coupling of affinity ligands have been documented (Rhemrev-Boom, 2009). Hyperbranched polyglycerols made from controlled polymerization of glycidol can form dendritic molecules as well as nanoparticles or microparticles containing pendent diols, which can be activated by periodate to form aldehydes for coupling ligands (Sunder *et al.*, 1999, 2000).

Glycidol has also been used to modify crosslinked agarose despite the fact that agarose already has periodate-oxidizable diols within its matrix structure. In this case, glycidol forms branched polyglycerin tethers that project off the agarose resin and are highly mobile within the porous structure of each particle. Periodate oxidation of the terminal diols on these polyglycerin groups forms aldehydes that can be used to couple enzymes at multiple lysine amino sites on their surface. Such multipoint attachment aids in enzyme stabilization to create immobilized reactors of high thermal stability and reusability for industrial processes (Ichikawa *et al.*, 2002; Ming *et al.*, 2006; Kuroiwa *et al.*, 2008). Site-directed mutagenesis of penicillin G acylase followed by immobilization on glycidyl-agarose resulted in increased stability and activity of the enzyme (Abian *et al.*, 2004). This technique also can be used on hydroxyl-containing monolithic supports, membranes, and on the surfaces of hydroxylic microfluidic channels to form reactive tethers for enzyme or affinity ligand immobilization (Albrecht *et al.*, 2010).

The following methods should be carried out in a fume hood using the appropriate personal protective equipment to avoid exposure to the epoxide-containing reactant, glycidol. The first two procedures describe aqueous reactions of glycidol with hydroxylic supports in the presence of base, while the second one involves a non-aqueous reaction using BF_3 etherate as catalyst for the epoxide reaction in dioxane.

(A) AQUEOUS GLYCIDOL REACTION FOR HIGH DENSITY MODIFICATIONS

The following protocol is designed to create a high concentration of glycidol polymer modifications throughout the hydroxylic support material. This will form numerous terminal diols for subsequent periodate oxidation, but the protocol also will create considerable polymer occlusion within the pore structure of some supports. This procedure has been determined to work well for certain polymeric supports, but the optimal level of glycidol modification for a specific application should be determined experimentally. See method (B) for a reaction that will yield a lower degree of glycidol modification.

1. Wash 100 ml of a support material, for instance Trisacryl GF-2000 or Toyopearl HW-65F, with 500 to 1000 ml of deionized water using a sintered glass filter funnel to remove the preservatives or storage solutions that are present in the commercial products. Finally, wash the gel with 100 ml of 1-*N* NaOH (caution: caustic solution) and drain to a wet cake, but do not allow it to dry.
2. Carefully add the washed gel to 100 ml of 1-*N* NaOH and resuspend it with stirring.
3. Add 100 ml of glycidol solution to the stirring gel suspension along with 1 g of sodium borohydride ($NaBH_4$). Note: With some matrices optimization of the amount of glycidol to add should be done to prevent unacceptable decreases in porosity due to internal glycidol polymer formation within the particles.
4. Continue the reaction overnight with constant stirring using an overhead paddle stirrer.
5. When the reaction is complete, carefully transfer the gel slurry to a sintered glass filter funnel, and wash extensively with water (1–2 l), 1-*M* NaCl (1 l), and again with water. The glycidol-modified gel can be stored until use at 4°C as a 50% aqueous slurry containing a preservative or oxidized immediately with periodate to form aldehyde groups according to the previous protocol.

(B) AQUEOUS GLYCIDOL REACTION FOR MEDIUM-DENSITY MODIFICATIONS

The following protocol will result in glycidol modifications within a hydroxylic support material at a much lower level than method (A) above. This process has been found to work well for the modification of agarose gels to create numerous periodate-oxidizable sites within the matrix and to form a more hydrophilic interior within the support (Guisan, 1988).

1. Wash 100 ml of a support material containing hydroxyl groups—for instance, agarose, Trisacryl

GF-2000, or Toyopearl HW-65F—with 500 to 1000 ml of deionized water using a sintered glass filter funnel to remove the preservatives or storage solutions, which usually are present in the commercial products. Finally, wash the gel with 100 ml of 0.375-*N* NaOH and drain to a wet cake, but do not allow it to dry.
2. Carefully add the washed gel to 100 ml of 0.375-*N* NaOH and resuspend it with stirring.
3. Very slowly add 34 ml of glycidol solution to the stirring gel suspension along with 1 g of sodium borohydride ($NaBH_4$). The glycidol should be added dropwise to prevent the solution from heating beyond about 25°C.
4. Continue the reaction overnight with constant stirring using an overhead paddle stirrer.
5. When the reaction is complete, carefully transfer the gel slurry to a sintered glass filter funnel, and wash extensively with water (1–2 l), 1-*M* NaCl (1 l), and again with water. The glycidol-modified gel can be stored until use at 4°C as a 50% aqueous slurry containing a preservative or oxidized immediately with periodate to form aldehyde groups according to the previous protocol.

(C) GLYCIDOL REACTION IN DIOXANE

An alternative glycidol modification method was described by Eriksson (1987), in which a high-percentage agarose gel that had been crosslinked with divinyl sulfone was further modified with glycidol in dioxane. This process results in a more hydrophilic agarose matrix when supports containing a high percentage of agarose are used (up to 20% agarose).

1. Wash 10 ml of a support material with 100 ml of deionized water to remove preservatives and other storage solution components. Next, sequentially wash the support into dioxane by using slowly increasing concentrations of the solvent in water until the agarose is in 100% solvent. This can be done by washing first with 50 ml of dioxane:water at a ratio of 1:3 (v/v), then washing with 50 ml of dioxane:water at 1:1, then washing with dioxane : water at 3:1, and finally washing with 100 ml of 100% dioxane to fully remove the last traces of water.
2. Suspend the agarose support in an equal volume of dioxane and stir in a fume hood using a paddle stirrer or a rotating mixer. Add 3 ml of glycidol with mixing followed by 0.25 ml BF_3 etherate.
3. React for 1 h at room temperature with continuous mixing.
4. When the reaction is complete, carefully transfer the gel slurry to a sintered glass filter funnel and wash with 100 ml dioxane followed by a sequential transfer back into aqueous solution by reversing the dioxane:water ratios used in step 1. Finally, wash with 100 ml of water and store the gel at 4°C in an equal volume of water containing a preservative. The glycidol modified support may be periodate-oxidized to contain aldehyde groups according to the protocol described previously.

Immobilization of Ligands Using Reductive Amination

The following protocols are generalized procedures for the immobilization of amine-containing small ligands, spacer molecules, or proteins onto periodate-oxidized support materials, which contain aldehyde residues available for coupling by reductive amination. The reactions should be performed in a fume hood to avoid exposure to hazardous or toxic compounds, especially the cyanoborohydride used in the reduction step. Two methods are described for reductive amination: the first one using a reaction buffer at physiological pH and the second protocol using an initial incubation at pH 10 to form the Schiff bases followed by reduction at pH 7.2. The first method works well for the majority of ligands and should be used for proteins that are sensitive to the more alkaline pH reaction. However, if ligand coupling densities or coupling yields are lower than desired, especially using proteins, the pH 10 protocol typically provides increased coupling efficiency, which can exceed 95% yield.

The sodium cyanoborohydride used for the following reactions may be obtained as the pure solid or as a 5-*M* $NaCNBH_3$ solution in 1-*N* NaOH (Aldrich). The solution is more convenient to use, because the solid may be susceptible to static charge during weighing, which causes fine particles to fly away and increases the hazards of handling the compound. The only caveat in using the alkaline cyanoborohydride solution is that after addition the final pH of the reaction should be checked and adjusted back to pH 7.2 if necessary.

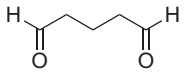
(A) COUPLING AT pH 7.2

1. Wash 100 ml of the periodate-oxidized support material containing aldehyde groups into coupling buffer (0.1-*M* sodium phosphate, pH 7.2) and drain to a wet cake. Other buffer components may be added to the coupling buffer, such as the addition of 0.15-*M* NaCl or alternative buffer salts; however, avoid amine-containing compounds like Tris, glycine, or imidazole, which will compete in the reaction. In general, avoid buffer compounds containing primary or secondary amines as well as any other nucleophile that could react with an aldehyde. In addition, certain detergents and other amphiphilic components

have been shown to decrease the stability of the intermediate Schiff base and these additives should be used only after validating that they have no affect on the immobilization reaction (Viguera *et al.*, 1990). Reductive amination coupling in aqueous solution has been shown to effectively occur between pH 4 and 10, with an optimal range for cyanoborohydride reduction of pH 6 to 8.

2. Suspend the washed support material containing aldehyde residues in an equal volume of 0.1-*M* sodium phosphate, pH 7.2, into which an amine-containing ligand has been dissolved. Notes: For protein ligands, a typical concentration range may be 3 to 5 mg/ml gel, but much higher concentrations may be used if a high density of coupled protein on the gel is desirable. In some cases, reactions containing protein at up to 20 mg/ml gel can be performed while still maintaining excellent coupling yields (>85%). For instance, high-capacity protein A supports often are reacted at levels exceeding 10 mg protein A per ml gel to obtain maximal binding capacity for immunoglobulins. However, optimization of ligand density on the affinity support should always be done to avoid having too much or too little ligand present, which could cause significant nonspecific binding at the high end or unacceptably low capacity at the low end. High densities of immobilized protein could also result in an affinity support in which it is difficult to effect elution of the target molecule after binding. For small amine-containing affinity ligands, a concentration of 2 to 3 mg ligand/ml gel for the immobilization reaction may be sufficient to obtain good binding capacity on the resultant affinity gel. Alternatively, a concentration representing 5 to 10 times the concentration of reactive aldehydes on the matrix may be used to ensure a high density of the final coupled ligand. The ultimate concentration of ligand used in the reaction should be optimized by performing a series of coupling reactions at different initial ligand concentrations and determining the performance of the affinity supports in capturing and eluting the desired target molecule. The coupling of diamine spacer molecules should be done at high concentration (i.e., 1-*M*) to avoid internal crosslinking or bead aggregation during the coupling reaction.
3. Stir the gel/ligand slurry in a fume hood using a paddle stirrer or using a rotator to maintain constant mixing.
4. Add to the gel slurry 0.63 g of solid sodium cyanoborohydride ($NaCNBH_3$; MW = 62.84) [toxic!] or 2 ml of 5-*M* $NaCNBH_3$ in 1-*N* NaOH with stirring. If the alkaline solution of cyanoborohydride is used, check the pH and readjust to 7.2, if required. Continue the reaction for 4 h to overnight at room temperature. The amount of cyanoborohydride added—whether as the pure solid compound or as the solution—results in a 50-m*M* solution in the final reaction slurry, which is in a total volume of 200 ml. A shorter coupling time may be sufficient for many ligands, but the optimal conditions to give acceptable yields for a particular ligand should be determined by doing a series of coupling reactions at different time points. Reactions at 4°C may also be done for thermally sensitive proteins or ligands, but reaction times likely will have to be extended to get the same level of coupling as a room temperature reaction.
5. Transfer the gel slurry to a sintered glass filter funnel (in the fume hood) and wash with several bed volumes of water to remove most of the unreacted ligand and reaction byproducts.
6. Unreacted aldehyde residues remaining on the support should be blocked by the addition of a small amine-containing compound, such as ethanolamine or Tris. Ethanolamine typically works best, and the compound is small enough to react with all remaining aldehydes to form hydrophilic terminal hydroxyl groups on the matrix upon coupling. Wash the support once with an equal volume of 1-*M* ethanolamine, pH 7.2, and then transfer the wet gel cake to a clean flask or vessel used for mixing the reaction. Add with stirring 100 ml of 1-*M* ethanolamine, pH 7.2, along with 0.63 g (or 2 ml of the 5-*M* $NaCNBH_3$ solution) of sodium cyanoborohydride. Readjust the pH if necessary and continue the blocking reaction for 30 min at room temperature.
7. Wash the support extensively with water, 1-*M* NaCl, and again with water to remove all unreacted components from the gel. Additional wash solutions may be utilized to completely remove ligands that may have some nonspecific binding potential and remain noncovalently bound to the immobilized ligand, such as the use of acidic and alkaline washes as well as washes containing denaturants (such as guanidine). After washing, the affinity gel may be stored as a 50% aqueous slurry containing a preservative at 4°C.

(B) COUPLING AT pH 10



This protocol may be used to increase the amount of ligand coupled to the support using reductive amination if the pH 7.2 protocol does not give sufficient coupling yields or does not result in high enough ligand density on the support. In this method, the formation of Schiff bases is first done at pH 10, where they occur more efficiently, and then the pH is adjusted to 7.2 for the reductive amination step. This two-step protocol typically results in much greater coupling yields than

the previous procedure, especially when immobilizing proteins.

1. Wash 100 ml of a periodate-oxidized support into coupling buffer (0.1-*M* sodium carbonate, pH 10) and drain to a wet cake. Other buffer components may be added to the coupling buffer, such as the addition of 0.15-*M* NaCl or alternative buffer salts; however, avoid amine-containing compounds like Tris, glycine, or imidazole, which will compete in the reaction.
2. Suspend the washed support material containing aldehyde residues in an equal volume of 0.1-*M* sodium carbonate, pH 10, into which an amine-containing protein or ligand has been dissolved. See the notes in step 2 of the previous pH 7.2 coupling protocol that contains suggestions as to the amount of ligand to add to the coupling reaction.
3. Stir the gel/ligand slurry for 4 h to overnight at room temperature using a paddle stirrer or using a rotator to maintain constant mixing. For sensitive proteins, the reaction may be carried out at 4°C, but may require additional time to form the Schiff bases.
4. Transfer the reaction slurry to a sintered glass filter funnel, drain the gel of excess solution, and wash with 2 × 100 ml of 0.1-*M* sodium phosphate, pH 7.2, to reduce the pH for the reduction reaction. Drain to a wet cake.
5. Transfer the gel cake back to a clean vessel and suspend it in 100 ml of 0.1-*M* sodium phosphate, pH 7.2, and stir using a paddle stirrer. Add to the gel slurry 0.63 g of solid sodium cyanoborohydride ($NaCNBH_3$; MW = 62.84) [toxic!] or 2 ml of 5-*M* $NaCNBH_3$ in 1-*N* NaOH. If the alkaline solution of cyanoborohydride is used, subsequently check the pH of the solution and readjust to 7.2, if required.
6. React with mixing at room temperature for 4 h or at 4°C overnight.
7. Transfer the gel slurry to a sintered glass filter funnel (in the fume hood) and wash with several bed volumes of water to remove most of the unreacted ligand and reaction byproducts.
8. Aldehyde residues remaining on the support should be blocked by the addition of a small amine-containing compound, such as ethanolamine or Tris. Ethanolamine typically works best, and the compound is small enough to react with all remaining aldehydes to form hydrophilic terminal hydroxyl groups on the matrix upon coupling. Wash the support once with an equal volume of 1-*M* ethanolamine, pH 7.2, and then transfer the wet gel cake to a clean flask or vessel used for mixing the reaction. Add with stirring, 100 ml of 1-*M* ethanolamine, pH 7.2, along with 0.63 g (or 2 ml of the 5-*M* $NaCNBH_3$ solution) of sodium cyanoborohydride. Readjust the pH if necessary and continue the blocking reaction for 30 min at room temperature.
9. Wash the support extensively with water, 1-*M* NaCl, and again with water to remove all unreacted components from the gel. Additional wash solutions may be utilized to completely remove ligands that may have some nonspecific binding potential and remain noncovalently bound to the immobilized ligand, such as the use of acidic and alkaline washes as well as washes containing denaturants (such as guanidine). After washing, the affinity gel may be stored as a 50% aqueous slurry containing a preservative at 4°C.

Glutaraldehyde Activation

Glutaraldehyde is a 5-carbon, *bis*-aldehyde compound that can be used to activate amine- or hydrazide-containing supports to form reactive groups for the subsequent immobilization of amine-containing ligands. Given its structure, it may appear that the aldehydes in this crosslinker might undergo reactions with two amines much the same as that seen using similar aldehyde-containing supports for immobilization using reductive amination (described previously). It also might be expected that a bifunctional glutaraldehyde molecule would form two Schiff bases with two amine-containing molecules, which could then be reduced with cyanoborohydride to form secondary amine linkages. However, the nature of glutaraldehyde coupling is far more complex than a straightforward reductive amination process using its terminal aldehydes. Glutaraldehyde undergoes significant transformation reactions in aqueous solution (and even in some solvents), resulting in a range of potential derivative forms (Figure 15.34), which can create a variety of intermediary reactive species. These transitional forms can then have a number of potential reaction routes with amines beyond simple Schiff base formation. In this regard, glutaraldehyde activation of amine-containing chromatography supports and subsequent coupling to amine-containing ligands can potentially entail Schiff base formation with aldehydes, the Michael-type addition of amines to α,β-unsaturated sites within glutaraldehyde polymers, covalent reactions with a dimeric cyclic glutaraldehyde species, or ring formation through an aldol condensation product which subsequently can react with amines to form cyclic quaternary pyridinium complexes (see Chapter 2, Section 4.4, and Chapter 5, Section 6.2) (Monsan, 1978; Migneault *et al.*, 2004).

Glutaraldehyde

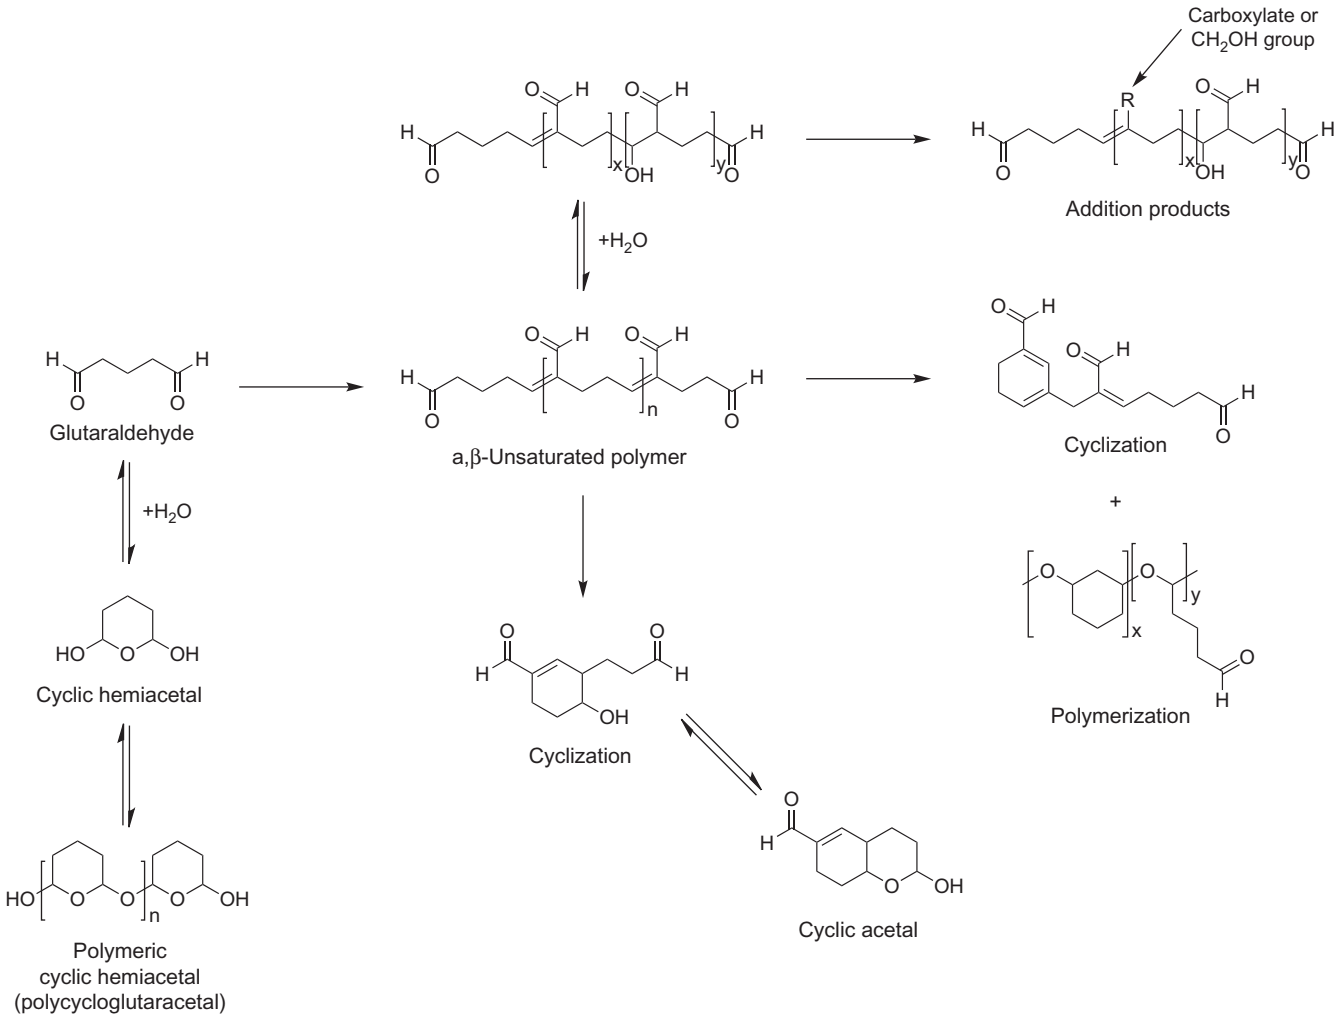


FIGURE 15.34 The potential transformations of glutaraldehyde in aqueous solution are complex and create many different reactive species. Once water reacts with one of the aldehydes of glutaraldehyde, the molecule can cyclize to form a hemiacetal derivative, which can also polymerize in solution to create polycycloglutaracetal. The acetal derivatives are reactive with amine-containing molecules through addition to the anomeric carbon atoms on each outer ring. Glutaraldehyde may also form a variety of unsaturated polymers at alkaline pH, which can undergo numerous transformations, including the creation of high-molecular-weight polymers that can precipitate out of solution. The cyclic acetal derivative can react with an amine-containing molecule by addition to the double bond on its left ring and through addition to the anomeric carbon atom on the right hemiacetal ring. Reactions with the unsaturated polymer form of glutaraldehyde typically occur through Michael-type addition to the double bonds along the polymer backbone.

The formation of aldol condensation unsaturated constructs and the potential for creating cyclic hemiacetal entities due to the intra- and intermolecular reactions of glutaraldehyde in aqueous alkaline solution both may result in nondescript oligomerization and layering of the active intermediates within and on a support material during activation. Formation of these polymeric glutaraldehyde species, once started, is not easy to control and could cause clogging of pore structures within chromatography supports as well as difficulty in reproducing the activation and immobilization reactions. In most cases, however, through careful adjustment of the initial glutaraldehyde activation conditions, side reactions such as polymerization can be limited and result in more defined reaction products that work well for immobilization of amine-containing affinity ligands.

In acidic or neutral pH conditions, glutaraldehyde can undergo an intramolecular cyclization reaction to form a hemiacetal ring (tetrahydro-2H-pyran-2,6-diol) that subsequently can polymerize through 6,6′-oxo linkages to form what some people call it by the nonstandard name “polycycloglutaracetal”. The monomeric hemiacetal or the polymeric polycycloglutaracetal can react with amines by nucleophilic attack at the anomeric carbons bearing the hydroxyl groups (on both sides of a

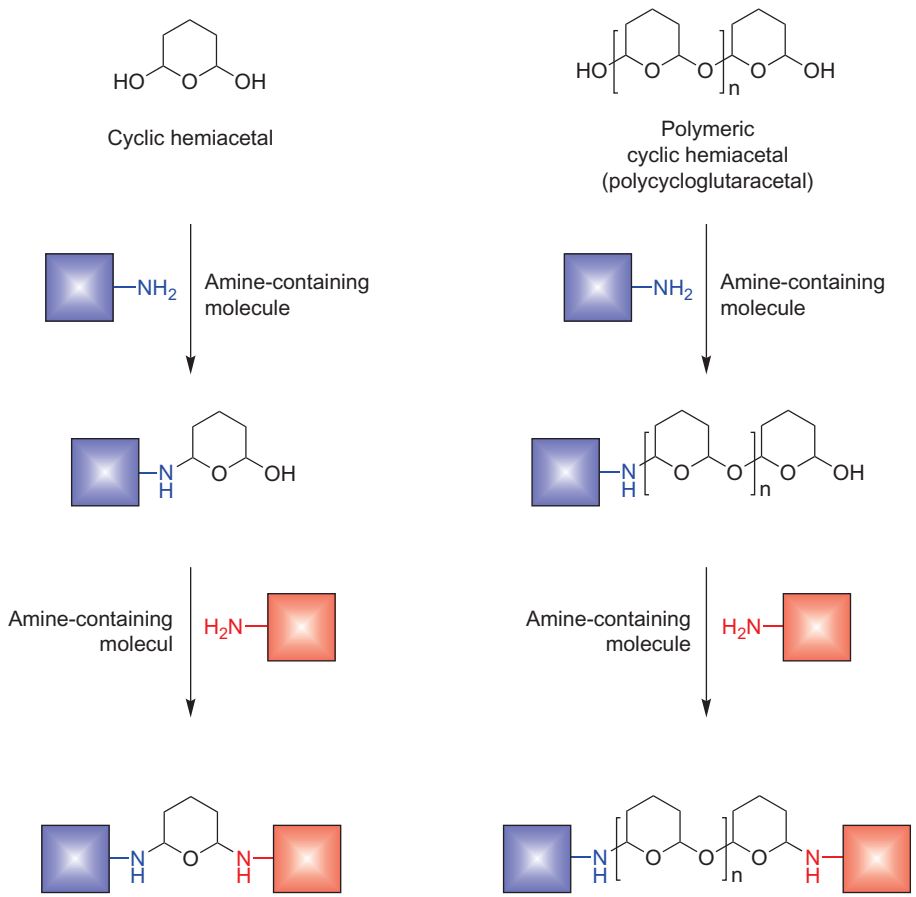

FIGURE 15.35 The glutaraldehyde cyclic hemiacetal can react with two amine-containing molecules to result in addition to the anomeric carbon atoms on both sides of its ring structure.

single cyclic acetal ring or at both ends of the polymer). Subsequent bond formation results in a substitution reaction that creates a secondary amine linkage along with the loss of one molecule of water (Figure 15.35). The reactions of monomeric glutaraldehyde hemiacetal may be one of the principal species responsible for stable ligand coupling without the need for reduction of Schiff bases, which normally would be necessary to stabilize aldehyde–amine complexes. This monomeric form may also be the primary type observed in immobilization reactions using an activation reaction with dilute glutaraldehyde done for a brief period of time (Betancor *et al.*, 2006) (Figure 15.36). In this case, the initial activation step of an amine-containing chromatography support, such as monoaminoethyl-*N*-aminoethyl (MANAE)–agarose, involves the reaction of one anomeric carbon of the cyclic acetal with the amine on the matrix to form a secondary amine bond. The other anomeric carbon atom of the acetal then can be used to couple amine-containing ligands after removal of excess glutaraldehyde species.

Under slightly more alkaline pH conditions (~pH 8.5), hemiacetal formation of glutaraldehyde can be accompanied by aldol dimerization to result in a bicyclic derivative, which can undergo reactions at two sites within the molecule (Tashima *et al.*, 1991) (Figure 15.37). Coupling of amine-containing molecules to this dimeric compound occurs by nucleophilic substitution at the anomeric hemiacetal carbon atom as well as through Michael-type addition to the double bond on the aldol addition ring product (Figure 15.38). This dimeric form of glutaraldehyde may be the predominant species observed in some activation and immobilization reaction protocols, wherein the activation step is done by the addition of a relatively high concentration of glutaraldehyde that is reacted for an extended period of time (Betancor *et al.*, 2006). This glutaraldehyde dimer is an extremely potent reactant with amines and it has been implicated as the form responsible for the best crosslinking performance in tissue fixation, protein conjugation, and in the immobilization of enzymes (Robertson and Schultz, 1970; Makino *et al.*, 1988).

Dimeric cyclic glutaraldehyde can be used to activate amine-containing chromatography supports, such as a MANAE–agarose matrix, to link initially to

the α,β–unsaturated double bond to create an intermediate reactive derivative. The initial activation reaction is done at relatively high concentrations of glutaraldehyde at neutral pH and for an extended period to ensure that the reaction occurs with a glutaraldehyde dimer instead of a hemiacetal monomer (Betancor *et al.*, 2006). The activated support then can be coupled with amine-containing ligands through covalent attachment to the anomeric carbon of the hemiacetal ring with loss of one molecule of water to form a secondary amine linkage (Figure 15.39). Both of these reactions require no reducing step as is common with coupling aldehydes to amine-containing molecules, and the coupling occurs rapidly and in high yield.

In even more alkaline pH conditions, glutaraldehyde can undergo transformation by a series of aldol condensation reactions that creates, after dehydration and loss of the hydroxyl groups along with the adjacent hydrogens, numerous α,β-unsaturated sites within glutaraldehyde polymers of indeterminate length (Rembaum *et al.*, 1978). The resultant polymers reportedly also can contain a number of carboxylic, hydroxylic, and aldehyde groups along its length, although the exact composition is not well characterized (Margel and Rembaum, 1980). The presence of carboxylate functionalities presumably is due to further redox reactions that occur with the initial polymer in the presence of oxygen. Aldol polymerization of glutaraldehyde at pH 11 or above reportedly can be so severe that precipitation occurs in aqueous solution (Monsan *et al.*, 1975). Kawahara *et al.* (1992) indicated that extensive polymerization also can occur if the glutaraldehyde is dissolved in anhydrous solvent as well as high pH aqueous solutions. This form of polyglutaraldehyde long has been used to activate amine-containing microparticles for the subsequent coupling of amine-containing ligands (Rembaum *et al.*, 1978; Margel and Rembaum, 1980) (see also Chapter 14). However, it is likely that the other

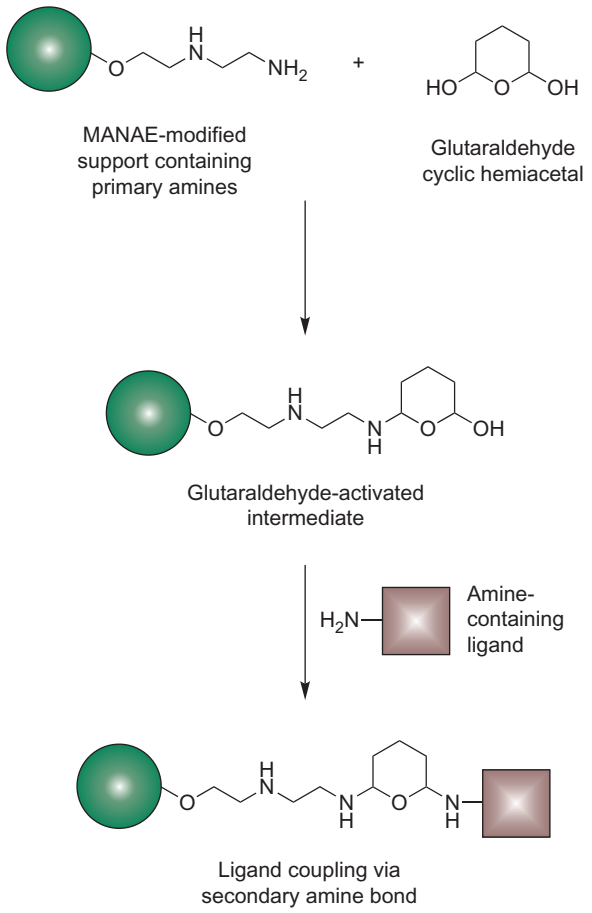

FIGURE 15.36 The activation of MANAE–agarose with glutaraldehyde monomer (under dilute glutaraldehyde conditions) and coupling of an amine-containing ligand.

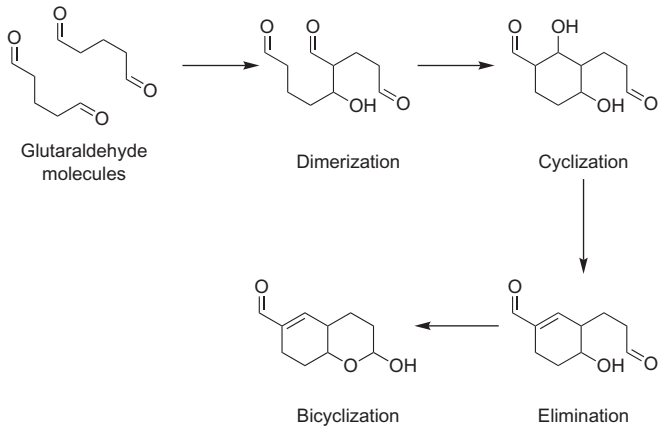

FIGURE 15.37 Formation of a dimeric, bicyclic glutaraldehyde.

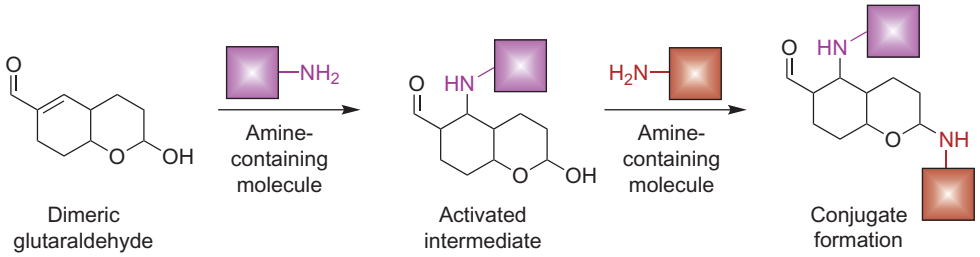

FIGURE 15.38 Reaction of glutaraldehyde dimer with two amine-containing compounds.

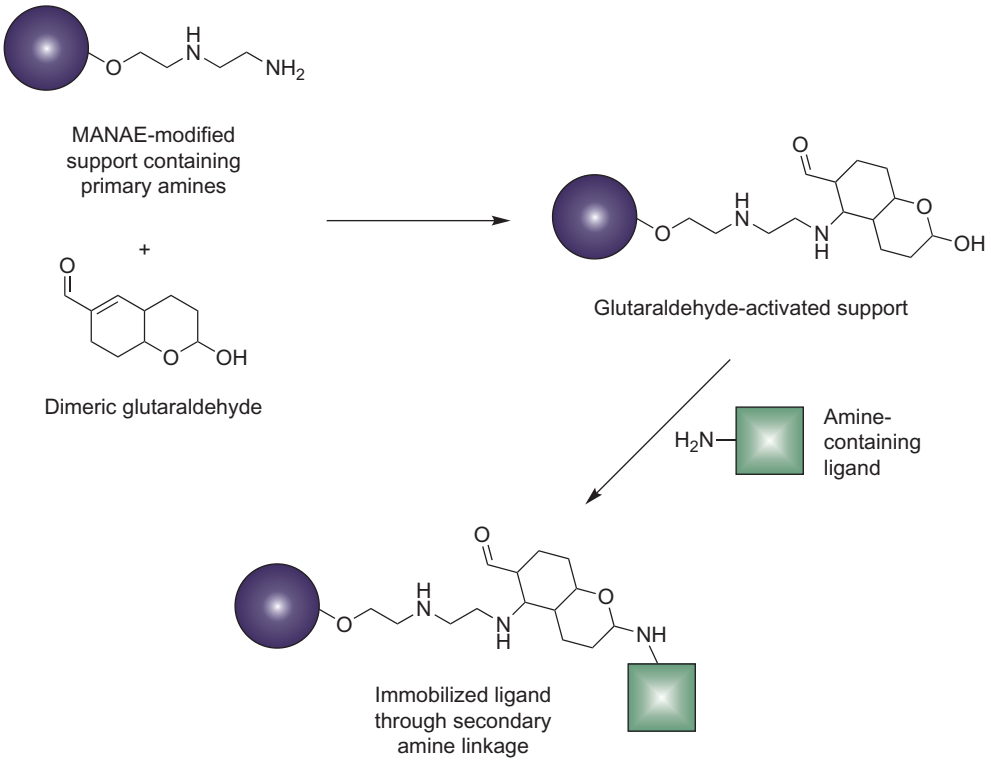

FIGURE 15.39 Activation of MANAE–agarose with dimeric glutaraldehyde and coupling of an amine-containing ligand.

monomer and dimer species described above may also contribute to the overall coupling reactions occurring with glutaraldehyde, depending on the exact activation procedure being used.

Aldol-mediated polyglutaraldehyde formation can be used to activate amine-containing supports by initially coupling through Michael-type addition reactions to various double bonds within the polymer strands. After activation with an excess of this polymeric form, the remaining uncoupled polyglutaraldehyde can be washed off the matrix and the activated intermediate used to immobilize an amine-containing ligand (Figure 15.40). Since polyglutaraldehyde contains both aldehydes and double bonds, activation of supports with this species likely involves two routes of amine reactivity. The Michael-type addition of amines to the double bond sites will result in secondary amine linkages, which have no requirement for further stabilization by reduction. However, amines may also link to the polymer through Schiff base formation with the aldehydes still present in each polymer strand. These Schiff bases may need a reductive amination reaction using sodium cyanoborohydride to stabilize them against hydrolysis and form secondary amine bonds. Particularly, if ligands are being immobilized that contain only a single amine group, then it is recommended that reduction be carried out to prevent ligand leakage through hydrolysis.

Glutaraldehyde and its derivatives that form in aqueous solution potentially can react with a number of nucleophilic groups on proteins or other ligands, such as amines, thiols, and imidazole nitrogens, as well as phenolic –OH groups (Habeeb and Hiramoto, 1968). The relative reactivity of glutaraldehyde toward some of the most predominant functional groups in proteins has been estimated to be ε-amine > α-amine > guanidinyl > secondary amine > hydroxyl groups (Migneault *et al.*, 2004). Thiol reactivity with glutaraldehyde-reactive species is also possible, but it has been reported to occur only in the presence of amine functionalities (Okuda *et al.*, 1991). The bifunctional nature of the glutaraldehyde monomeric or dimeric forms makes it suitable for activation of chromatography supports followed by immobilization of affinity ligands containing nucleophiles, such as amines. Due to the diverse reactions of glutaraldehyde in aqueous solution, the stability of coupling to amine-containing ligands typically is far greater than the stability of the initial Schiff bases created from aldehyde-containing supports as they react with amine-containing ligands (see previous section). Normally without reductive amination coupling of amino ligands to aldehyde-containing supports, the immobilized ligand will leach off the matrix as the Schiff bases slowly hydrolyze in aqueous solution. By contrast, glutaraldehyde immobilization is more resistant to ligand leakage even without a subsequent

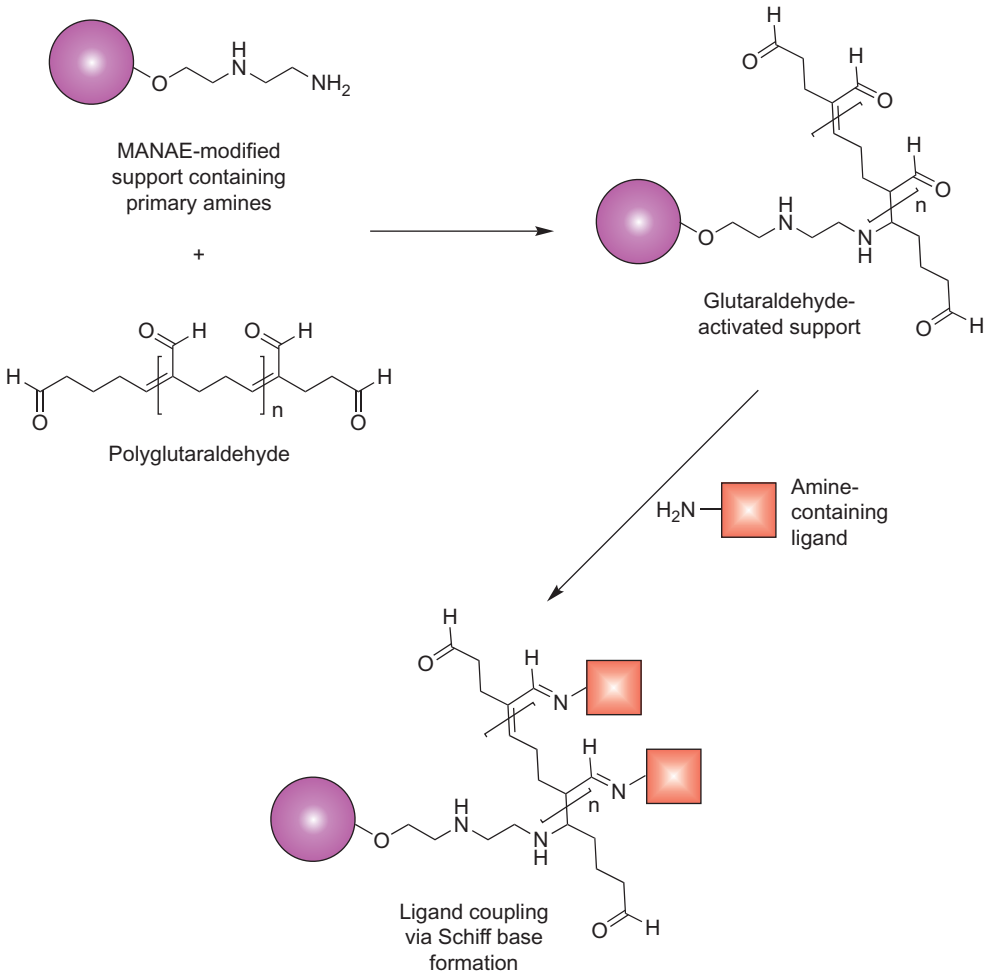

FIGURE 15.40 Activation of MANAE–agarose with polyglutaraldehyde (aldol-mediated) followed by coupling of an amine-containing ligand to form a secondary amine linkage.

reduction step, because most of the ligand coupling reactions involve addition reactions without the intermediate formation of a Schiff base.

Due to the diverse nature of glutaraldehyde reactions, the exact reactive species that is formed after activation may be less certain than when using other activation methods. Nevertheless, the immobilization reaction can be designed to take place with high efficiency and yield. In addition, recently it has been shown that by carefully controlling the level of glutaraldehyde activation of an amine-containing support at neutral pH, the result can be fairly well constrained to either a highly reactive dimeric species or a somewhat less reactive and predominantly monomeric glutaraldehyde derivative (Betancor *et al.*, 2006). The major reactive species created on an amine-containing support can be predetermined by the amount and concentration of glutaraldehyde addition as well as by the time of the reaction. By contrast, activation of an amine-containing support under highly alkaline conditions will result in a greatly polymerized glutaraldehyde intermediate that reacts with nucleophiles on ligands mainly through the addition to double bonds (although Schiff base formation may also occur).

The use of glutaraldehyde to activate and couple enzymes for the preparation of immobilized reactors remains one of the most popular methods for preparation of these catalytic supports (Burteau *et al.*, 1989; Van Aken *et al.*, 2000; Dos Reis-Costa *et al.*, 2003; Magnan *et al.*, 2004; Seyhan and Alptekin, 2004; Betancor *et al.*, 2006; Ma *et al.*, 2011; Matosevic *et al.*, 2011). Unlike reductive amination processes described in the previous section, immobilization using glutaraldehyde usually does not require the use of a reducing agent, such as the hazardous sodium cyanoborohydride. Especially when coupling multivalent protein molecules, immobilization onto a glutaraldehyde-activated support can create multiple attachment sites that firmly link the ligand with minimal potential for leakage. Thus, if care is taken to control the initial activation reaction,

the resultant preparation of an affinity support can be performed reproducibly and give high activity in its intended application.

The following protocols can be used to activate amine-, amide-, or hydrazide-containing supports with glutaraldehyde for subsequent coupling of amine-containing ligands. The first two procedures are based on the method of Betancor *et al.* (2006). These activations can be performed using any chromatographic support material containing available primary amines, such as the use of an agarose support that has been modified with a diamine spacer to contain free terminal amino groups. One such support described in the literature is mono-aminoethyl-*N*-aminoethyl (MANAE)–agarose, which contains low-pKa amino groups that are highly reactive using neutral pH buffers (Fernandez-Lafuente *et al.*, 1993). In one regard, the final level of glutaraldehyde activation can be controlled by regulating the amount of these amines produced initially on the support material.

Glutaraldehyde should be handled with care in a fume hood while using the appropriate personal protective equipment to prevent contact or exposure to the solutions or vapors. All waste should be treated as aqueous hazardous waste and disposed of according to environmental regulations and local policy.

ACTIVATION PROTOCOLS

(A) Glutaraldehyde Activation to Form a Monomeric-Reactive Species

This protocol forms a reactive intermediate with moderate rates of reactivity for coupling amine-containing ligands.

1. Wash 100 ml of an amine-containing support material using gentle vacuum filtration in a sintered glass filter funnel (such as MANAE–agarose, which can be prepared by methods described in this chapter for coupling diamine spacers to chromatography supports) with several bed volumes of deionized water to remove any storage solution. Finally, wash the support with 200 ml of activation buffer (0.2-*M* sodium phosphate, pH 7.0). The support material and all wash solutions as well as the reaction should be maintained at 25°C. Note: Using a buffer pH of >8 will result in glutaraldehyde polymerization and an uncontrolled reaction.
2. In a fume hood, add the moist gel cake to a clean vessel that can be used to stir or rotate the gel during the activation and coupling reactions. Add 200 ml of 0.5% (v/v) glutaraldehyde dissolved in coupling buffer with mixing to resuspend the support in the solution.
3. React with mixing for 1 h.
4. Remove the gel slurry from the reaction vessel and drain the excess glutaraldehyde solution into a suction filter flask using vacuum filtration in a sintered glass filter funnel (in a fume hood). Wash the activated support extensively with 25-m*M* sodium phosphate, pH 7.0, buffer and then with deionized water. The activated support can be stored at 4°C until ready for ligand coupling.

(B) Glutaraldehyde Activation to Form a Dimeric-Reactive Species

This protocol forms a reactive intermediate with extremely high reactivity for coupling amine-containing ligands.

1. Wash 100 ml of an amine-containing support material using gentle vacuum filtration in a sintered glass filter funnel (such as MANAE–agarose) with several bed volumes of deionized water to remove any storage solution. Finally, wash the support with 200 ml of activation buffer (0.2-*M* sodium phosphate, pH 7.0). The support material and all wash solutions as well as the reaction should be maintained at 25°C.
2. In a fume hood, add the moist gel cake to a clean vessel that can be used to stir or rotate the gel during the activation and coupling reactions. Add 200 ml of 15% (v/v) glutaraldehyde dissolved in coupling buffer with mixing to resuspend the support in the solution.
3. React with mixing for 15 h at 25°C.
4. Remove the gel slurry from the reaction vessel and drain the excess glutaraldehyde solution into a suction filter flask using vacuum filtration in a sintered glass filter funnel (in a fume hood). Wash the activated support extensively with 25-m*M* sodium phosphate, pH 7.0, buffer and then with deionized water. The activated support can be stored at 4°C until ready for ligand coupling.

IMMOBILIZATION OF LIGANDS ON GLUTARALDEHYDE-ACTIVATED SUPPORTS

The coupling of amine-containing ligands such as proteins or enzyme reactors to glutaraldehyde supports prepared according to the previous activation protocols will proceed rapidly under low ionic strength conditions (i.e., using 25-m*M* potassium phosphate, pH 7, with no additional salt added). Under high ionic strength conditions (25-m*M* potassium phosphate, pH 7, containing 0.5-*M* NaCl) the dimeric glutaraldehyde activation process (protocol (B), above) will react and couple ligand almost as fast as when using low ionic strength buffers; however, when using the monomeric glutaraldehyde activation process (protocol (A), above) it results in slower coupling rates, which could take many hours or even overnight to go to completion (Betancor *et al.*, 2006). The reason coupling takes place faster under low salt conditions is thought to be due to the formation of an initial ionic interaction between the protein molecules to be

coupled and the underlying secondary amines to which the glutaraldehyde derivatives first are linked during activation. The initial ion-exchange character of the activated support facilitates recruitment of the protein to the immediate proximity of the reactive groups, thus accelerating immobilization. Adding high salt obviates these charge interactions and thus slows down the overall reaction process.

Protocol

1. Wash 100 ml of a glutaraldehyde-activated support containing dimeric glutaraldehyde (activation protocol (B), above) with 2 bed volumes of 25-m*M* potassium phosphate, pH 7.0 (coupling buffer), and drain to a wet cake. The addition of salt (NaCl) to the coupling buffer may be done for ligands that require it, but the use of additional ionic strength may also require increased reaction times to accommodate a somewhat slower reaction rate (see previous discussion). Transfer the support to a vessel that can be used to mix the gel suspension during the coupling reaction by end-over-end rotation or by using a paddle stirrer.
2. Dissolve an amine-containing ligand such as a protein, enzyme, or small ligand in 100 ml of coupling buffer. The ligand should be at a concentration of at least 2-fold greater than the quantity desired to be immobilized. For protein ligands, reacting at a concentration of 3 to 5 mg/ml resin is often sufficient. However, if a high density of immobilized protein or enzyme is desired, reactions can be done at concentrations of 10 to 20 mg/ml to obtain better coupling yields. For small ligands, the reaction should be done at a concentration that exceeds the level of glutaraldehyde activation or at least by using a 2-fold greater amount of ligand than the anticipated final immobilization level. To obtain an optimal affinity support for a given application, it may be necessary to perform a series of reactions using different ligand concentrations to determine the best coupling concentration to use.
3. Mix the ligand solution with the activated support and mix to resuspend the resin.
4. React with mixing for 2 h at room temperature or at 25°C. If a monomeric glutaraldehyde-activated support is used (activation protocol (A), above), then the reaction time should be extended by at least an hour. If high salt was added to the coupling buffer (e.g., 0.5-*M* NaCl) in step 1 and 2, then the reaction using dimeric glutaraldehyde activation should be extended to 3 h, and if monomeric glutaraldehyde activation was used with high salt, it should be extended to an overnight reaction.
5. Remove the reaction slurry and transfer to a filter flask. Drain the excess reaction solution and wash with water to remove the majority of uncoupled ligand. If the remaining active groups are not to be blocked, then the wash should be done extensively with water, 1-*M* NaCl, and again with water.
6. Reactive groups remaining on the support should be blocked by the addition of a small amine-containing compound, such as ethanolamine or Tris. Ethanolamine typically works best, and the compound is small enough to react with all remaining active sites to form hydrophilic terminal hydroxyl groups on the matrix upon coupling. In a fume hood, wash the support once with an equal volume of 1-*M* ethanolamine, pH 7.0, and then transfer the wet gel cake to a clean flask or vessel used for mixing the reaction. Add with stirring, 100 ml of 1-*M* ethanolamine, pH 7.0, along with 0.63 g of sodium cyanoborohydride (or 2 ml of a 5-*M* $NaCNBH_3$ solution in 1-*N* NaOH). Cyanoborohydride is extremely toxic and should be handled with care in a fume hood. The use of a reducing agent in the final blocking step is optional, but it is included here to ensure that if there are any aldehydes present in the activated support they too will be blocked by the ethanolamine addition (by reducing any Schiff bases formed by the reaction of the amine on ethanolamine with the aldehyde groups). Note that if the ligand is sensitive to the presence of cyanoborohydride, use the ethanolamine solution without adding the reducing agent. Readjust the pH if necessary and continue the blocking reaction for 30 min at room temperature.
7. Wash the support extensively with water, 1-*M* NaCl, and again with water to remove all unreacted components from the gel. Additional wash solutions may be utilized to completely remove ligands that may have some nonspecific binding potential and remain noncovalently bound to the immobilized ligand, such as the use of alternating acidic and alkaline washes as well as washes containing denaturants (such as guanidine). After washing, the affinity gel may be stored as a 50% aqueous slurry containing a preservative at 4°C.

NHS Ester and NHS Carbonate Activation

N-Hydroxysuccinimide (NHS) esters are activated carbonyl groups that may be formed from carboxylates through the use of a carbodiimide-mediated esterification reaction done under aqueous or nonaqueous conditions. They may also be formed through transesterification or transfer reactions using reagents such as Sakakibara's reagent, which is the NHS ester of trifluoroacetate, TSTU (*N*,*N*,*N*′,*N*′-tetramethyl(succinimido) uronium tetrafluoroborate), or disuccinimidyl carbonate

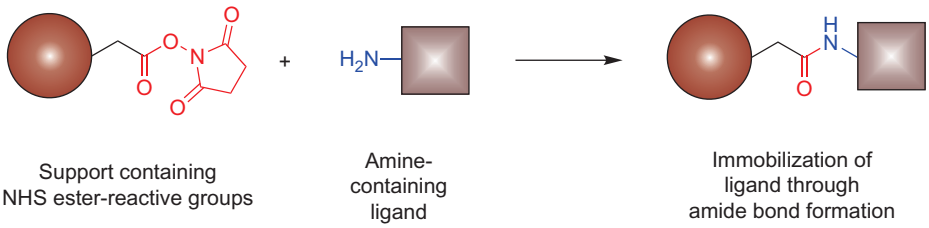

FIGURE 15.41 Reaction of an NHS ester-activated support with amine-containing ligands to form an amide bond.

(DSC) (Sakakibara and Inukai, 1965; Wilchek *et al.*, 1994). NHS esters are electrophilic reactive groups that can couple with nucleophiles such as amines to form stable amide bonds. They have been used extensively in the design of crosslinkers and modification reagents to form covalent conjugates with amine-containing proteins or other amine-containing molecules (Chapter 3, Section 1.4). NHS esters also can be used to immobilize amino-ligands onto chromatography supports in a rapid, single-step reaction that typically occurs in high yield (Prokudina *et al.*, 2011) (Figure 15.41).

Chromatography supports containing NHS esters are available commercially from several sources, and most contain a spacer arm that terminates in the activated carboxylate (e.g., Thermo Fisher, Bio-Rad, GE Healthcare). These supports thus are synthesized first by building a spacer arm off the chromatography support and then forming the NHS esters by activation of the carboxylates. A wide range of spacer molecules can be considered for this purpose, including hydrophobic aliphatic compounds such as 6-aminocaproic acid or hydrophilic spacers such as those containing PEG-based cross-bridges (i.e., amino–PEG_4–carboxylate; Thermo Fisher, Quanta BioDesign). Usually, the spacers are attached to the support through their amino end by coupling to an amine-reactive resin material, such as any of the amine-reactive immobilization chemistries described in this chapter. Once the carboxylate spacer derivative is formed on the support, it then can be activated to create the NHS ester groups using a number of different reaction routes.

When working with microparticles or nanoparticles, the formation of the NHS ester reactive group often is done in aqueous solution immediately prior to adding an amine-containing molecule to the particles for coupling (Chapter 14). This is accomplished by using a water soluble carbodiimide such as EDC (Chapter 4, Section 1) in the presence of NHS or sulfo-NHS (the sulfonated form promotes greater water solubility). The active NHS esters are formed despite the fact that the aqueous environment also causes continual hydrolysis of the esters back to unreactive carboxylates. This activation strategy works well with small nonporous particles if the ligand to be immobilized is added immediately after the activation step or even during the activation process. However, when working with chromatography supports that are made of larger porous particles, it is best to create the NHS ester groups in a nonaqueous environment so that competing hydrolysis is eliminated and maximal activation levels are obtained throughout the inner bead structures.

Although the use of a carbodiimide-mediated formation of NHS ester groups is common when working with carboxylate microparticles or nanoparticles, a major potential side reaction has been reported in the formation of NHS esters using carbodiimides on hydroxylic supports that have been modified to possess carboxylate spacers (Wilchek and Miron, 1987). If a reaction involving the carbodiimide DCC with added NHS is used to create the NHS ester groups on a carboxylate support under nonaqueous conditions, as is also typical for synthesizing most NHS ester-containing bioconjugation reagents, the formation of a *bis*-NHS derivative of β-alanine can be created at the same time that NHS esters are being formed with the carboxylate spacers on the matrix. This side reaction results from the initial interaction of DCC with the hydroxyl on NHS to form a carbodiimide-activated NHS group. This ability of carbodiimides to react with hydroxyl groups correlates to the reported activation of hydroxyls on chitosan using the carbodiimide EDC (Chiou and Wu, 2004). The DCC–NHS intermediate in this side reaction goes on to react with two additional equivalents of NHS, which then is followed by a Lossen rearrangement to create a reactive carbamate ester on the amino end of β-alanine and an NHS ester on the carboxylate end (Gross and Bilk, 1968) (Figure 15.42). This bifunctional compound then reacts with any remaining hydroxyl groups within the original matrix to create unstable ester linkages. The other end still can react with amine-containing ligands to form a covalent bond, but the immobilized product formed from this side reaction is unstable due to the potential for ester hydrolysis, and thus it can continually leach off the matrix in aqueous solution (Figure 15.43). This side reaction may be the main reason why many NHS ester-mediated immobilization reactions result in leaky supports.

To overcome these potential side reactions a two-step protocol might be used wherein the carboxylate

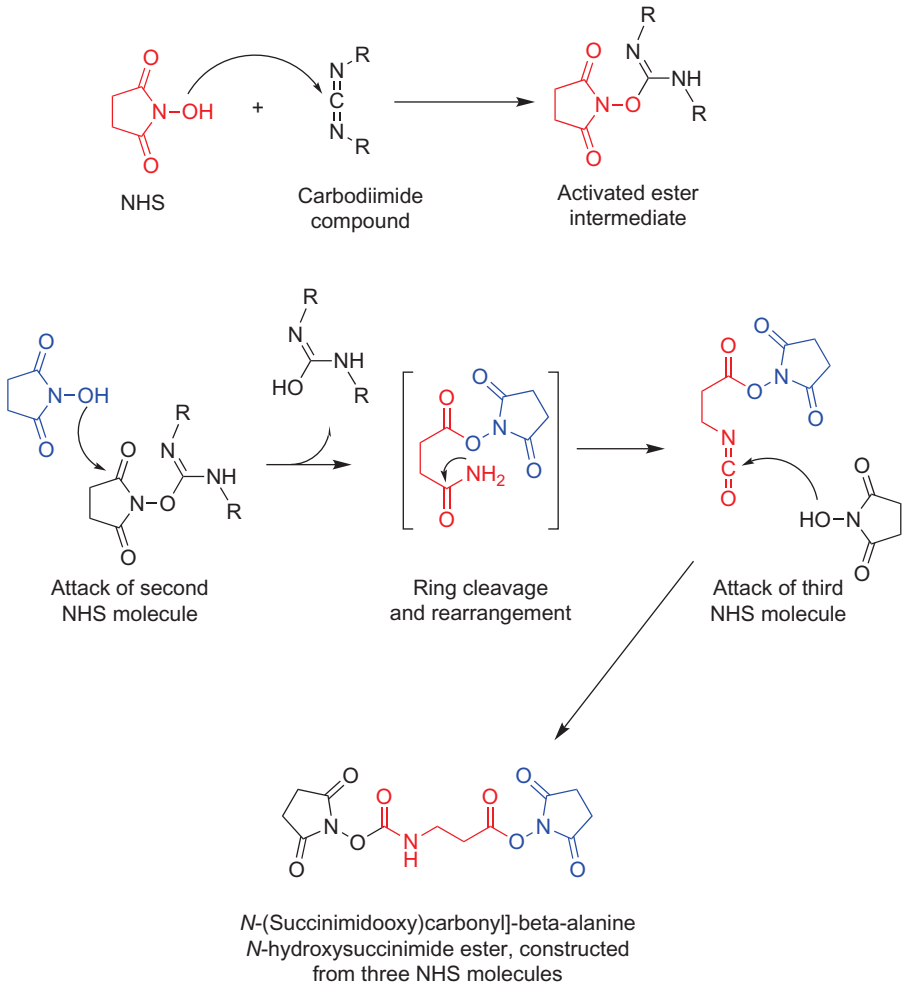

FIGURE 15.42 Reaction of NHS with DCC to form an activated β-alanine byproduct, which can form when using carbodiimides to create NHS esters in organic solvent.

support first is activated with a carbodiimide such as DCC in nonaqueous conditions, then the support is washed free of excess carbodiimide and reacted with NHS to form the final NHS esters. However, this procedure has been found to result in decreased activation yields and is cumbersome (Wilchek and Miron, 1987). Fortunately, there are now alternative strategies to creating NHS esters on hydroxylic support materials that have the ability to give highly stable reaction products without the potential side reactions that carbodiimides plus NHS are known to cause. One route was developed by Wilchek *et al.* (1994) specifically to avoid the problems of using carbodiimides with NHS and hydroxylic supports.

The coupling reagent TSTU originally was developed as an amide bond-forming agent for peptide synthesis (Knorr *et al.*, 1989; Bannwarth and Knorr, 1991). It is able to directly activate a carboxylate group to an NHS ester in a single step without the formation of detrimental side reaction products or other reactive components having crosslinking potential. Uronium coupling reagents react with carboxylate groups through an initial attack on the central positively charged carbon atom of the tetramethyl uronium component (Figure 15.44). This is followed by a rearrangement leading to the formation of an intermediary uronium ester with the carboxylate along with displacement of the leaving group attached to the uronium part of the reagent. In the case of TSTU, it is the NHS group that gets removed in this step. Next, the hydroxyl of the released NHS group in turn attacks the carbonyl carbon of this intermediate uronium ester, which causes displacement of the tetramethyl uronium group and formation of the final NHS ester on the carboxylate. Most TSTU activation reactions are done in nonaqueous solvent (e.g., dioxane or DMF), which preserves the

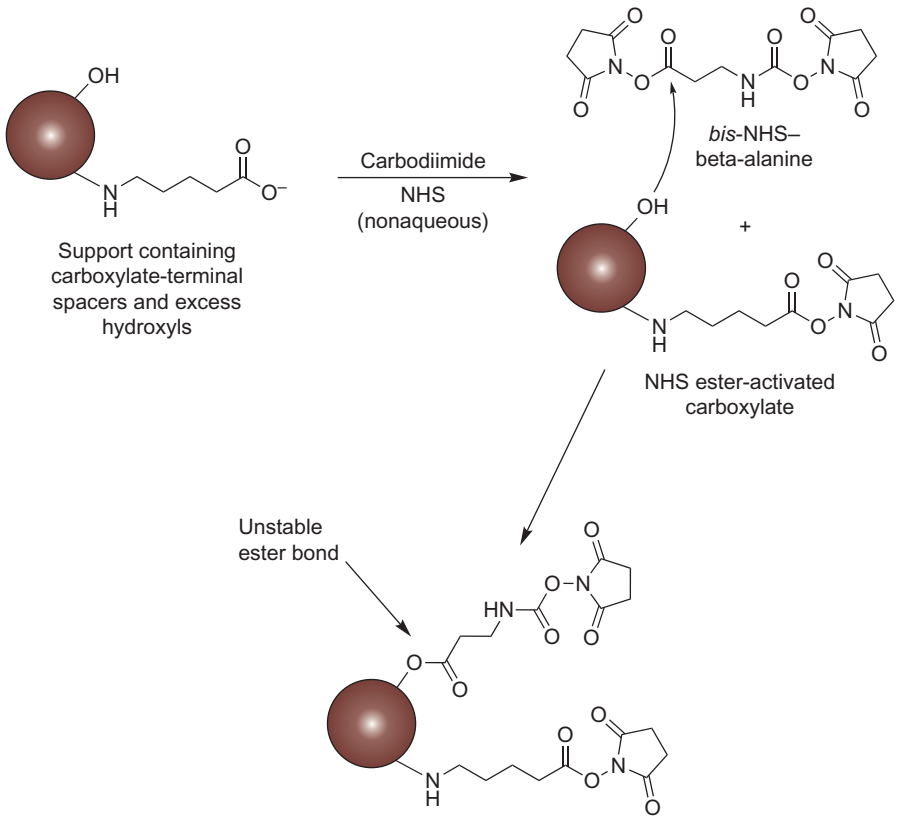

FIGURE 15.43 Reaction of activated β-alanine with the hydroxyl groups remaining on a support, which was modified to contain carboxylates.

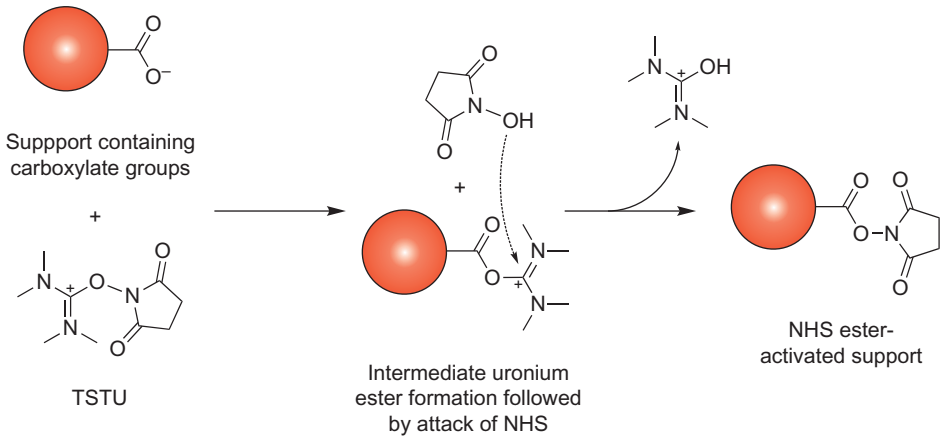

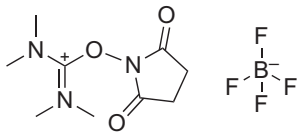

FIGURE 15.44 Mechanism of NHS ester formation using TSTU.

NHS ester from hydrolysis; however, the reagent may also be used in a mixture of organic solvent and water. In addition to Bannwarth and Knorr (1991) demonstrating an organic/water reaction environment consisting of a 2:2:1 mixture of DMF/dioxane/water, Andersson *et al.* (1993) used the coupling reagent to activate a carboxylate derivative of a saccharide in an aqueous/organic solvent mixture and used the NHS ester to conjugate the saccharide to a protein.

TSTU
2-succinimido-1,1,3,3-tetramethyl-uronium tetrafluoroborate (tetrafluoroborate salt)

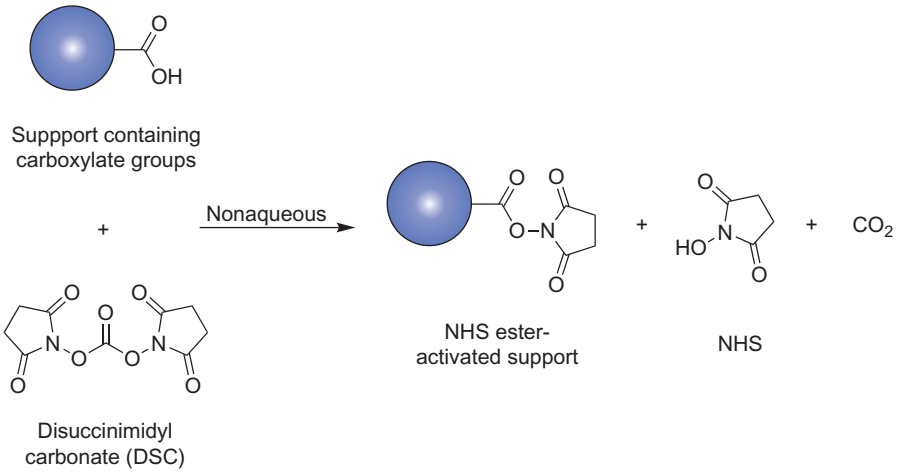

FIGURE 15.45 DSC activation of carboxylate supports to form NHS esters.

In addition to the use of TSTU to create NHS ester-activated derivatives, the bifunctional reagent *N*,*N*′-disuccinimidyl carbonate (DSC) also can be used to form these reactive groups on carboxylate-containing matrices (Ogura *et al.*, 1979; MacBeath and Schreiber, 2000). In this reaction, which is done in a nonaqueous environment, DSC reacts directly with the carboxylate to transfer one of its NHS groups to the acid in a transesterification process (Figure 15.45). The result is the single-step formation of an NHS ester on the carboxylate-containing support, which is then washed free of excess reactants and stored in nonaqueous solution to maintain stability of the ester until use. The byproducts of this process are CO_2 and NHS, both of which are completely innocuous. This reaction also avoids the potential side reactions of a carbodiimide/NHS reaction to form NHS esters. In similar methods, other *bis*-carbonates have been used to activate carboxylates, such as *tert*-butyl carbonates (Basel and Hassner, 2002). The formation of NHS esters on carboxylate supports with *bis*-carbonates can be performed in anhydrous DMF (or other appropriate water-miscible solvents) using 100-m*M* DSC along with an equal concentration of an organic base as a proton acceptor, such as *N*,*N*-diisopropylethylamine (DIEA).

As an alternative approach, reactive NHS esters also can be created directly on hydroxyl-containing chromatography supports without the need to add an intermediary carboxylate spacer. In this strategy, the hydroxylic resin is washed into nonaqueous solvent and activated using the reagent DSC. This compound reacts with a hydroxyl on the matrix with loss of one NHS group to form an *N*-succinimidyl carbonate reactive group, which is similar in reactivity toward amine nucleophiles as that of an NHS ester formed from a carboxylate (Wilchek and Miron, 1985). This same activation process has been used successfully to activate the hydroxyl groups on PEG compounds for subsequent coupling to amine-containing molecules (Chapter 18, Section 2.1). The immobilization of amine-containing ligands onto DSC-activated supports results in the formation of carbamate linkages (Figure 15.46), which are identical to the bonds formed from the reaction of amines with CDI-activated matrices (see this chapter, *CDI-Activated Supports*). Carbamates have been found to be very secure linkages that are similar to amide bonds in chemical stability. Another advantage of DSC activation of hydroxyl supports is that the hydroxyl is reformed by hydrolysis if an amine ligand is not coupled during the immobilization reaction. This leaves an uncharged, hydrophilic group on the matrix if hydrolysis occurs as opposed to a typical NHS ester, which upon hydrolysis, creates a carboxylate group bearing a negative charge. Thus, if a spacer arm on the matrix is not required to present the affinity ligand to its intended binding target, then direct activation of a hydroxylic support with DSC potentially is a better choice than an NHS ester formed from a carboxylate spacer. Even if a spacer arm is desirable to create an immobilized ligand, the use of a PEG spacer containing a terminal hydroxyl group could be created to subsequently activate the spacer with DSC. The use of PEG spacers would form a highly hydrophilic environment that will dramatically lower the nonspecific binding potential of the final affinity support. In addition, if a hydroxylic matrix first is modified to contain carboxylate spacers for conversion to NHS esters using DSC, it is likely that some remaining hydroxyls also are converted to the NHS carbonate in the activation process. Therefore, this result would produce both amide and carbamate bonds in the final immobilized ligand support, the relative proportion of which would depend on the ratio of activated carboxylates to activated hydroxyls.

A final option using DSC for the activation of chromatography supports is to use it to activate amine-containing

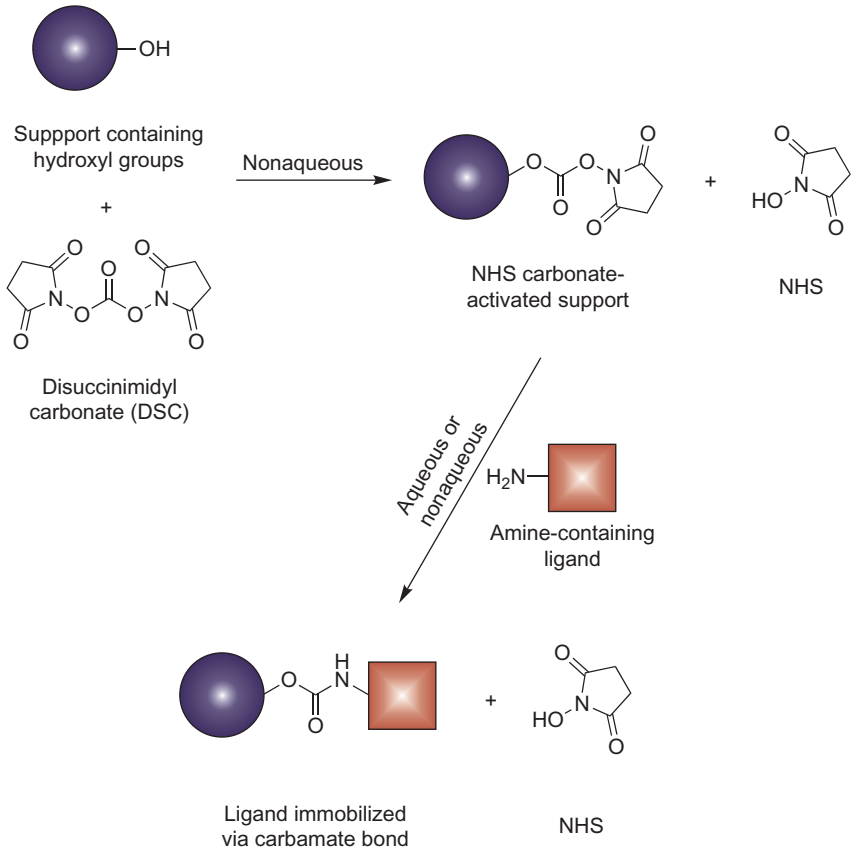

FIGURE 15.46 DSC activation of hydroxyl supports followed by coupling to amine-containing ligands to form carbamate bonds.

matrices. A beaded chromatography support modified to contain amine spacers can be created through the coupling of a diamine compound to an activated matrix, which then results in terminal primary amines on the support for further activation and coupling reactions (see section on coupling spacer molecules). DSC can be used to directly activate these amines to reactive NHS carbamates, which in turn can be coupled to amine-containing ligands to form an isourea linkage (a urethane bond) (Figure 15.47). This reaction has been used successfully to couple immobilized proteins with other amine-containing molecules (MacBeath and Schreiber, 2000) and to activate amine spacers on a slide surface for immobilization of amine-containing ligands (Niemeyer, 2004). This procedure offers a way of coupling amine-containing ligands to an amine-containing support without further modification of the amino spacers to convert them to a different functionality for activation. However, it should be kept in mind that the underlying amines on this support may create positively charged sites, especially with regard to any DSC-activated amines that do not couple to ligands in the immobilization reaction, because the hydrolysis product regenerates the original amine. Thus, using this method there may be some potential for nonspecificity in the final affinity support from ion-exchange effects due to leftover or uncoupled amines.

The following protocols represent methods that can be used to create amine-reactive NHS esters on chromatography supports. Carbodiimide-based methods using DCC in organic solvent can also be done, but are not included in the recommended protocols due to the likely side reactions involving the formation of the bifunctional β-alanine crosslinking agent described previously, which would result in an affinity support having a high potential for ligand leakage. Note that for protocols related to the activation and coupling of ligands to carboxylate-containing microparticles or carboxylated nanoparticles using the carbodiimide EDC with NHS to form intermediate NHS esters, the reader should refer to Chapter 14.

All solvents used in the following protocols should be as anhydrous as possible to avoid the potential for hydrolysis of the NHS ester groups during storage of the activated supports.

ACTIVATION PROTOCOLS

(A) NHS Ester Activation Procedure using TSTU

The following procedure is based on the method of Wilchek *et al.* (1994) using TSTU in a reaction with

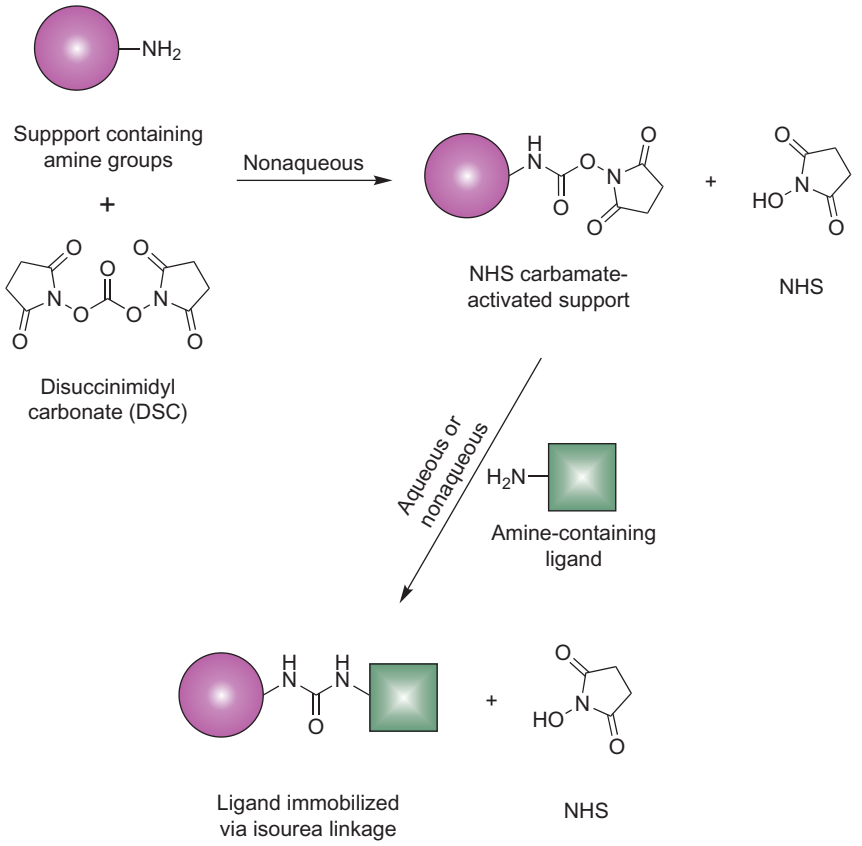

FIGURE 15.47 Activation of amine-containing supports with DSC and subsequent coupling of amine-containing ligands.

carboxylate groups on a chromatography support to form reactive NHS esters that can be used to couple with amine-containing ligands.

1. Wash 100 ml of a hydroxylic chromatography support material (such as crosslinked agarose) that has been modified to contain carboxylate groups with 0.3-*N* HCl and then with water (several bed volumes each) using a sintered glass filter funnel. In a fume hood, sequentially wash the support into increasing concentrations of dioxane-in-water (such as 25% (v/v), 50%, and 75% dioxane/water) and finally with 100% solvent for at least 10 to 20 bed volumes to remove the last traces of water. Drain to a wet gel cake and then pull a gentle vacuum on the filter funnel while breaking up the gel cake with a spatula to obtain moist, evenly divided pieces, which still contain dioxane within the internal pores of the beads. Remove the vacuum as soon as the gel is uniformly divided and appears as a white fluffy snow-like consistency. Be careful not to allow the support to dry, as this will cause particle collapse and irreversible damage to the pore structure.
2. In a fume hood, prepare a 100-ml solution of 0.1-*M* TSTU (*N*,*N*,*N*′,*N*′-tetramethyl(succinimido)uronium tetrafluoroborate) in DMF. Add the washed gel cake to the TSTU solution with stirring to resuspend the gel. Next add 0.244 g of 4-(dimethylamino)pyridine (DMAP) to the gel suspension to prepare a 0.2-*M* DMAP solution and mix to dissolve. A small amount of additional DMF may be added if necessary to aid in stirring the mixture.
3. Mix the reaction for 1 h by rotation or using an overhead paddle stirrer.
4. Wash the activated support with several bed volumes each of DMF, methanol, and isopropanol to remove excess reactants and reaction byproducts. The NHS ester-activated support can be stored as a 50% slurry in isopropanol at 4°C until use.

(B) NHS Ester Activation of Carboxylate Supports using DSC

1. Wash 100 ml of a carboxylate-containing chromatography support material (such as crosslinked agarose that has been modified to contain carboxylate groups) with water (at least several bed volumes) using a sintered glass filter funnel. In a fume hood, sequentially wash the support into increasing concentrations of

acetone-in-water (such as 25% (v/v), 50%, and 75% acetone/water) and finally with 100% dry acetone for at least 10 to 20 bed volumes to remove the last traces of water. Alternative solvents include dioxane, DMF, DMAC, or DMSO, which can be substituted for acetone depending on the compatibility of the matrix to a particular solvent. Drain to a wet gel cake and then pull a gentle vacuum on the filter funnel while breaking up the gel with a spatula to obtain moist, evenly divided pieces, which still contains acetone within the internal pores of the beads. Remove the vacuum as soon as the gel is uniformly divided and appears as a white fluffy snow-like consistency. Be careful not to allow the support to dry too much, as this will cause particle collapse and irreversible damage to the pore structure.

2. In the fume hood, prepare 100 ml of a solution consisting of 80 mg/ml DSC in dry acetone. Stir vigorously to dissolve. There may be some insoluble DSC left in the solution as a fine suspension, but this material will be driven into solution as the activation reaction proceeds.
3. Add the acetone wet gel cake to the DSC solution with stirring to uniformly resuspend the support. To this suspension, add 6.5 g of DMAP to provide a base to catalyze the reaction; alternatively, add 7.5 ml of anhydrous triethylamine (TEA). Mix the gel suspension using an overhead stirring paddle or by end-over-end rocking in the fume hood.
4. React for 1 h at room temperature with mixing.
5. In the fume hood, wash the activated support with acetone to thoroughly remove excess reactant and reaction byproducts. Wash with at least 10 bed volumes of solvent to ensure removal of the last traces of unreacted DSC.
6. Store the NHS ester-activated support as a 50% slurry in dry acetone at 4°C until use.

(C) NHS Carbonate Activation of Hydroxylic Supports using DSC

1. Wash 100 ml of a hydroxyl-containing chromatography support material (such as agarose, Toyopearl, or Trisacryl) with water (3–5 bed volumes) using a sintered glass filter funnel. In a fume hood, sequentially wash the support in increasing concentrations of acetone-in-water (such as 25% (v/v), 50%, and 75% acetone/water) and finally with 100% dry acetone for at least 10 to 20 bed volumes to remove the last traces of water. Alternative solvents include dioxane, DMF, DMAC, or DMSO, which can be substituted for acetone depending on the compatibility of the matrix to a solvent. Drain to a wet gel cake and then pull a gentle vacuum on the filter funnel while breaking up the gel cake with a spatula to obtain moist, evenly divided pieces, which still contain acetone within the internal pores of the beads. Internal pores of the beads, with a spatula to obtain moist, evenly divided pieces. Remove the vacuum. Be careful not to allow the support to dry too much, as this will cause particle collapse and irreversible damage to the pore structure.
2. In the fume hood, prepare 100 ml of a solution consisting of 80 mg/ml DSC in dry acetone. Stir vigorously to dissolve. There may be some insoluble DSC left in the solution as a fine suspension, but this material will be driven into solution as the activation reaction proceeds.
3. Add the acetone wet gel cake to the DSC solution with stirring to uniformly resuspend the support. To this suspension, add 6.5 g of DMAP (alternatively, add of 7.5 ml of anhydrous TEA) to provide a base to catalyze the reaction. Mix the gel suspension using an overhead stirring paddle or by end-over-end rocking in the fume hood.
4. React for 1 h at room temperature with mixing.
5. In the fume hood, wash the activated support with acetone to thoroughly remove excess reactant and reaction byproducts. Wash with 5 to 10 bed volumes of solvent to ensure removal of the last traces of unreacted DSC.
6. Store the NHS carbonate-activated support as a 50% slurry (the volume of the support is equal to half the total volume of the slurry) in dry acetone at 4°C until use. As an alternative storage solvent, the activated gel may be washed into dry isopropanol and stored in this solvent. Avoid the use of methanol, as some transesterification may occur with the NHS esters to form methyl esters upon storage.

The activation of an amine-containing support using DSC can be performed similar to methods described in previous protocols, except for substitution of a support modified to contain a terminal amino spacer for the hydroxylic or carboxylate supports described above.

LIGAND COUPLING TO NHS ESTER- OR NHS CARBONATE-ACTIVATED SUPPORTS

The following protocols describe general methods for coupling amine-containing ligands to NHS ester- or NHS carbonate-activated chromatography supports. This process can be used successfully to immobilize proteins or other amine-containing affinity ligands as well as amine-containing spacer molecules. During the coupling reaction, avoid introducing any other primary or secondary amine-containing components into the coupling buffer—such as Tris, glycine, imidazole, ammonium ions, or other small molecules containing a reactive amine—as these will interfere with the desired immobilization of ligand. Amine reactions with reactive ester supports will occur efficiently in aqueous solution

at pH 7 to 9.0, so the coupling buffer pH may be modified somewhat to promote ligand stability or solubility if necessary; however, be aware that the higher the pH of the reaction, the greater the rate of hydrolysis of the NHS esters, so use care when reacting at the high end of this pH range. The immobilization reaction may also be done entirely in nonaqueous solution or in a combination of organic solvent/aqueous buffered solution to promote ligand solubility, when necessary. Nonaqueous conditions will eliminate the potential for hydrolysis and thus promote higher yields when immobilizing small amine-containing ligands. To perform immobilizations in 100% organic solvent, an organic base should be added as a proton acceptor to catalyze the coupling reaction, such as triethylamine (TEA), diisopropylethylamine (DIEA), or dimethylaminopyridine (DMAP).

(A) Aqueous Reaction Protocol

1. Prepare an amine-containing ligand solution consisting of a protein or small molecule dissolved in 100 ml of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 (coupling buffer), at a concentration of 1 to 20 mg protein/ml or 1 to 5 mg/ml of a small amine-containing molecule. Alternative coupling buffers for immobilization onto NHS-activated supports include 0.1-*M* MOPS (pH 7.0), 0.1- to 0.2-*M* phosphate (pH 7.2–7.5), 0.1 to 0.2-*M* $NaHCO_3$ (pH 8.0), or 0.1-*M* sodium borate (pH 8.5), which all may or may not contain NaCl. The pH of the ligand solution may be varied from approximately pH 7 to 9 to take into account differential reactivities of some ligands. The optimal concentration of ligand that is used for the immobilization reaction should be determined experimentally to obtain the best performance of the affinity matrix after coupling. This can be done using only 1 to 2 ml of activated support for each immobilization trial and proportionally reducing the quantities of reagents used for the reactions. Diamine spacer molecules should be coupled at much higher concentrations to avoid internal crosslinking while promoting coupling to only one end of the linker (i.e., 0.5–1.0 *M*). See the section on spacer arm coupling in this chapter for additional information.
2. In a fume hood, transfer 100 ml of an NHS ester- or NHS carbonate-activated support stored in isopropanol or acetone to a clean sintered glass filter funnel in the hood positioned over a suction filter flask. Drain the matrix of excess solvent by applying a vacuum and break up the resin with a plastic spatula into small pieces as the solvent is removed, then remove the vacuum to prevent gel drying. Wash the resin quickly with 2 to 3 bed volumes of deionized water to remove the majority of remaining solvent. When working with small quantities of activated support, this operation can be performed using spin columns for solvent removal and washings. Finally, wash the activated support with 100 ml of coupling buffer and drain to a wet cake. Perform all aqueous washing operations quickly to avoid extensive hydrolysis of the reactive groups prior to mixing with ligand solution.
3. Immediately add the washed support to the ligand solution with stirring to uniformly mix and suspend the resin within the medium. Continue mixing using an overhead paddle stirrer or by rotation using a sealed container. React for at least 1 h at room temperature. For sensitive ligands, all solutions can be cooled to 4°C and the reaction also performed in the cold; however, the reaction time should be at least doubled to accommodate a slower reaction rate. The majority of coupling will occur in the first 30 min at room temperature.
4. Upon completion of the reaction, transfer the support slurry to a clean sintered glass filter funnel suspended in a suction filter flask, drain excess ligand solution, and wash with several bed volumes of coupling buffer. The initial washes may be saved to determine the amount of ligand that coupled to the support. This is done by measuring the remaining ligand in washes and comparing this amount to the quantity initially reacted. The difference is the amount of ligand immobilized onto the support.
5. Block unreacted NHS ester groups by adding to the support an equal volume of 1-*M* ethanolamine in coupling buffer and mixing for 30 min. The amino end of ethanolamine will couple to the remaining NHS ester groups and leave hydrophilic hydroxyl groups on the support.
6. Wash the support extensively with water, 1-*M* NaCl, and water, using at least 5 bed volumes of wash for each solution. Store the immobilized ligand support at 4°C as a 50% aqueous slurry containing a preservative.

(B) Nonaqueous Coupling Protocol

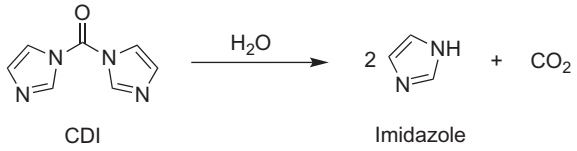
1. In a fume hood, dissolve an amine-containing ligand in 100 ml of a dry organic solvent at a concentration of 1 to 5 mg/ml. Suitable solvents include acetone, dioxane, DMF, DMSO, DMAC, ethanol, and isopropanol. The use of methanol may also be done, but it could more easily than other alcohols undergo transesterification with the NHS ester-reactive groups and slow down or reduce the coupling yield. Other water-miscible but dry solvents may be used as long as the solvent does not harm or unduly collapse the particle structure of the activated chromatography support. Add to this solution a 2-times mole excess of an organic base over the

amount of ligand present, such as TEA, DIEA, or DMAP to catalyze the coupling reaction.

2. Drain 100 ml of an NHS ester-activated support of excess solvent by using a sintered filter funnel suspended in a suction filter flask in a fume hood. If the coupling reaction is to be done in a solvent other than the one in which the activated support was stored, then wash the matrix into the coupling solvent by initially pulling a vacuum on the support in the filter funnel while breaking up the resin into small pieces with a spatula. Do not let the support dry in the filter funnel during the process. Remove the vacuum and resuspend the matrix in an equivalent volume of the desired solvent. Then wash with several volumes of this solvent to fully exchange the matrix into it. Drain to remove excess solvent.
3. Add the activated support to the ligand solution with stirring to uniformly resuspend the resin. Mix in a fume hood by using a paddle stirrer or by rotation in a sealed container. Continue the reaction for 1 h at room temperature with constant mixing.
4. Transfer the gel reaction slurry to a clean sintered glass filter funnel and drain the excess ligand solution. Wash with several bed volumes of solvent to remove the majority of not-coupled ligand. Retain the washes to determine the amount of ligand that coupled to the matrix, if desired.
5. Block unreacted NHS ester groups by adding to the support an equal volume of 1-*M* ethanolamine in solvent and mixing for 30 min. The amino end of ethanolamine will couple to the remaining NHS ester groups and leave hydrophilic hydroxyl groups on the support.
6. Wash the support extensively with solvent to remove all traces of ethanolamine and any remaining uncoupled ligand (at least 5–10 bed volumes). Next, wash the support into aqueous solution by sequentially washing with increasing amounts of water in solvent until 100% water is used and all traces of solvent have been eliminated from the resin. The final affinity support may be stored at 4°C as a 50% slurry in water containing a preservative.

Carbonyl Diimidazole (CDI) Activation

N,*N*′-Carbonyl diimidazole (CDI; also called 1,1′-carbonyl diimidazole) is a highly reactive carbonylating compound originally developed for use in peptide synthesis, but which is also capable of activating carboxylates and hydroxyls on chromatography supports for the immobilization of amine-containing ligands (Paul and Anderson, 1960; Bartling *et al.*, 1973; Bethell *et al.*, 1979, 1987; Hearn *et al.*, 1981, 1983; Batista-Viera *et al.*, 2011). CDI is extremely sensitive to hydrolysis in water, where it decomposes to give two molecules of imidazole



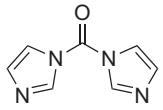


FIGURE 15.48 Hydrolysis of CDI in water to form CO_2 and imidazole.

with loss of CO_2. Placing CDI in an aqueous solution will result in vigorous fizzing as the CO_2 is released (Figure 15.48). All activation procedures, therefore, must be done in nonaqueous conditions using extremely dry solvents. Typically, water-miscible solvents are used so that the support can be washed in and out of aqueous solution by exchange with increasing or decreasing concentrations of the solvent in water. Solvents that work well in this process include acetone, dioxane, DMSO, DMF, and DMAC. Avoid alcohols such as methanol, ethanol, or isopropanol, as the hydroxyls on these compounds will react with CDI.

CDI
N,*N*'-Carbonyl diimidazole

The activation of a carboxylate group with CDI proceeds through transamidination to give a secondary amide with imidazole. This intermediate acyl imidazolide is reactive towards amines in proteins and other molecules, because the imidazole is a good leaving group. A coupling reaction involves attack of the nucleophilic amino group nitrogen on the carbonyl of the acyl imidazolide to displace the imidazole group and form an amide linkage with the ligand (Figure 15.49). Carboxylate-containing supports that can be activated with CDI include chromatography resins modified to contain a carboxylate-terminal spacer (see section on spacer arms, this chapter), membranes similarly modified with carboxylates, and small microparticles or nanoparticles that contain carboxylates (see Chapter 14, Section 4.2).

Hydroxyl-containing supports can also can be activated using CDI, including those that contain primary or secondary hydroxyls (Hearn *et al.*, 1983). In this case, CDI can be used to activate the hydroxyls to reactive imidazolyl carbamates, an intermediate that is similar in its reactions to NHS carbonates (described in the previous section). Hydroxylic resins activated in this manner can then be used to immobilize amino ligands through displacement of the imidazole leaving group on the carbonyl with subsequent formation of an alkyl carbamate linkage (Figure 15.50). The resulting urethane derivative

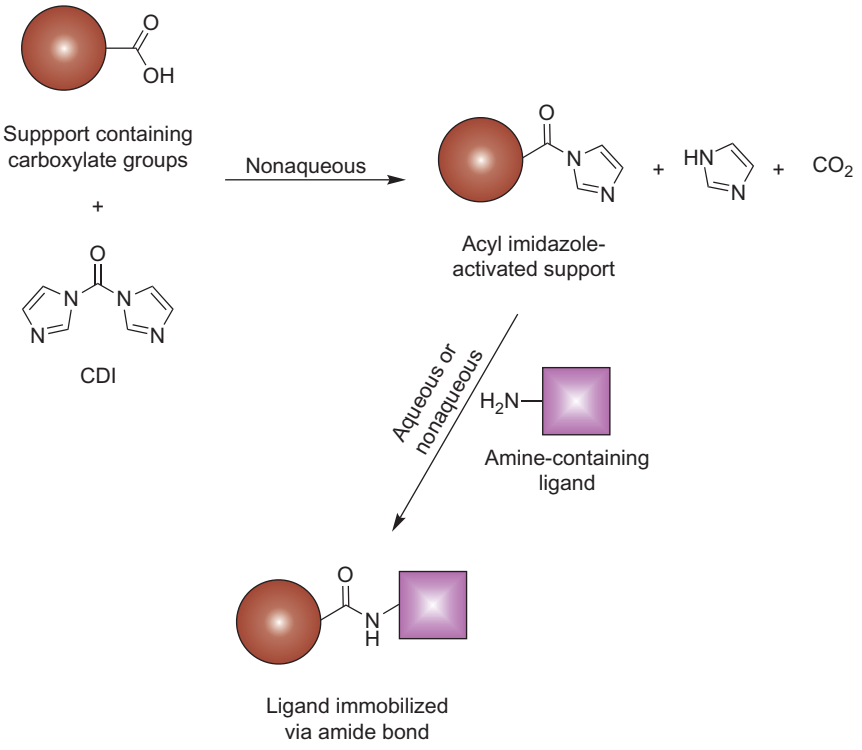

FIGURE 15.49 Activation of carboxylates with CDI and reaction with amine-containing ligands.

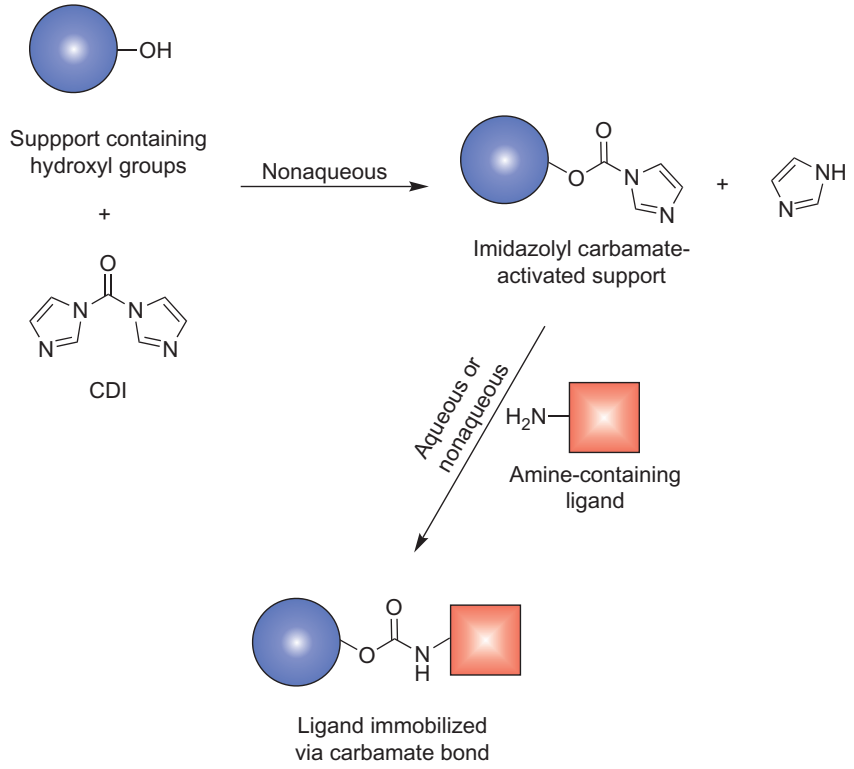

FIGURE 15.50 Activation of hydroxyls with CDI and reaction with amine-containing ligands.

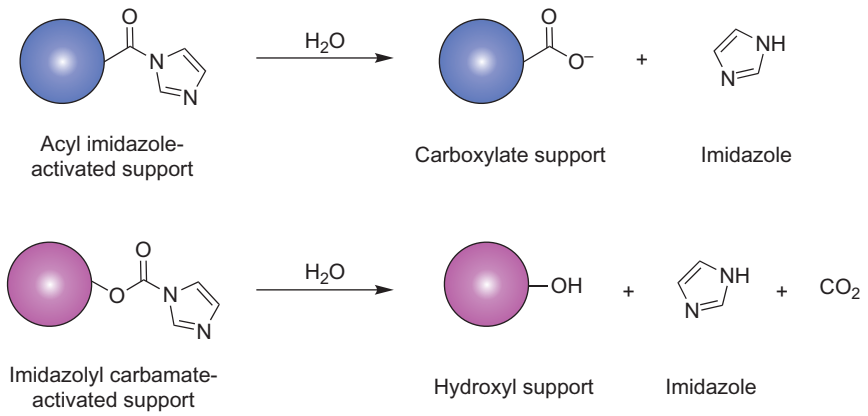

FIGURE 15.51 Hydrolysis of CDI-activated hydroxylic supports and CDI-activated carboxylate supports to give hydroxyls and carboxyls, respectively.

creates an uncharged bond on the support that has excellent chemical stability toward ligand leakage. While both the activation of carboxylates and the activation of hydroxyls with CDI produce an intermediate reactive carbonyl derivative, the respective bonds they form with amines are different, as are the hydrolysis products that are formed if a ligand does not couple in aqueous solution. If a CDI-activated carboxylate undergoes hydrolysis instead of ligand coupling, the result is a reformation of the original carboxylic acid group on the support. However, if a CDI-activated hydroxyl group is hydrolyzed, the result is loss of imidazole and CO_2 along with reformation of the original hydroxyl. Thus, if a carboxylate support that has been activated with CDI should hydrolyze during a coupling reaction, it can create negatively charged groups on the matrix, which may cause subsequent nonspecific binding during affinity separations; whereas, if a hydroxylic support activated with CDI undergoes hydrolysis, it reverts back to a hydrophilic and uncharged hydroxyl, which helps to reduce nonspecific interactions (Figure 15.51). These reactions and their hydrolysis products are similar to the activation of hydroxylic- or carboxylic-containing supports with DSC (described previously).

CDI-activated carboxylate supports or CDI-activated hydroxyl supports both will react nearly exclusively with primary amines on proteins and other ligands, even in the presence of secondary amines (Rannard and Davis, 2000). This surprising specificity can be used to advantage during the immobilization of spacer arms or small ligands, which may contain both primary and secondary amines within their structure. This may also be an important consideration in certain ligand immobilization needs in choosing CDI activation over the use of NHS ester- or NHS carbonate-activated supports, because they have the potential to react with secondary amines as well as primary amines.

Amine-containing supports may also be activated with CDI to give an intermediate imidazolyl isourea derivative. This reactive group also can be coupled with primary amines on ligands to result in an isourea (or urethane) bond (Figure 15.52). While the activation of amine-containing supports is less frequently performed than the activation of carboxylate- or hydroxyl-containing supports, it does open up an additional route of activation and ligand coupling that avoids having to convert the amine to some other functionality prior to activation. The only potential deficiency of this method is the fact that amine-containing supports typically have greater nonspecific binding with biomolecules due to their net positive charge at physiological pH. Hydrolysis rather than ligand coupling of the CDI-activated intermediate would cause a reversion to a primary amine on the support, which would be the major cause of a positively charged affinity support.

Hydroxylic supports (such as agarose, Trisacryl, or Toyopearl matrices) that are activated with CDI and stored in nonaqueous solvent are stable for years if kept in a sealed container at 4°C. In addition, the stability of the imidazolyl carbamate reactive groups is much greater toward hydrolysis in aqueous coupling buffer than NHS ester- or NHS carbonate-activated supports. At pH 8.5 to 9.0 in sodium borate buffer, a CDI-activated agarose support can take up to 30 h at room temperature to completely lose activity due to hydrolysis. By comparison NHS ester or NHS carbonate supports have half-lives due to hydrolysis measured in minutes in this pH range.

The immobilization of amine-containing ligands onto CDI-activated supports can be performed in nonaqueous or aqueous environments. It is particularly advantageous to couple small, organic soluble ligands in 100% organic solvent, as it eliminates the potential

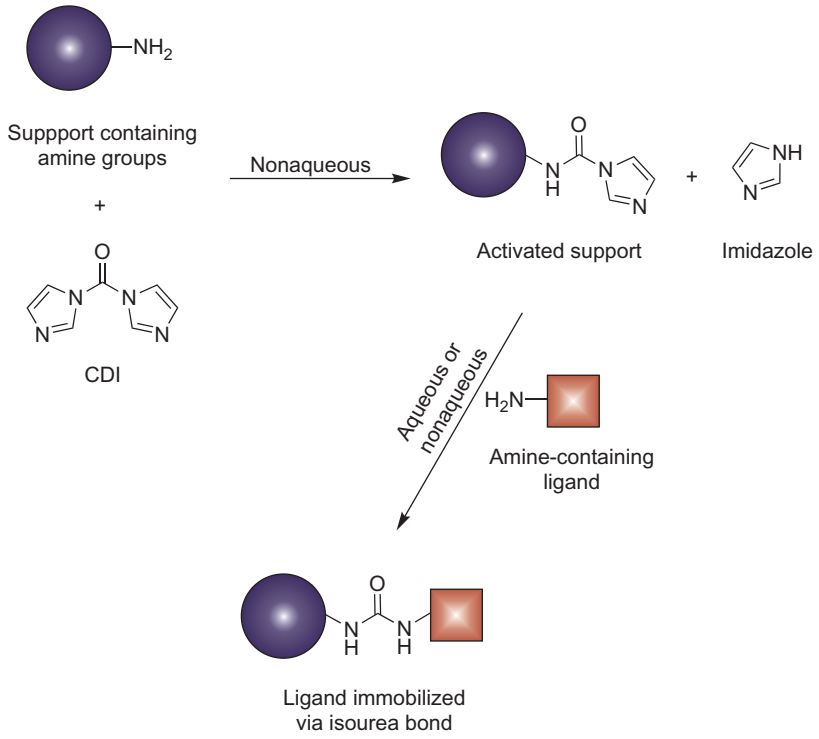

FIGURE 15.52 CDI activation of amine-containing supports and coupling to amine ligands.

for hydrolysis during the reaction, thus maximizing the coupling yield. For aqueous-phase reactions, as in the coupling of proteins or other amine-containing biomolecules, the optimal pH for immobilization often is dependent on the pI or pK_a of the ligand. For maximal efficiency of coupling, the reaction conditions should be controlled at a pH representing at least 1 pH unit above the ligand's pI or pK_a point. This ensures that a majority of amines on the ligand will be unprotonated and thus at their maximal potential nucleophilicity for reaction with the active groups on the matrix.

CDI ACTIVATION PROTOCOL

The following protocols describe the activation of supports using CDI followed by a number of coupling methods that can be used to immobilize affinity ligands. Regardless of the support being used, the activation reaction should be done in anhydrous organic solvent to avoid hydrolytic breakdown of CDI or the active intermediate formed on the matrix. Make certain to use extensive solvent washing protocols to completely remove any traces of water from a hydrated support prior to the addition of CDI. Finally, when working with solvents all operations should be carried out in a fume hood using personal protective equipment and precautions to avoid static electricity. Dispose of all solvents according to hazardous organic waste guidelines.

1. Wash 100 ml of a hydroxyl-, carboxyl-, or amine-containing chromatography support material (such as crosslinked agarose) with water (at least several bed volumes) to remove preservatives and storage solution components. In a fume hood, sequentially wash the support into increasing concentrations of acetone-in-water (such as 25% (v/v), 50%, and 75% acetone/water) and finally with 100% dry acetone for at least 10 to 20 bed volumes to remove the last traces of water. Drain the support to a wet gel cake and then pull a gentle vacuum on the filter funnel while breaking up the gel cake with a spatula to obtain moist, evenly divided pieces, which still contain acetone within the internal pores of the beads. Be careful not to allow the support to dry, as this will cause particle collapse and irreversible damage to the pore structure of some matrices. Remove the vacuum as soon as the support is fully divided into small pieces (it will look like moist, fluffy snow). Note: Alternative solvents can be used for the activation process including dioxane, DMF, DMAC, or DMSO, which can be substituted for acetone depending on the compatibility of the matrix to a particular solvent. For example, some supports such as dextran will maintain their swollen particle nature best in solvents such as DMSO or DMF, whereas acetone will cause them to

unacceptably shrink and restrict access to the inner pore structures.
2. In the fume hood, dissolve 10 g of CDI in 100 ml of dry acetone with stirring.
3. Add the acetone wet gel cake to the CDI solution with stirring to uniformly resuspend the support. Mix the gel suspension using an overhead paddle stirrer or by end-over-end rocking in a sealed container within the fume hood.
4. React for 1 h at room temperature with mixing.
5. In the fume hood, wash the activated support with acetone to thoroughly remove excess reactant and reaction byproducts. Wash with at least 10 bed volumes of solvent to ensure removal of the last traces of unreacted CDI.
6. Store the CDI-activated support as a 50% slurry in dry acetone at 4°C until use.

Using the above protocol, the CDI-activated support may contain as much as 100 µmoles of reactive groups per milliliter (using crosslinked agarose), which is more than sufficient for coupling primary amine-containing affinity ligands of all types at very high density, if required.

LIGAND COUPLING TO CDI-ACTIVATED SUPPORTS

The following ligand coupling protocols represent generalized methods that should be optimized for a particular ligand to obtain the best possible affinity support performance in its intended application. CDI-activated supports typically have slower reaction kinetics when coupling proteins as compared to NHS ester-activated supports and therefore extended reaction times often are necessary to realize the best coupling yields (i.e., 16–24 h). However, for coupling small amine-containing ligands or spacer molecules, maintaining a high concentration should give maximal yields within 1 to 2 h at room temperature. Take care, however, in creating an immobilized ligand at very high density on the support, because this may cause nonspecific binding or result in too high an affinity toward the target molecule, making it difficult to elute it from the support.

For ligands that are more soluble or stable in organic solvent, the entire coupling reaction can be performed under nonaqueous conditions using the same solvent used in the activation process, if appropriate. If a nonaqueous reaction is performed, the addition of an organic base (e.g., TEA, DIEA, DMAP) at a concentration that is 2 to 3 times that of the CDI activation level on the matrix will catalyze the process and increase the reaction rate. Reactions performed in organic solvent have the advantage of not undergoing hydrolysis, thus increasing potential yields of the ligand coupling process. Alternatively, a mixture of aqueous buffer with solvent can be used to maintain the solubility of some ligands. In this situation, the ligand may be first dissolved in organic solvent and then added to the reaction buffer just prior to adding the activated support. The final amount of solvent added to an aqueous/organic solvent reaction is often determined by the percentage of solvent that can be tolerated by the buffered solution before buffer salts begin to precipitate. The maximal level of organic solvent addition can be discovered by making a series of solutions with increasing amounts of organic solvent to an aqueous coupling buffer and then identifying which concentrations do not cause buffer precipitation.

(A) Aqueous Coupling Protocol

1. In a fume hood, drain 100 ml of CDI-activated support of solvent using a sintered glass filter funnel suspended in a suction filter flask. Gently pull a vacuum to remove most of the excess solvent while breaking up the support into small, finely divided pieces, but be careful not to allow the matrix to dry out. Stop using suction as soon as the support is divided into small pieces. When coupling ligands that might precipitate or be damaged by the presence of some residual solvent, the support should be quickly washed using several bed volumes of cold deionized water to remove the organic phase. Drain the support to a wet gel cake.
2. Dissolve the ligand to be coupled in 100 ml of a buffered solution at pH 8.5 to 11, or in a buffer having a pH at least 1 pH unit above the pK_a or pI of the ligand or protein. Proteins may be coupled at a concentration of 1 to 20 mg/ml or, for small molecules, at a concentration of 1 to 5 mg/ml of an amine-containing ligand. The optimal concentration of ligand that is used for the immobilization reaction should be determined experimentally to obtain the best performance of the affinity matrix after coupling. Suitable coupling buffers include 0.1-*M* sodium borate, pH 8.5 or 0.1- to 0.5-*M* sodium carbonate, pH 9 to 11. Avoid buffers or solution additives that contain amines, such as Tris, glycine, or imidazole, as these will compete with the ligand coupling reaction.
3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for at least 24 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. When using conditions at a pH of less than 9, the reaction time should be extended to 30 h to obtain maximal coupling yields. The reaction may be performed at 4°C or at room temperature, depending on the stability of the ligand or protein being immobilized. Excess CDI-reactive groups

on the support may be blocked by the addition of ethanolamine to the reaction slurry at a final concentration of at least 0.1-*M*. Note: Titrate the ethanolamine solution to the proper pH by addition of HCl before adding it to the reaction solution. Continue to mix for 1 h at room temperature.

4. Filter and wash the affinity support to remove uncoupled ligand and reaction byproducts using coupling buffer, water, 1-*M* NaCl, and again with water. Depending on the ligand being coupled, other wash solutions may be used to completely remove unreacted ligand, such as detergents, denaturants, and high or low pH conditions. Finally, store the affinity support in water containing a preservative at 4°C until used.

(B) Nonaqueous Coupling Protocol

1. In a fume hood, drain 100 ml of CDI-activated support of excess acetone using a sintered glass filter funnel suspended in a suction filter flask.
2. Dissolve the amine-containing ligand to be coupled in 100 ml of acetone (or another water-miscible solvent) at a concentration of 1 to 5 mg/ml, which is normally sufficient for the immobilization of a small organic compound. The optimal concentration of ligand to be used in the coupling reaction should be determined experimentally on small quantities of activated support to identify the best affinity support performance in its intended application. Add an organic base to the ligand solution, such as DMAP, DIEA, or TEA, to make a final concentration of 2-m*M*.
3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for 1 to 2 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. Longer reaction times may be used if appropriate. Excess CDI-reactive groups on the support may be blocked by the addition of ethanolamine to the reaction slurry at a final concentration of at least 0.1 *M*. Continue to mix for 1 h at room temperature.
4. Transfer the gel slurry to a sintered glass filter in the fume hood that is suspended in a suction filter flask and wash extensively (at least 10 bed volumes) with solvent to remove the remaining ligand and reaction byproducts. If the ligand is detectable, continue to wash the support until no further ligand is detected in the washings. Finally, drain the support of excess solvent by pulling a gentle vacuum on the filter flask while breaking up the support into small, finely divided pieces using a spatula, but be careful not to allow the matrix to dry out. Once the support is broken into small pieces, remove the vacuum and resuspend the gel in water with mixing. Continue to wash the support with water until all traces of solvent have been removed. Additional washes with 1-*M* NaCl as well as low and high pH conditions may be carried out as appropriate. Finally, wash with water and store the affinity support as a 50% slurry in water containing a preservative at 4°C until used.

Activation Using FMP (2-Fluoro-1-Methylpyridinium)

Ngo in 1986 first described the use of 2-fluoromethylpyridinium (FMP), as the toluene-4-sulfonate salt, in a simple process to activate primary and secondary hydroxyls on supports and surfaces for the coupling of amine- or thiol-containing ligands. Under nonaqueous conditions, FMP reacts with hydroxyl groups on chromatography supports to form an intermediate reactive methylpyridinium ether group, which can be coupled to ligands in aqueous or nonaqueous conditions to give stable secondary amine or thioether linkages. The immobilization reaction occurs in buffered solutions within the pH range of 5 to 10, but with greater reaction rates observed in the higher pH range. The coupling of ligands may also be performed in dry solvents with the addition of an organic base to catalyze the reaction (e.g., TEA, DIEA, DMAP) for ligands that are insoluble in aqueous solution.

The leaving group in the FMP coupling reaction (due to nucleophilic displacement with amino- or thiol-containing ligands) is 1-methyl-2-pyridone, which is a convenient chromophore that can be used to determine the activation level of an FMP-activated support. The molar extinction coefficient of this leaving group is 5900 $M^{-1}cm^{-1}$ at 297 nm, which also permits the coupling reaction to be followed provided the reaction is performed under nonaqueous conditions to eliminate simultaneous hydrolysis. Even in aqueous buffers, FMP-activated supports display relatively low hydrolysis rates. In acidic conditions, the activated support hydrolyzes extremely slowly and even after months of storage retains a significant number of reactive groups. Ngo (1988) found that in 10-m*M* phosphoric acid, an FMP-activated support stored at 4°C for months was still able to couple 15 mg/ml of BSA. Even under alkaline conditions the activated support hydrolyzes slowly with a half-life of about 130 h at pH 7 and about 35 h at pH 9. Long-term storage in aqueous solution, however, still is not recommended, because some reactive groups will degrade over time and the reproducibility of coupling ligands may be negatively affected. One benefit of FMP-mediated immobilization is that if the activated support does hydrolyze during ligand coupling, the result is to reform the original hydroxyls on the support, thus leaving behind no groups that potentially can cause nonspecific binding. In addition, successful ligand coupling

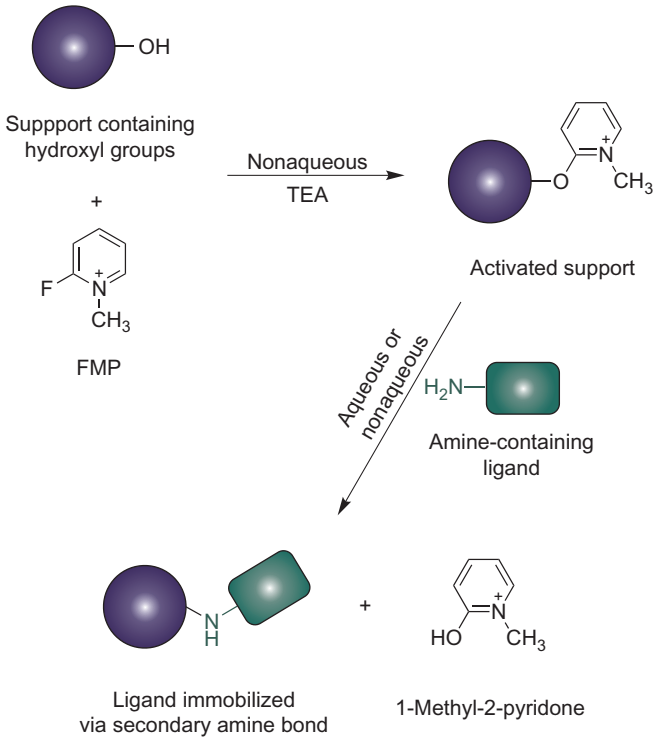

FIGURE 15.53 Activation of a hydroxylic support with FMP and coupling of amine- or thiol-containing ligands.

displaces the pyridone group, which bears the oxygen originating from the hydroxyl on the support material. Therefore, the net result of the immobilization reaction is to replace the hydroxyl group on the matrix with the nucleophile of the ligand, forming a new, chemically stable bond (Figure 15.53). This process is similar to that of tosyl and tresyl activation, which also replaces the activated hydroxyl with the amino group of the ligand (see tosyl and tresyl activation discussion, this chapter).

Amine- or thiol-containing ligands react with the FMP-activated support within the first several hours to result in at least 90% yields with regard to the amount of reactive groups that can react. Thiols appear to react at slightly greater rates due to their somewhat greater nucleophilicity. FMP-activated agarose or Toyopearl type supports should be able to immobilize proteins such as BSA at densities of 10 to 20 mg/ml gel.

After the coupling reaction is complete, the residual reactive groups should be blocked with a small molecule to ensure that no further reactivity remains that might couple molecules nonspecifically from subsequent samples applied to the affinity gel. This blocking step is especially important with FMP-activated matrices, because of the extended hydrolytic stability of the reactive groups. Blocking with ethanolamine, for example, will remove these active groups and result in numerous hydrophilic hydroxyls being created in their place.

FMP ACTIVATION PROTOCOL

The following protocols describe two methods of activating hydroxyl-containing supports with FMP in nonaqueous environments. The first one uses acetone and DMF as the solvents and the second method uses acetone and acetonitrile. Other solvents may be used for the activation step, but they should be water miscible so that water can be removed from the support by washing and anhydrous to prevent hydrolysis of the activation agent before the hydroxyls are activated.

(A) ACTIVATION OF TOYOPEARL SUPPORTS WITH FMP IN DMF

1. Wash 100 ml of a Toyopearl resin (such as HW-65 or HW-75) with water (at least several bed volumes) to remove preservatives and storage solution components. In a fume hood, sequentially wash the support into increasing concentrations of acetone-in-water (such as 25% (v/v), 50%, and 75% acetone/water) and finally wash with 100% anhydrous acetone for at least 10 to 20 bed volumes to remove the last traces of water. Drain the support to a wet gel cake and then pull a gentle vacuum on the filter funnel while quickly breaking up the gel cake with a spatula to obtain moist, evenly divided pieces, which still contains acetone within the internal pores of the beads. Be careful not to allow the support to dry. Remove the vacuum and add 200 ml of anhydrous DMF with stirring. Filter to remove excess DMF and then further wash the support with 500 ml of DMF to remove the acetone. Finally, filter off the excess solvent and keep as a moist gel cake.
2. In the fume hood, dissolve with stirring 7.1 g of FMP (5 mmoles; as the toluene-4-sulfonate salt) in 100 ml of dry DMF containing 6 mmoles TEA (3.03 g or 4.18 ml) as catalyst. Alternative organic base catalysts may be used, including DIEA or DMAP, which serve to accept protons during the course of the activation reaction.
3. Add the DMF wet gel cake to the FMP solution with stirring to uniformly resuspend the support. Mix the gel suspension using an overhead paddle stirrer or by end-over-end rocking in a sealed container within the fume hood.
4. React for 1 h at room temperature with mixing.
5. In the fume hood, wash the activated support with 500 ml of DMF to thoroughly remove excess reactant and reaction byproducts. Filter off excess DMF under a gentle vacuum and break up the gel cake into small pieces with a spatula. Resuspend the gel in acetone and then wash with at least 10 bed volumes of acetone.
6. Store the FMP-activated Toyopearl support as a 50% slurry in dry acetone at 4°C until use.

(B) ACTIVATION OF CROSSLINKED AGAROSE SUPPORTS WITH FMP IN ACETONITRILE

1. Wash 100 ml of a hydroxyl-containing, crosslinked agarose support (such as Sepharose CL-4B) with water (at least several bed volumes) to remove preservatives and storage solution components, then sequentially wash the gel in a fume hood with increasing concentrations of acetone-in-water (25% (v/v), 50%, and 75% acetone/water; 500 ml each). Finally, wash with 100% anhydrous acetone for at least 10 bed volumes to remove the last traces of water. Drain the support to a wet gel cake and then wash with at least 500 ml of dry acetonitrile. Finally, filter off the excess solvent and keep as a moist gel cake.
2. In a fume hood, dissolve 7.1 g of FMP (toluene-4-sulfonate salt) in 300 ml of acetonitrile containing 4.18 ml of TEA.
3. Add the FMP solution to the moist gel cake and stir to uniformly mix the suspension.
4. Continue to react with mixing for 1 h at room temperature using an overhead paddle stirrer or end-over-end rocker.
5. In the fume hood, wash the activated support with 500 ml of acetonitrile to thoroughly remove excess reactant and reaction byproducts. Filter off excess acetonitrile under a gentle vacuum and break up the gel cake into small pieces with a spatula. Resuspend the gel in acetone and then wash with at least 10 bed volumes of acetone to remove the acetonitrile.
6. Store the FMP-activated agarose support as a 50% slurry in dry acetone at 4°C until use.

LIGAND COUPLING TO FMP-ACTIVATED SUPPORTS

The following immobilization protocols are generalized methods for coupling amine- or thiol-containing affinity ligands to FMP-activated chromatography supports. The optimal protocol for a given affinity ligand should be discovered through experimentation using different coupling conditions and concentrations of ligand to produce the best-performing affinity support in the intended application. The first procedure is an aqueous coupling method that is appropriate for immobilizing proteins or small water soluble molecules. In the second procedure, a nonaqueous method is described that can be used to maximize the coupling yield (without competing hydrolysis) or for use with ligands that are not soluble in aqueous buffers.

(A) AQUEOUS COUPLING PROTOCOL

1. In a fume hood, drain 100 ml of the FMP-activated support of solvent using a sintered glass filter funnel suspended in a suction filter flask. Gently pull a vacuum to remove most of the excess solvent while breaking up the support into small, finely divided pieces using a spatula, while also being careful not to allow the matrix to dry out. Stop using suction as soon as the support is divided into small pieces. When coupling ligands that might precipitate or be damaged by the presence of some residual solvent, the support should be quickly washed using several bed volumes of deionized water to remove the majority of acetone still present within the gel. Drain the support to a wet gel cake.
2. Dissolve the ligand to be coupled in 100 ml of a buffered solution at pH 7 to 9. As a guideline, proteins may be coupled at a concentration of 1 to 20 mg/ml or for small molecules, at a concentration of 1 to 5 mg/ml for an amine-containing ligand (or thiol-containing ligand). The optimal concentration of ligand that is used for the immobilization reaction should be determined experimentally to obtain the best performance of the affinity matrix after coupling. Suitable coupling buffers include 0.1 *M* sodium borate, pH 8.5, or 0.1- to 0.5-*M* sodium carbonate, pH 8.5 to 9. More physiological coupling conditions may also be used, such as 0.1-*M* sodium phosphate, pH 7.5, especially for molecules sensitive to higher pH conditions. Avoid buffers or solution additives that contain amines or thiols, such as DTT, 2-mercaptoethanol, glutathione, Tris, glycine, or imidazole, as these will compete with the ligand coupling reaction.
3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for at least 2 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. For ligands that have slower reaction kinetics with the FMP reactive group, the reaction time may be increased to overnight. In addition, when using conditions at a pH of less than 9, the reaction time can be extended to as much as 30 h to obtain maximal coupling yields. The reaction may be carried out at 4°C or at room temperature, depending on the stability of the ligand being immobilized.
4. Filter and wash the affinity support to remove uncoupled ligand and reaction byproducts using coupling buffer, water, 1-*M* NaCl, and again with water. Depending on the ligand being coupled, other wash solutions may be used to completely remove unreacted ligand, such as detergents, denaturants, and high or low pH conditions. Finally, store the affinity support in water containing a preservative at 4°C until used.

(B) NONAQUEOUS COUPLING PROTOCOL

1. In a fume hood, drain 100 ml of the FMP-activated support of excess acetone using a sintered glass filter funnel suspended in a suction filter flask.

2. Dissolve the amine-containing ligand to be coupled in 100 ml of acetone (or another water-miscible solvent) at a concentration of 1 to 5 mg/ml, which is normally sufficient for the immobilization of a small organic compound. If a bifunctional spacer molecule is to be coupled to the activated gel, such as a diamine compound, then much higher concentrations should be used (i.e., 0.5–1.5-*M*) to avoid internal crosslinking of the support during the reaction. The optimal concentration of ligand to be used in the coupling reaction should be determined experimentally on small quantities of activated support to identify the best affinity support performance in its intended application. Add an organic base to the ligand solution, such as DMAP, DIEA, or TEA, to make a final concentration of 2-m*M*.
3. In a suitable vessel, mix the activated wet gel cake with the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for 1 to 2 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. Longer reaction times may be used if needed to obtain maximal yields, if appropriate.
4. Transfer the gel slurry to a clean sintered glass filter in the fume hood that is suspended in a suction filter flask and wash it extensively (at least 10 bed volumes) with solvent to remove the remaining ligand and reaction byproducts. Wash with considerably more solvent if the initial concentration of ligand or spacer molecule in the reaction medium was particularly high. If the ligand is easily detectable in the filtrates, continue to wash the support until no further ligand is detected in the washings. Finally, drain the support of excess solvent by pulling a gentle vacuum on the filter flask while breaking up the support into small, finely divided pieces using a spatula, but be careful not to allow the matrix to dry out. Once the support is broken into small pieces, remove the vacuum and resuspend the gel in water with mixing. Continue to wash the support with water until all traces of solvent have been removed. Additional washes with 1-*M* NaCl as well as low and high pH conditions may be done as appropriate to remove any noncovalently bound ligand molecules. Finally, wash with water and store the affinity support as a 50% slurry in water containing a preservative at 4°C until used.

Activation Using Organic Sulfonyl Chlorides

Organic sulfonyl chlorides are activating agents that can facilitate the conjugation of hydroxyl-containing compounds to other nucleophiles, particularly amine-containing ligands. They have also been used in organic synthesis for many years (Tipson, 1944; Brown *et al.*, 1967; Beard *et al.*, 1973; Kabalka *et al.*, 1986; Whitaker *et al.*, 2006) and were first applied to the immobilization of ligands onto hydroxylic chromatography supports by Nilsson and Mosbach (1980) (also see Nilsson and Mosbach, 1981, 1984; Nilsson *et al.*, 1981). Perhaps the most well-known organic sulfonyl chloride compounds used for synthesis are 4-toluenesulfonyl chloride, which also is referred to as tosyl chloride or TsCl (or TosCl), and methanesulfonyl chloride (also called mesyl chloride or MsCl). The sulfonyl chloride group of TsCl or MsCl can react with a hydroxyl or an amine to form a sulfonyl ester or a sulfonamide group, respectively (Carey and Sundberg, 2007) (Figure 15.54). The sulfonyl ester formed with hydroxyls is further reactive with other nucleophiles, such as amine-containing affinity ligands, to facilitate their covalent linkage to activated chromatography supports.

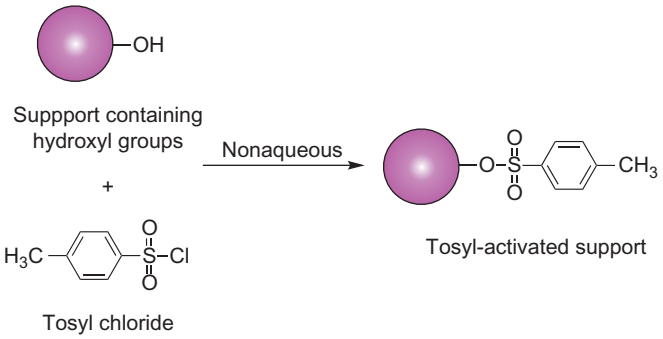

FIGURE 15.54 Activation of a hydroxylic matrix with TsCl to form reactive sulfonate esters.

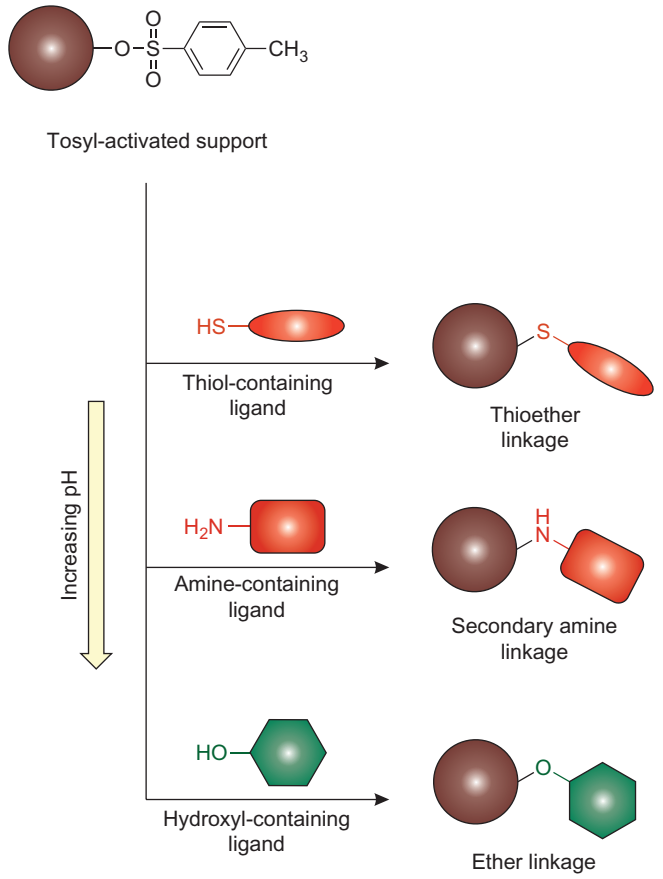
Tosyl chloride (*p*-toluenesulfonyl chloride)

Mesyl chloride (methane sulfonyl chloride)

Sulfonate esters that are formed from the activation of hydroxyl groups on chromatography supports with TsCl create particularly good leaving groups, which get displaced as an amine-containing ligand couples to the matrix (Figure 15.55). In this case, the reaction essentially converts the hydroxyl on the support to a secondary amine derivative that bonds the ligand to the matrix. Tosylates also can react with other nucleophiles, such as with hydroxyl groups under higher pH conditions (as the alkoxide, RO^-) to form ether linkages, with thiols (as the thiolate anion RS^-) to form thioether bonds, and also under alkaline conditions with OH^-, which causes hydrolysis back to the hydroxyl. Reaction with these groups in nonaqueous conditions requires the presence of an organic base to act as a proton acceptor to catalyze the coupling.



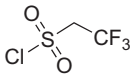


FIGURE 15.55 Reactions of active tosylates with amines, thiols, and hydroxyls.

The attack of a nucleophile on a sulfonate ester can occur through one of two reaction mechanisms, S_N1 or S_N2, the path of which may be governed by the solvent environment and the chemical groups immediately adjacent to the ester (Cremlyn, 1996; James and Cremlyn, 2002). The normal site of nucleophilic attack is on the carbon atom attached to the sulfonyl ester, which causes cleavage of the ester with concomitant bond formation of the nucleophile to the carbon atom. However, it has been demonstrated that nucleophilic attack can also occur onto the sulfur atom of the sulfonyl ester, which in this case may cause displacement of the constituent attached to the sulfonate opposite to the ester. The result of this reaction is the formation of a sulfonamide linkage with amine nucleophiles and retention of the sulfonate onto the originally activated hydroxyl group on the matrix (Figure 15.56).

Using TsCl or MsCl, the alternative reaction product consisting of a sulfonamide is an extremely minor side reaction that may not occur to any appreciable extent when immobilizing amine-containing ligands. Nevertheless, the reaction mechanism for coupling ligands using tresyl chloride (2,2,2-trifluoroethanesulfonyl chloride) has been found to be quite different. Tresyl chloride was first used for organic synthesis reactions by Crossland *et al.* (1971) and later employed for the activation of agarose chromatography supports by Mosbach and Nilsson (1981). It was Crossland *et al.* (1971) that demonstrated that the reaction of a tresyl ester with an amine compound resulted in the loss of 2,2,2-trifluoroethane sulfonate as the leaving group. This reaction process was believed to be true for tresyl-activated hydroxylic chromatography supports, as well (Nilsson and Mosbach, 1981). However, it subsequently was discovered that the actual reaction mechanism leads to the formation of a sulfonamide linkage on the matrix with an amine-containing ligand, not a secondary amine linkage as in the use of tosyl chloride coupling (Demiroglou and Jennissen, 1990; Demiroglou *et al.*, 1994). Careful elemental analysis indicated that the sulfur atom remains behind and the fluorine atoms are released in the immobilization process. In addition, the reaction of a thiol-containing ligand was found to yield a thiosulfate ester bond, which can have avid binding characteristics toward some proteins in affinity separations, particularly antibodies (Hutchens and Porath, 1986; Scoble and Scopes, 1997; Hansen *et al.*, 1998) (Figure 15.57).

The unique reaction mechanism of tresyl ester-activated supports may be due to the presence and strong electron-withdrawing properties of the trifluoro group. This may create a more powerful electrophilic center at the sulfur atom than that normally produced at the carbon atom when using tosyl ester-mediated activation and coupling. Thus, an attack by a nucleophile such as an amine would occur at the sulfur atom center of the sulfonate group instead of at the carbon atom immediately adjacent to the ester, which in turn would cause displacement of the trifluoroacetyl group. Under basic conditions with an abundance of OH^- ions, this group is further transformed after displacement within the reaction medium into acetic acid and three fluorine ions (F^-). In addition, the strong electron-withdrawing effects of the trifluoroacetyl group results in faster reaction kinetics for tresyl ester-activated supports than for tosyl ester-activated ones.

Sulfonyl chloride activation and coupling has been used for the immobilization of numerous affinity ligands onto hydroxylic supports of all types. In addition to its use in the activation of beaded chromatography supports, tosyl chloride has been used to activate partially hydrolyzed rayon/polyester cloth for the

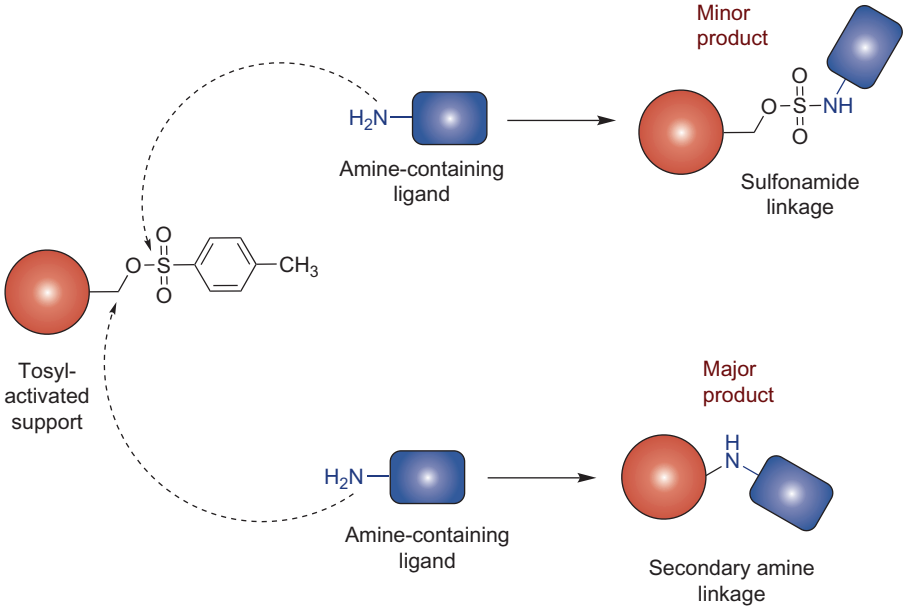

FIGURE 15.56 Alternative routes of nucleophilic attack on sulfonyl esters.

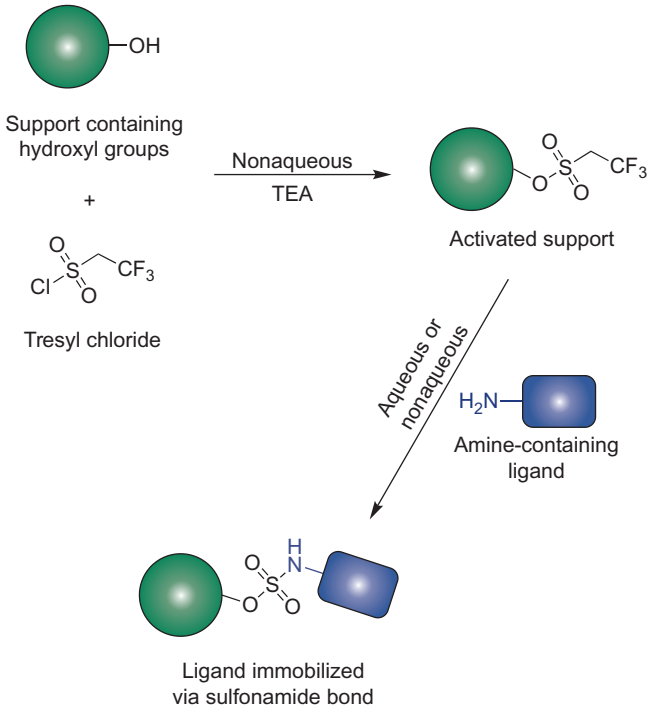

FIGURE 15.57 Tresyl chloride activation and coupling reactions.

coupling of antibodies and other proteins for purification of target molecules (Boyd and Yamazaki, 1993) as well as for the immobilization of Aspergillus oryzae β-galactosidase onto cotton cloth (Albayrak and Yang, 2002) and for the general coupling of amine nucleophiles onto cellulose (Heinze *et al.*, 2001). Even relatively inert membranes, such as polypropylene, have been modified using oxygen-plasma treatment to produce –OH functionalities and then activated with tosyl chloride for the coupling of peptides (Gérard *et al.*, 2011). In addition, tresyl chloride activation has been used to immobilize fibronectin onto titanium solid phases (Hayakawa *et al.*, 2003) and to couple antibodies onto PEG-modified particles for use in immunoassays (Chen *et al.*, 2009).

Still another alternative sulfonyl chloride compound to that of TsCl or tresyl chloride has been described for activation of chromatography supports. The reagent 4-fluorobenzenesulfonyl chloride (called fosyl chloride or fosCl) has been used to activate hydroxylic groups on polymeric supports for the coupling of proteins and other biomolecules (Chang *et al.*, 1992). It was found that the strong electron-withdrawing properties of the fluorobenzene group provides enhanced reaction rates for the activation and coupling steps over that of tosyl chloride.

SULFONYL CHLORIDE ACTIVATION PROTOCOL

The following activation protocol is a generalized procedure for the use of tosyl chloride to activate hydroxyl groups on beaded chromatography supports. Other sulfonyl chloride compounds may be used under similar conditions, such as tresyl chloride, mesyl chloride, or fosyl chloride. The activated support may be used to couple amine-containing affinity ligands and proteins as well as thiol-containing and hydroxyl-containing molecules. All procedures should be carried out in a well-ventilated fume hood to avoid exposure

to potentially toxic or reactive compounds and solvent fumes. The use of a sintered glass filter funnel suspended in a suction filter flask can facilitate the washing steps.

1. Wash 100 ml of a hydroxyl-containing chromatography support (such as crosslinked agarose, Toyopearl, or Trisacryl resin) with water (at least several bed volumes) to remove preservatives and storage solution components. In a fume hood, sequentially wash the support into increasing concentrations of acetone-in-water (such as 25% (v/v), 50%, and 75% acetone/water). Finally, wash with 100% dry acetone for at least 10 to 20 bed volumes to remove the last traces of water. Drain the support to a wet gel cake and then pull a gentle vacuum on the filter funnel while breaking up the gel cake with a spatula to obtain moist, evenly divided pieces, which still contains acetone within the internal pores of the beads. Be careful not to allow the support to dry, as this will cause particle collapse and irreversible damage to the pore structure of some matrices. Remove the vacuum as soon as the support is fully divided into small pieces (it will look like moist, fluffy snow). Note: alternative solvents can be used for the activation process including dioxane, DMF, DMAC, or DMSO, which can be substituted for acetone depending on the compatibility of the matrix to a particular solvent. For example, some supports such as dextran will maintain their swollen particle nature best in solvents such as DMSO or DMF, whereas acetone will cause them to unacceptably shrink and restrict access to the inner pore structures for activation. Whichever solvent is used for the activation reaction, it should be anhydrous to prevent decomposition of the sulfonyl chloride by hydrolysis.
2. In the fume hood, dissolve 11.75 g of tosyl chloride (61.6 mmoles) in 100 ml of dry acetone with stirring. If an alternative sulfonyl chloride activating agent is to be used, add an equivalent mole quantity to the acetone solvent, and dissolve with mixing.
3. Add the acetone wet gel cake to the tosyl chloride solution with stirring to uniformly resuspend the support. Add 123 mmoles of an organic base as a proton acceptor to catalyze the activation by taking up generated HCl from the sulfonyl chloride as it reacts with the hydroxyls on the support. Suitable bases include pyridine, triethylamine (TEA), diisopropylethylamine (DIEA), or dimethylaminopyridine (DMAP). Mix the gel suspension using an overhead paddle stirrer or by end-over-end rocking in a sealed container within the fume hood.
4. React for 1 h at room temperature with mixing.
5. In the fume hood, wash the activated support with acetone to thoroughly remove excess reactant and reaction byproducts. Wash with at least 10 bed volumes of solvent to ensure removal of the last traces of unreacted tosyl chloride.
6. Store the tosyl ester-activated support as a 50% slurry in dry acetone at 4°C until use.

LIGAND COUPLING TO SULFONYL CHLORIDE-ACTIVATED SUPPORTS

The following methods are generalized procedures for the immobilization of amine-containing ligands onto sulfonyl chloride-activated supports. Nonaqueous reactions may be carried out for small organic molecules or spacer arms that are soluble in organic solvent. Aqueous reactions are more appropriate for the coupling or proteins or other biological molecules that are soluble and stable in a buffered medium. Thiol-containing or hydroxyl-containing ligands may also be coupled to sulfonyl chloride-activated supports using similar protocols. Thiol-containing molecules will typically react faster than amines and will require buffers at the lower end of the pH spectrum described below. Hydroxyl-containing ligands, however, will need conditions at the high end of the pH range, as they are less nucleophilic at lower pH values.

(A) AQUEOUS COUPLING PROTOCOL

1. In a fume hood, drain 100 ml of the sulfonyl ester-activated support of solvent using a sintered glass filter funnel suspended in a suction filter flask. Gently pull a vacuum to remove most of the excess solvent while breaking up the support into small, finely divided pieces, but be careful not to allow the matrix to dry out. Stop using suction as soon as the support is divided into small pieces. When coupling ligands that might precipitate or be damaged by the presence of some residual solvent, the support should be washed quickly using several bed volumes of cold deionized water to remove the organic phase. Drain the support to a wet gel cake.
2. Dissolve the ligand to be coupled in 100 ml of a buffered solution at pH 8.5 to 10. Proteins may be coupled at a concentration of 1 to 20 mg/ml or for small molecules at a concentration of 1 to 5 mg/ml of an amine-containing ligand. The optimal concentration of ligand that is used for the immobilization reaction should be determined experimentally to obtain the best performance of the affinity matrix after coupling. Coupling buffers that may be used in this reaction include 0.1-*M* sodium borate, pH 8.5, or 0.2- to 0.5-*M* sodium carbonate, pH 9 to 10. If the ligand to be coupled is stable at the higher alkaline pH conditions, then the use of 0.25-*M* sodium carbonate, pH 9.5 will provide excellent coupling yields. Avoid buffers or solution

additives that contain amines, such as Tris, glycine, or imidazole, as these will compete with the ligand coupling reaction. If a tresyl-activated support is being used to immobilize ligands, then the reaction can be done in a sodium phosphate buffer at pH 7.5 to 8.0 (such as 0.2-*M* sodium phosphate, pH 7.5), because the reaction rate is much greater even at lower pH values.

3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for 24 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. The reaction may be performed at at 4°C or at room temperature, depending on the stability of the ligand being immobilized. Note that the reaction rate using tresyl-activated supports should be much faster than tosyl reactions, thus maximal coupling levels may be reached within 2 to 4 h. The exact time of the coupling reaction should be optimized for the best performance of the affinity support being produced.
4. Filter and wash the affinity support to remove uncoupled ligand and reaction byproducts using coupling buffer, water, 1-*M* NaCl, and again with water. Depending on the ligand being coupled, other wash solutions may be used to completely remove unreacted ligand, such as washing with detergent solutions, denaturants, and high or low pH conditions. Finally, store the affinity support in water containing a preservative at 4°C until used.

(B) Nonaqueous Coupling Protocol

1. In a fume hood, drain 100 ml of a sulfonyl ester-activated support of excess acetone (or other solvent) using a sintered glass filter funnel suspended in a suction filter flask. Do not allow the support to dry.
2. Dissolve the amine-containing ligand to be coupled in 100 ml of acetone (or another water-miscible solvent) at a concentration of 1 to 5 mg/ml, which is normally sufficient for the immobilization of a small organic compound. The optimal concentration of ligand to be used in the coupling reaction should be determined experimentally on small quantities of activated resin to identify the best affinity support performance in its intended application. For organic solvent-based reactions, add an organic base to the ligand solution, such as DMAP, DIEA, or TEA, to make a final concentration of 2-m*M*.
3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for 1 to 2 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. Longer reaction times may be used if appropriate.
4. Transfer the gel slurry to a sintered glass filter in the fume hood that is suspended in a suction filter flask and wash extensively with at least 10 bed volumes of solvent to remove the remaining ligand and reaction byproducts. If the ligand is detectable, continue to wash the support until no further ligand is detected in the washings. Finally, drain the support of excess solvent by pulling a gentle vacuum on the filter flask while breaking up the support into small, finely divided pieces using a spatula, but be careful not to allow the matrix to dry out. Once the support is broken into small pieces, remove the vacuum and resuspend the gel in water with mixing. Continue to wash the support with water until all traces of solvent have been removed. Additional washes with 1-*M* NaCl as well as low and high pH conditions may be done as appropriate to remove any noncovalently bound ligand. Finally, wash with water and store the affinity support as a 50% slurry in water containing a preservative at 4°C until used.

Azlactone-Activated Supports

An oxazolone is a heterocyclic anhydride that can be prepared from an *N*-acyl amino acid derivative through a dehydration and cyclization reaction. A particular type of oxazolone, an oxazol-5(4H)-one, is also known as an azlactone and consists of a five-membered ring that contains nitrogen and oxygen within its heterocyclic structure (see structure). Oxazolones have been used for many years in organic synthesis and have also become important constituents within organic compounds as potential drug candidates for a variety of applications in medicinal chemistry (Rao and Filler, 1986; Bala *et al.*, 2011). The creation of azlactone groups can be accomplished from carboxylic acids through the reaction of α-methyl alanine in a two-step process using a condensing agent as the catalyst. This process is a variant of the classic Erlenmeyer–Plöchl azlactone synthesis, which was described in the late 1800s to prepare oxazolones (Plöchl, 1884; Erlenmeyer, 1893). Under anhydrous conditions, a carboxylate will react with a condensing agent to form an activated intermediate, which then goes on to react with the amine of α-methyl alanine to form an amide linkage (an *N*-acyl amino acid derivative). This intermediate can undergo a subsequent condensation reaction through cyclization of the amino acid carboxylate end *via* dehydration, which results in the azlactone functionality being formed (Figure 15.58). Suitable condensing agents to drive this reaction include anhydrides, alkyl chloroformates, and carbodiimides in a nonaqueous environment. A preferred cyclization agent is acetic anhydride, which can be used as the solvent to form the azlactone functional groups on a dry carboxylate-containing

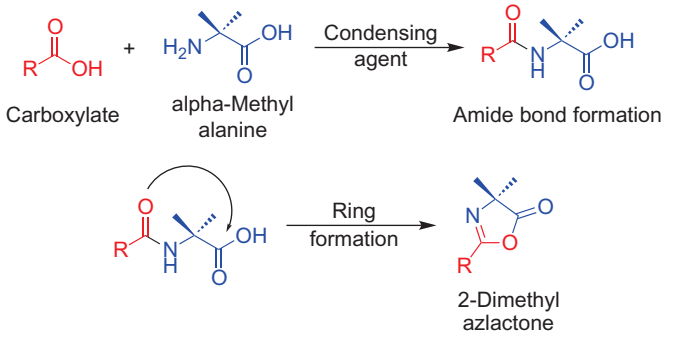

FIGURE 15.58 Formation of an azlactone from a carboxylate and α-methyl alanine in the presence of a cyclization catalyst.

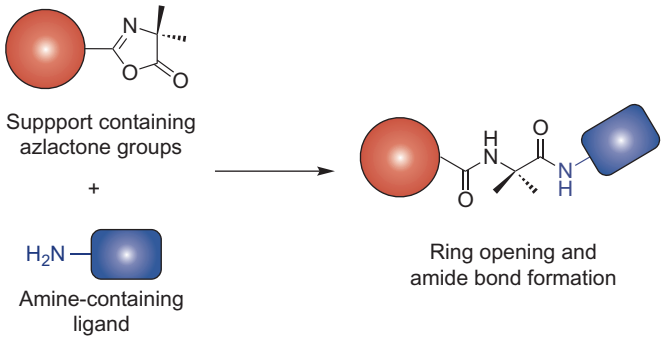

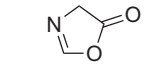

FIGURE 15.59 Reaction of an α-methyl alanine-containing azlactone with an amine.

support material. The reaction proceeds at 80 to 100°C by mixing for 2 h.

General structure of an azlactone (oxazol-5(4H)-one)

The formation of similar cyclic azlactones on carboxylate-containing chromatography supports can be used to create electrophilic reactive groups that can be exploited for the immobilization of amine-containing (nucleophilic) ligands. The creation of solid support materials containing azlactone reactive groups was first described by 3M Corporation (U.S. patents 4,871,824 and 4,737,560; Coleman *et al.*, 1990; Hermanson *et al.*, 1995). To eliminate the potential for nucleophilic attack on the azlactone C4 site, the amino acid used to form the azlactone should contain substitutions on the C4 carbon. A particularly convenient choice of amino acid in this regard is α-methyl alanine (or 2-dimethyl glycine). The two methyl groups prevent substitution at the C4 carbon after ring formation and therefore direct all nucleophile coupling reactions at the C5 position, which results in the desired ring opening process combined with amide bond formation with an amine-containing molecule (Figure 15.59).

Polymeric chromatography supports containing azlactone groups may be created more conveniently at the time of resin production through the use of an azlactone-containing vinyl monomer in a copolymerization reaction with other monomers. The reactive monomer vinyldimethyl azlactone (or 2-vinyl-4,4′-dimethylazlactone) has been used along with *N,N′*-methylene bisacrylamide as a crosslinking monomer to create polymeric beaded particles for affinity chromatography (Coleman *et al.*, 1990; Stanek *et al.*, 2005) (Figure 15.60). This route of polymer formation yields a reactive support immediately upon

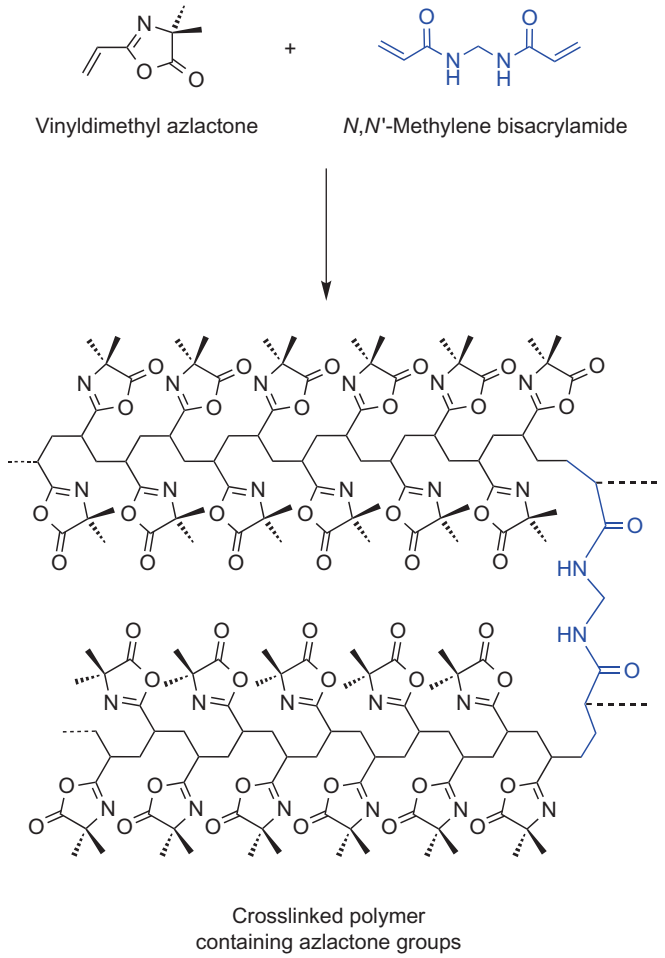

FIGURE 15.60 Synthesis of azlactone beads from vinyldimethyl azlactone and methylene bisacrylamide.

manufacture without the need to create a carboxylate support first and then activate the carboxylates to azlactones. The degree of reactivity in such polymers may be modulated by controlling the ratio of the azlactone-containing monomer to the other non-functionalized monomer(s) present in the final support. Using this

method, particles have been made that contain from approximately 100 μmoles/ml of azlactone groups up to a level of about 300 μmoles/ml, depending on the percentage of vinyldimethyl azlactone used in the copolymerization process. This type of support was previously commercialized under the Emphaze name through 3M and Pierce, and it now is available under the UltraLink name from Thermo Scientific (Pierce).

Supports prepared with azlactone groups should be stored in anhydrous organic solvent or kept dried as a stabilized particle powder to prevent hydrolysis of the reactive groups. Although the hydrolysis rate of the azlactone ring is slow during coupling reactions compared to the rate of ligand immobilization, the continuous exposure of the activated support to an aqueous environment will still degrade the reactive groups over time. Drying supports often requires the addition of excipients to stabilize the particles to prevent irreversible collapse or pore size damage. The UltraLink support is dried from a solution containing a small amount of detergent to decrease surface tension and allow rapid rehydration within the internal pore structures of the beads upon the addition of the dry support to a reaction medium. Therefore, ligand coupling reactions can be performed simply by means of the measured addition of the activated support to the appropriately buffered ligand solution and mixed to uniformly distribute the particles throughout the solution. Amine-containing ligands such as proteins can react with azlactone groups in a buffered environment over a pH range of 4 to 9, and even more extreme pH conditions may be used for coupling spacer arms or small organic molecules that are stable to highly alkaline conditions. For instance, coupling a diamine spacer to an azlactone-activated support can be done at a concentration of 0.5 to 1.5-*M* without pH adjustment (pH >12) to accelerate the reaction and increase immobilization densities. Ligand coupling to the azlactone groups results in the formation of amide bonds with formation of a short spacer arm created from the ring opening process (Figure 15.59). A comparison of the coupling of protein A, protein G, protein A/G, avidin, and streptavidin using two different buffers at pH 7.5 and pH 9.0 was made by Hermanson *et al.* (1995). In general, higher coupling yields were observed at pH 9.0 for three different ligand loading levels in each immobilization reaction.

An azlactone-activated support can have an initial degree of hydrophobic character due to the presence of the heterocyclic reactive groups. Many hydrophilic charged molecules such as proteins have difficulty approaching close enough to the activated support surfaces to facilitate efficient coupling using reasonable reaction times. This problem can be overcome through the use of buffer additives that are lyotropic in nature and which can have the effect of salting out and pushing the proteins closer to the surfaces for coupling. Suitable lyotropic salts for this purpose can be chosen from the Hofmeister series, such as the addition of sodium sulfate to the coupling buffer at a concentration of 0.8 to 1.5-*M*. The salt concentration should be adjusted to maintain protein solubility while maximizing the rate of immobilization to the support. Using these conditions, the immobilization reaction can be complete within 1 h and achieve maximal yields. Protein A has been coupled to azlactone-activated supports at densities of over 30 mg/ml and immunoglobulins have been immobilized to levels of over 20 mg/ml. After the coupling reaction is carried out, any excess reactive groups should be blocked using a small molecule such as ethanolamine. Once an affinity support is prepared using these methods, the support material reverts to a hydrophilic surface with relatively low nonspecific binding potential to the matrix itself.

Azlactone activation has been used for the coupling of affinity ligands to beaded chromatography supports (Coleman *et al.*, 1990; Hermanson *et al.*, 1995; Stanek *et al.*, 2005), for the immobilization of ligands onto various polymeric constructs (Laquièvre *et al.*, 2012), for modification and subsequent immobilization onto surfaces (Lokitz *et al.*, 2009), and to couple enzymes to monolithic supports for use in microfluidic devices (Logan, 2007). Surface polymer scaffolds have also been built to immobilize affinity ligands using multilayer copolymers incorporating vinyldimethyl azlactone groups (Barringer *et al.*, 2009). The use of the vinyl monomer is advantageous in creating copolymer constructs of many different structures as well as for photografting azlactone-reactive groups onto existing materials for immobilization of amine-containing biomolecules.

LIGAND COUPLING TO AZLACTONE-ACTIVATED SUPPORTS

The following procedure describes a generalized method for the coupling of protein affinity ligands to 10 ml of an azlactone-activated beaded chromatography support. Similar methods may be used to immobilize biomolecules onto activated membranes, surfaces, or monolithic supports containing azlactone groups. Two additional procedures are subsequently presented that describe methods for coupling small amine-containing molecules, such as organic ligands and spacer arms, using aqueous or nonaqueous conditions.

(B) Protein Immobilization onto Azlactone Supports

1. Dissolve the protein to be immobilized at a concentration of 1 to 20 mg/ml in 20 ml of coupling buffer (sufficient for coupling to 10 ml

of swollen azlactone beads) consisting of 0.1-*M* buffer concentration and at a pH range of 4 to 9. Most proteins react best at the high end of the recommended pH range, but some optimization might have to be carried out to obtain the best coupling yield and affinity ligand performance for a particular protein to be coupled. Also add to the coupling buffer a lyotropic salt to enhance the rate of protein coupling to the azlactone-activated support. A suggested coupling buffer is 0.1-*M* sodium carbonate, pH 9.0, with the addition of 0.6-*M* sodium citrate as the lyotropic agent. An alternative lyotrope that may be used is sodium sulfate at a concentration of 0.8-*M*. A more neutral pH coupling buffer that has been used successfully is 0.1-*M* sodium phosphate at pH 7.5, containing 0.6-*M* sodium citrate or 0.8-*M* sodium sulfate. The concentration of the lyotropic salt may be lowered for proteins that have solubility issues at the recommended concentrations; however, the recommended levels for sodium citrate or sodium sulfate have been found to work well for antibody (IgG) immobilizations, for avidin or streptavidin, as well as for the coupling of immunoglobulin binding proteins such as protein A or protein G to an azlactone support. In addition, other buffer components may be used to stabilize the protein in the reaction medium at different pH levels, but avoid additives that contain amines or other nucleophiles that would compete with the reaction—for example, Tris, imidazole, thiol reducing agents, glycine, and ammonium ions. If the activated particles are added as a dry powder, prepare enough ligand solution to equal at least twice the volume of the hydrated beads. This volume is required because half of the ligand solution volume will be used to hydrate and fill the pore structure of the particles, while the other half will create a 50% slurry for efficient mixing. If the support is in a hydrated state prior to addition of the ligand solution, then prepare an equal volume to the amount of swollen support used.

2. Measure out a quantity of dry azlactone-activated particles corresponding to exactly half the volume of the ligand solution prepared in step 1—in this case, weigh out the equivalent of 10 ml of beads. For instance, a typical batch of UltraLink azlactone-activated beads has a swelling ratio of approximately 120 mg/ml hydrated gel (it varies slightly for each individual lot of manufactured particles, so refer to the lot-specific information to be precise). To yield 10 ml of hydrated beads, therefore, add 1.2 g of azlactone beads to the ligand solution with stirring to fully hydrate the particles and initiate the coupling reaction.
3. React with mixing for 1 to 2 h at room temperature using an overhead paddle stirrer or end-over-end rotation in a sealed container. The majority of protein coupling reactions will reach maximal yield in 1 h.
4. Wash the support with several bed volumes of water to remove excess reactants by using a sintered glass filter funnel suspended in a suction filter flask. Note that if the UltraLink support is used, it is supplied dry from the manufacturer with a small amount of Triton X-100 added to promote rapid rehydration within the pores. The presence of the detergent in the initial washings after coupling will prevent the accurate measurement of protein concentration by absorbance at 280 nm. However, the protein concentration that did not couple to the support may be determined by use of the BCA assay, which is detergent tolerant (Smith *et al.*, 1985). The measurement of the non-coupled protein in the washings can facilitate the determination of how much protein has coupled to the support by the difference between the amount of protein not coupled and the initial amount of protein used in the coupling reaction. Drain the support to a wet cake.
5. To block the remaining azlactone reactive groups, add 1 bed volume (10 ml) of 1-*M* ethanolamine, pH 9.0. Mix for 30 min. Note: Adjust the pH of the ethanolamine solution in a fume hood using the slow addition of 50% HCl while maintaining the solution on ice. Adjust to room temperature before using.
6. Wash the support with coupling buffer without containing the lyotropic agent, then wash extensively with 1-*M* NaCl and finally with water to completely remove unreacted molecules. Additional washes may be carried out using acid or basic pH conditions as well as employing the use of detergents or denaturants to ensure complete removal of any proteins still bound by noncovalent interactions. These additional wash conditions should be done only if the protein immobilized is stable to such environments and only if necessary to minimize the leaching of ligand molecules in subsequent chromatographic operations. Finally, store the affinity support in water or buffer containing a preservative at 4°C.

(B) Aqueous Coupling of Small Ligands or Spacers to Azlactone Supports

Affinity molecules may also be small organic compounds that can be immobilized onto an azlactone support through an available amine group. Additionally, amine-containing spacer arms may be coupled to the support to facilitate further derivatization or to create a different chemical functionality at its terminal end for subsequent coupling to a ligand through something other than an amine (e.g., a thiol). The aqueous coupling of small molecules to an azlactone support is performed somewhat differently from the coupling

methods typically used with proteins, because a lyotropic agent usually is not required to enhance the reaction rate and yield. Instead of using the salting out effect of a lyotrope to drive proteins toward the surface azlactone groups to enhance reaction rates, small-molecule coupling is improved through increased concentrations and higher pH conditions. Another caveat to consider is that if a molecule has more than one amine—as in diamine spacer arms, which makes multipoint attachment to the support more likely—then the concentration of ligand used during the reaction should be very high (i.e., 1.0–2.0 *M*) to prevent internal crosslinking or even bead-to-bead linking caused by both ends of the compound reacting with the support. In this case, the high concentration range encourages single point attachments by making it more likely that another molecule will react rather than a second site within the same molecule getting coupled. This is an especially important factor when coupling diamine spacers to any amine-reactive support, since the desired end product involves one amine getting immobilized and the other amine of the spacer remaining free for subsequent reactions. On the other hand, for spacer arms containing an amine on one end and another functional group, such as a carboxylate on the other end, the need for very high initial concentrations is not as important, since only one end of the molecule will be capable of coupling.

Coupling of Small Diamine Spacers

1. In a fume hood, dissolve a diamine spacer molecule, such as 3,3′-diaminodipropylamine (DADPA; also called *bis*(3-aminopropyl)amine), in water at a concentration of at least 1.5 *M*. When using diamines as the free base compounds (not as the hydrochloride salts), there is no need to adjust the pH once the solution is made. The pH will be extremely basic, but this will drive the coupling reaction to the azlactone groups on the support with higher efficiency (see additional information in the section on coupling spacer arms, this chapter). Prepare 20 ml of the diamine solution to react with 10 ml of hydrated azlactone beads.
2. Add 1.2 g of azlactone beads to the diamine solution with stirring to fully hydrate the particles and initiate the coupling reaction (this quantity is equivalent to 10 ml of particles once they are fully hydrated and swollen).
3. React for 1–2 h at room temperature with constant mixing by use of an overhead paddle stirrer or end-over-end mixing on a rotator (do not use a magnetic stirring bar).
4. Wash the amine-modified support using a sintered glass filter funnel in a fume hood. Wash extensively with water, 1-*M* NaCl, and again with water to remove excess diamine. Use 10 to 20 bed volumes of washes for each solution. The presence of amines on the support, which indicates successful coupling, can be monitored by reacting a small quantity of support with TNBS solution, which will give a bright orange color with primary aliphatic amines (see Chapter 2, Section 4.3). Store the amine support in water or buffer containing a preservative at 4°C.

Coupling Small, Water Soluble Amino Ligands

1. Dissolve an amine-containing ligand in 20 ml 0.1-*M* sodium carbonate, pH 9.0, at a concentration that will result in the desired density of affinity groups on the surface, which ultimately will be optimal for the chromatography application. For some ligands, such as peptides, the concentration may be in the range of 3 to 5 mg/ml of support. If a high density of coupling is desired, the concentration of ligand may be increased to at least double the amount of azlactone groups on the surface (i.e., 2 × 100 µmoles/ml).
2. Weigh out 1.2 g of azlactone beads (10 ml gel after hydration) and add them to the ligand solution with stirring.
3. React for 2 h to overnight at room temperature with constant stirring.
4. If the ligand was reacted at a level that would not couple to every azlactone group present on the support surface, then wash the support with several column volumes of water to remove the majority of remaining uncoupled ligand. Next, add to the support 10 ml of 1-*M* ethanolamine, pH 9.0, to block the remaining reactive groups. React for 1 h at room temperature with mixing.
5. Wash the support with coupling buffer and then with water, 1-*M* NaCl, and again with water to remove uncoupled ethanolamine and ligand. Wash with at least 10 to 20 bed volumes of each solution. Store the amine support in water or buffer containing a preservative at 4°C.

(C) Coupling Amine Containing Ligands in Organic Solvent

Some amine-containing ligands may be only sparingly soluble in aqueous buffer conditions. For this reason, it may be necessary to perform the immobilization reaction in organic solution to maximize the coupling yields and obtain an optimal affinity support. The following protocol describes an organic solvent reaction using azlactone particles (UltraLink). An important caveat is that the solvent chosen should maintain a swollen bead state so as not to restrict ligand access to the internal pore structures of the particles.

1. In a fume hood, dissolve an amine-containing ligand to be coupled in 20 ml of dry DMSO or DMF at a concentration of at least 2 to 5 mg/ml. The optimal

concentration of ligand in the immobilization reaction may have to be determined experimentally using small quantities of activated support and by varying the concentration of ligand to observe its affect on affinity chromatography performance. Other solvents may be used; however they should be water miscible and able to maintain a swollen bead state for the activated support.

2. Add 1.2 g of azlactone support (10 ml hydrated volume) to the ligand solution with stirring.
3. React for 1 to 2 h at room temperature with constant stirring.
4. Wash the support in a fume hood using a sintered glass filter suspended in a suction filter flask. Wash with at least 20 bed volumes of the organic solvent used for the coupling reaction. Continue to wash until no ligand is detected in the filtrate. Wash the support into water using progressively increasing concentrations of water in solvent (e.g., 30%, 70%) until 100% water is used. Wash with 100% water for at least 10 bed volumes to completely remove the last traces of solvent. Finally, store the affinity support as a 50% slurry in water or buffer at 4°C containing a preservative.

Cyanogen Bromide Activation

One of the first activation methods introduced for the coupling of affinity ligands to solid supports involves the use of cyanogen bromide (CNBr) to activate hydroxyl groups (Axen *et al.*, 1967). For many years, CNBr activation was the method of choice for coupling amine-containing ligands to agarose supports, especially for the immobilization of proteins. Pharmacia first commercialized CNBr-activated agarose in a dry form under the name CNBr Sepharose and the product is still sold by GE for affinity ligand immobilization. Meng *et al.* (2009) recently reported on methods for stabilizing CNBr-activated agarose in dry form, which preserves both the reactive group and the structure of the beaded support. Under alkaline conditions, CNBr reacts with the hydroxyl groups on a matrix to produce reactive cyanate esters and imidocarbonates (Figure 15.61). The relative yield of cyanate esters *versus* imidocarbonates may vary depending on the hydroxylic structure of the chromatography matrix. If closely spaced or adjacent hydroxyls mainly are present in the support, such as within dextran- or cellulose-containing matrices that contain many diols, then a cyclic imidocarbonate may become the predominate product. However, if primary hydroxyls or hydroxyls that are not immediately adjacent to one another are present within the support, such as in agarose matrices, then cyanate esters are the major product formed from the reaction (Kohn and Wilchek, 1982).

CNBr activation is highly versatile and has been used to activate hydroxyl groups on many different chromatography supports as well as on microparticles, nanoparticles, membranes, and even surfaces (Jurado *et al.*, 2002; Yavuz *et al.*, 2008; Arazawa *et al.*, 2012). The major disadvantages of using this coupling method are the high toxicity of the reagent (it emits hydrogen cyanide gas, which is deadly if inhaled), the potential for creating a positive charge on the support after ligand coupling due to the bond type that is formed (primarily an isourea linkage, which is positively charged at neutral pH), and the labile nature of the ligand linkage to the support (having a tendency to constantly leach immobilized ligands at levels higher than that observed using other coupling methods). The unfortunate disadvantages of using CNBr activation have led to a significant decrease in its use over the years and an increase in the use of alternative amine coupling chemistries that do not have these shortcomings.

CNBr-activated supports react with amine-containing ligands to potentially produce two linkages, depending on whether the starting activation form was

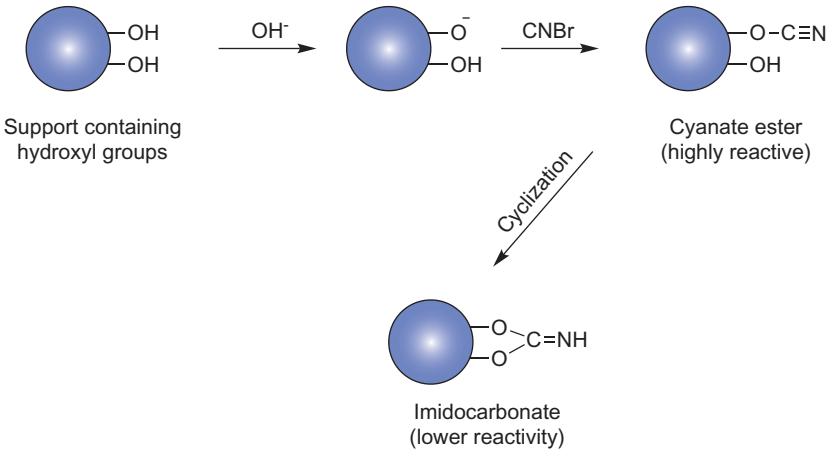

FIGURE 15.61 CNBr activation forming isocyanate and cyclic imidocarbonates.

a cyanate ester or a cyclic imidocarbonate. Cyanate esters rapidly react with amines under mildly alkaline pH conditions to form an isourea bond, whereas the cyclic imidocarbonate reactive group is far less reactive and couples with amines to create a substituted imidocarbonate linkage (Figure 15.62).

CNBr ACTIVATION PROTOCOL

The first procedure describes the original method reported by Cautrecasas (1970) of using titration with NaOH during the activation process to maintain the pH of the reaction. The second method describes the revised protocol of March *et al.* (1974), which involves reagent modifications that make the process easier to control. The reagent quantities may be proportionally scaled to activate different amounts of chromatography support materials. Read through the protocols thoroughly before setting up the activation reaction, because many of the steps are dependent on time, temperature, and pH, which all need to be controlled to result in successful and reproducible activation and coupling of an affinity ligand.

Caution: CNBr is highly toxic and may cause death if inhaled or ingested. Avoid contact with the solid compound and any solutions containing it. All operations should be carried out in a well-ventilated fume hood and using appropriate personal protective equipment. Dispose of all waste according to recommended safety protocols (see the product's MSDS data sheet for further details).

(A) Traditional Method: CNBr Activation using NaOH Titration (Cuatrecasas, 1970)

1. Wash the equivalent of 100 ml of settled chromatography support containing hydroxyl groups with 1 l of deionized water using a sintered glass filter funnel and a vacuum filter flask. Pull a gentle vacuum to facilitate the filtration process and collect all washes for proper disposal. After the wash, suction the support to a wet cake, stopping the filtration process by eliminating the vacuum at the point that the excess wash solution just enters the top of the gel. Do not allow the gel bed to get air within it or dry out at the top during the washing and filtering process. Note that if a monolithic support or a membrane is used in this procedure, then refer to the recommendations on handling these materials in Section 1 of this chapter.
2. Remove the washed and moist support from the filter funnel, transfer it to a beaker, and suspend it in 100 ml water by stirring. In a fume hood, set up an overhead paddle stirrer that will be used to mix the support during the activation procedure. Do not use a magnetic stir bar, as it will grind the support material and damage it. Insert a pH probe and a thermometer into the gel suspension to continuously monitor the pH and temperature during the activation reaction.
3. Prepare a 20% (w/w) solution of NaOH (i.e., 20 g/100 ml) by dissolving NaOH pellets in water or by dilution of a commercially available 50% solution. In addition, have available an ice bucket full of small, deionized ice chips to cool the reaction as it proceeds.
4. In the fume hood, weigh out 20 g of CNBr (**caution**: extremely toxic compound!) and add it to the stirring gel suspension. Maintain the pH of the reaction at pH 11 by dropwise addition of 20% NaOH solution. Also maintain the temperature of the reaction at about 25°C by periodic addition of crushed ice chips to the slurry.
5. Continue the activation reaction for 10 to 15 min at which point the CNBr should be completely

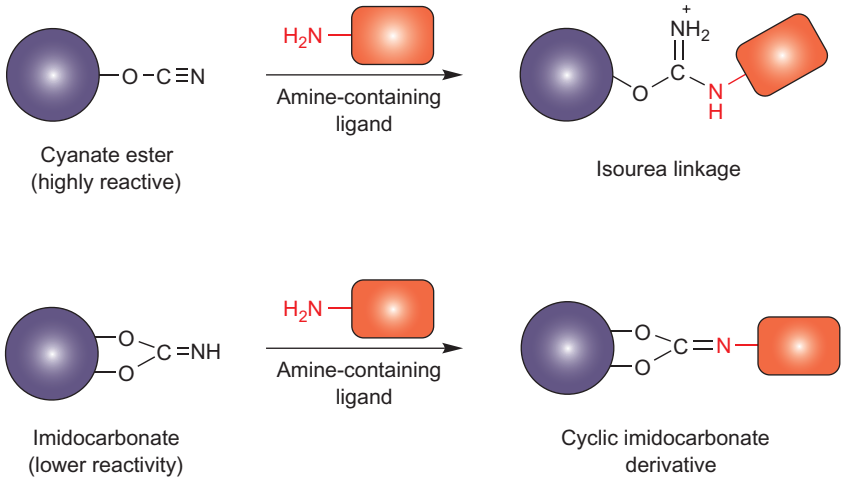

FIGURE 15.62 Ligand coupling to CNBr-activated supports.

dissolved and the rate of base consumption should be reduced. Transfer the activated support to a sintered glass filter funnel set up in the fume hood containing deionized ice chips to cool the reaction. Wash the support with 1 l of ice-cold deionized water followed by 500 ml of ice-cold 0.1-*M* sodium bicarbonate, pH 8.5 (coupling buffer). Drain the activated gel to a moist cake on the sintered glass filter pad.

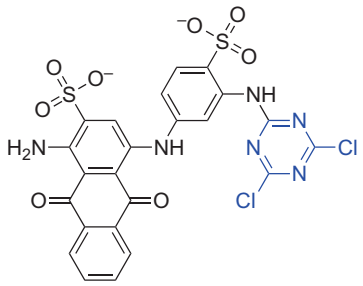
6. Use the activated support to immediately couple an amine-containing ligand according to the immobilization protocol described below.

(B) Alternative Protocol: 2-min CNBr Activation using Carbonate Buffer at Room Temperature (March et al., 1974)

1. Wash the equivalent of 100 ml of settled chromatography support containing hydroxyl groups with 1 l of deionized water using a sintered glass filter funnel and a vacuum filter flask. Pull a gentle vacuum to facilitate the filtration process and collect all washes for proper disposal. Next wash the support with several bed volumes of 2-*M* sodium carbonate (no pH adjustment required). After the carbonate wash, suction the support to a wet cake, stopping the filtration process by eliminating the vacuum at the point that the excess wash solution just enters the top of the gel. Do not allow the gel bed to get air within it or dry out at the top during the washing and filtering process. Note that if a monolithic support or a membrane is used in this procedure, refer to the recommendations on handling these materials in Section 1 of this chapter.
2. Remove the washed and moist support from the filter funnel, transfer it to a beaker, and suspend it in 100 ml 2-*M* sodium carbonate buffer by stirring. In a fume hood, set up an overhead paddle stirrer that will be used to mix the support during the activation procedure. Do not use a magnetic stir bar, as it will grind the support material and damage it. Stir the gel slurry at a rate that keeps the particles well mixed and suspended in the activation buffer.
3. In a well-ventilated fume hood, weigh out 10 g of CNBr (**caution**: extremely toxic compound!) and dissolve it in 5 ml of acetonitrile.
4. Add the CNBr solution to the stirring gel slurry and react for exactly 2 min at room temperature.
5. Immediately transfer the gel to a sintered glass filter in the fume hood and wash with 1 l of ice-cold water followed by 500 ml of ice-cold coupling buffer (0.1-*M* sodium bicarbonate, pH 8.5). Drain the activated gel to a moist cake on the sintered glass filter pad.
6. Immediately use the activated support to couple an amine-containing ligand according to the following protocol.

LIGAND COUPLING TO CNBr-ACTIVATED SUPPORTS

The following protocol describes the general method for coupling amine-containing ligands to a CNBr-activated chromatography support material. This process can be used successfully to immobilize proteins or other amine-containing affinity ligands as well as amine-containing spacer molecules. Avoid introducing any other amine-containing components into the coupling buffer during the reaction, such as Tris, glycine, ammonium ions, or other small molecules containing a reactive amine, as these will interfere with the desired immobilization of ligand. Amine reactions with CNBr-activated supports will occur efficiently between pH 8 and pH 9.5, so the coupling buffer pH may be modified somewhat to promote ligand stability or solubility if necessary.



Protocol

1. Suspend the CNBr-activated support in an equal volume of 0.1-*M* sodium carbonate buffer, pH 8.5 (coupling buffer), into which an amine-containing affinity ligand has been dissolved. For many protein ligands, a suggested starting concentration is 3 to 6 mg/ml. For low-molecular-weight ligands use a concentration at least 3 times greater than the level of CNBr activation. For the activation of agarose with CNBr, the typical activation level is about 20 to 40 µmoles/ml gel.
2. Mix the reaction slurry using a paddle stirrer for 24 h at 4°C.
3. Using a sintered glass filter funnel, wash the gel extensively with coupling buffer, then with 1-*M* NaCl, and water to remove excess unreacted ligand, which did not get immobilized.
4. Excess reactive groups on the matrix can be blocked by the addition of 1-*M* ethanolamine, pH 9, or 1-*M* Tris, pH 9. Suspend the washed gel in an equal volume of the blocking solution and stir for 1 h at room temperature.
5. Remove excess blocking agent by washing the affinity support extensively with 1-*M* NaCl and water. The final washes can be tested for the presence of amines through reaction with TNBSA, which will turn orange in solution upon coupling to aliphatic amines (see Chapter 2, Section 4.3). Finally, store the affinity support as a 50% slurry in water or buffer at 4°C containing a preservative.

Trichloro-s-Triazine (TsT) Activation

Cyanuric chloride or trichloro-*s*-triazine (TsT) is a trifunctional, symmetrical, heterocyclic aromatic compound that has been used for many decades as a reactive group in the construction of dyes for staining fabrics and articles of clothing. Dyes such as the Procion series react through covalent bonding of the dye to the

nucleophilic groups on the fabrics to create stable, nonfading, colored clothes (see structure of Procion Brilliant Blue). TsT can also be used to activate and form reactive groups on the surfaces of hydroxylic chromatography resins for the immobilization of affinity ligands. The three reactive chlorines of TsT potentially can covalently link to three separate nucleophilic groups on different molecules. The reaction of TsT in excess with the hydroxyl groups on chromatography support materials can result in two reactive sites remaining for coupling of amine-containing ligands. However, the reactivity of the triazine chlorine groups on TsT varies depending upon how many have already reacted. The first chlorine is the most highly reactive, and it can couple to the hydroxyls on supports under relatively mild conditions. The second reactive chlorine is able to couple with a nucleophile such as an amine, thiol, or even a hydroxyl group under slightly basic pH conditions with relatively rapid reaction kinetics. Finally, the last chlorine of TsT has the lowest reactivity, but it still can be used to couple with thiols or amines under mildly alkaline pH conditions and with hydroxyls under highly alkaline conditions. TsT activation has also been used to conjugate PEG molecules to proteins for the modulation of immunological properties (Abuchowski *et al.*, 1977) (Chapter 18, Section 2).

Procion Brilliant Blue

TsT activation of a hydroxyl-containing support such as agarose proceeds through loss of one chlorine (as HCl) with modification to the matrix through a hydroxyl by means of an ether linkage to the ring (Figure 15.63). If TsT is used in large excess, most of the active groups on the support will contain two remaining chlorines for coupling to affinity ligands. The activation process is best done under nonaqueous conditions to prevent hydrolysis of the TsT chlorines, and also while in the presence of two equivalents of organic base (e.g., DIEA) to accept the released protons produced during the process (Finlay *et al.*, 1978; Hodgins *et al.*, 1980). TsT-activated supports represent one of the few truly multi-purpose reactive groups—others being epoxides, iodoacetyl, and vinyl sulfones—that are able to couple with amine-, thiol-, and hydroxyl-containing ligands with success just by modulating the pH. In addition to the trichloro derivatives of triazine rings, the trifluoro derivatives have also been used with success for activation of support materials (Rerat *et al.*, 2010). The trifluorotriazine reactions proceed analogously to the use of TsT in the methods presented in this section.

After the initial activation of a support with TsT, the most reactive chlorine of the two remaining can be blocked with the relatively weak nucleophilic amine on aniline to create a monofunctional derivative. The last remaining chlorine of the cyanuric chloride ring is the most stable to hydrolysis, but it is still able to effectively couple to nucleophilic groups on affinity ligands under relatively mild conditions. The monofunctional derivative is best used for aqueous ligand coupling reactions with proteins or other biomolecules. However, ligands soluble in organic solvent may be coupled to the dichlorotriazinyl support (without blocking with aniline) and under nonaqueous conditions in the presence of an organic base to result in high-yield reactions devoid of any accompanying hydrolysis. Affinity ligands coupled

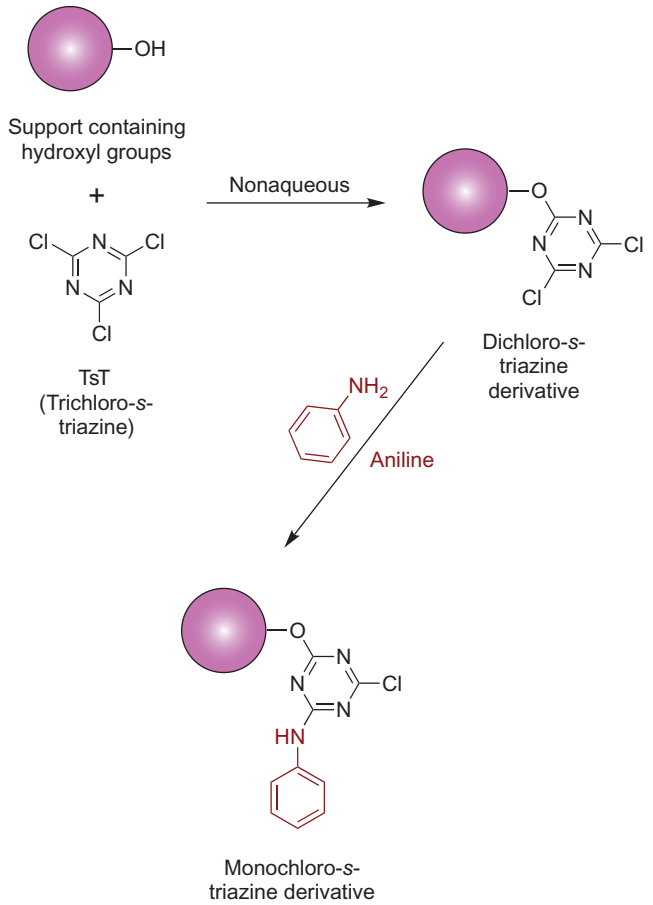


FIGURE 15.63 Activation of hydroxylic support with TsT and blocking with aniline to produce a mono-functional derivative.

using TsT activation result in more stable linkages relative to leakage than those coupled using CNBr activation (Hodgins *et al.*, 1980).

TsT mediated coupling has been used to immobilize a variety of biomolecules and synthetic organic ligands, including the coupling of peptides onto polypropylene membranes (Gérard *et al.*, 2011), a general activation method for the preparation of affinity membranes on polymers or carbohydrates (Avramescu *et al.*, 2008), as an activating agent of amino-substituted agarose to create rationally designed affinity ligands (Roque and Lowe, 2008), and as an activator of aminopropyl silica for the preparation of immobilized affinity ligands (Luong and Scouten, 2008).

TsT Activation Protocol

The following activation procedure should be carried out in a fume hood with the appropriate personal protective equipment to prevent contact or inhalation of solvents or reagents.

1. Wash 100 ml of a hydroxyl-containing chromatography support material (such as crosslinked agarose) with water (at least several bed volumes) to remove preservatives and storage solution components. In a fume hood, sequentially wash the support into increasing concentrations of acetone-in-water (such as 25% (v/v), 50%, and 75% acetone/water) and finally with 100% dry acetone for at least 10 to 20 bed volumes to remove the last traces of water. Note: Dioxane or acetonitrile can be substituted for acetone depending on the compatibility of the matrix to a particular solvent.
2. Drain the support to a wet gel cake, resuspend it in an equal volume of solvent by mixing, and transfer the slurry to a 500-ml, three-necked, round-bottom flask placed in a heating mantle within the fume hood. Mix the slurry using an overhead stirring motor with a paddle stirrer and add to the flask a water-jacketed condenser connected to cold flowing water and a thermometer.
3. In the fume hood, stir the gel slurry and heat to 50°C using the heating mantle to slowly increase the temperature. Use care not to overheat, as acetone boils at 56 to 57°C.
4. After the gel slurry has equilibrated at 50°C, add 20 ml of 2-*M* *N*,*N*-diisopropylethylamine (DIEA) in acetone. *N*,*N*-dimethylaniline may also be used as the proton acceptor, but avoid using organic bases such as TEA, pyridine, *N*-ethyl morpholine, or lutidine, because these will precipitate with TsT in the solvent (Hodgins *et al.*, 1980).
5. After 30 min of stirring, add 20 ml of 1-*M* TsT (highly purified) in acetone.
6. React for 1 h at 50°C with mixing.
7. In the fume hood, wash the activated support with acetone to thoroughly remove excess reactant and reaction byproducts. Wash with at least 10 to 20 bed volumes of solvent to ensure removal of the last traces of unreacted TsT and DIEA base.
8. Transfer the washed gel to a clean vessel and add 200 ml of 2-*M* aniline in acetone to block the most reactive chlorine on the triazine ring. Mix for 30 min at room temperature. Note: If the TsT-activated support is to be used to immobilize a solvent-miscible ligand, then it may be desirable not to block one of the two remaining acyl chlorides with aniline, because no hydrolysis will occur during the coupling reaction. If aniline blocking is not performed, then go to step 10.
9. Wash the TsT-activated support (now as the monochlorotriazine derivative) with at least 10 to 20 bed volumes of acetone to remove the last traces of unreacted aniline.
10. Store the activated support as a 50% slurry in dry acetone at 4°C until use.

TsT LIGAND-COUPLING PROTOCOL

TsT-activated supports that are stored in acetone or other anhydrous solvents may be used directly for coupling amine-containing ligands under nonaqueous conditions. In this case, a TsT-modified support that contains two remaining reactive chlorotriazine groups can be used (i.e., no blocking was done with aniline to eliminate the most reactive chlorine and leave only the least reactive one remaining). Alternatively, the activated gel may be filtered free of most solvent and reacted in aqueous buffer to couple proteins or other water soluble molecules. The following two protocols describe these methods in a general sense, but optimization should be performed to determine the best reaction conditions for a particular ligand and the optimal molar ratios for the best-performing affinity support. The reactions involved in coupling amine-containing ligands to TsT-activated supports are illustrated in Figure 15.64.

(A) Nonaqueous Coupling of Amine-Containing Ligands to TsT-Activated Supports

1. In a fume hood, drain 100 ml of the TsT-activated support of excess acetone (or other solvent) using a sintered glass filter funnel suspended in a suction filter flask. Do not allow the support to dry.
2. Dissolve the amine-containing ligand to be coupled in 100 ml of acetone (or another water-miscible solvent) at a concentration of 1 to 5 mg/ml, which is normally sufficient for the immobilization of a small organic compound. The optimal concentration of ligand to be used in the coupling reaction should be determined experimentally on small quantities of activated resin to identify the best affinity support

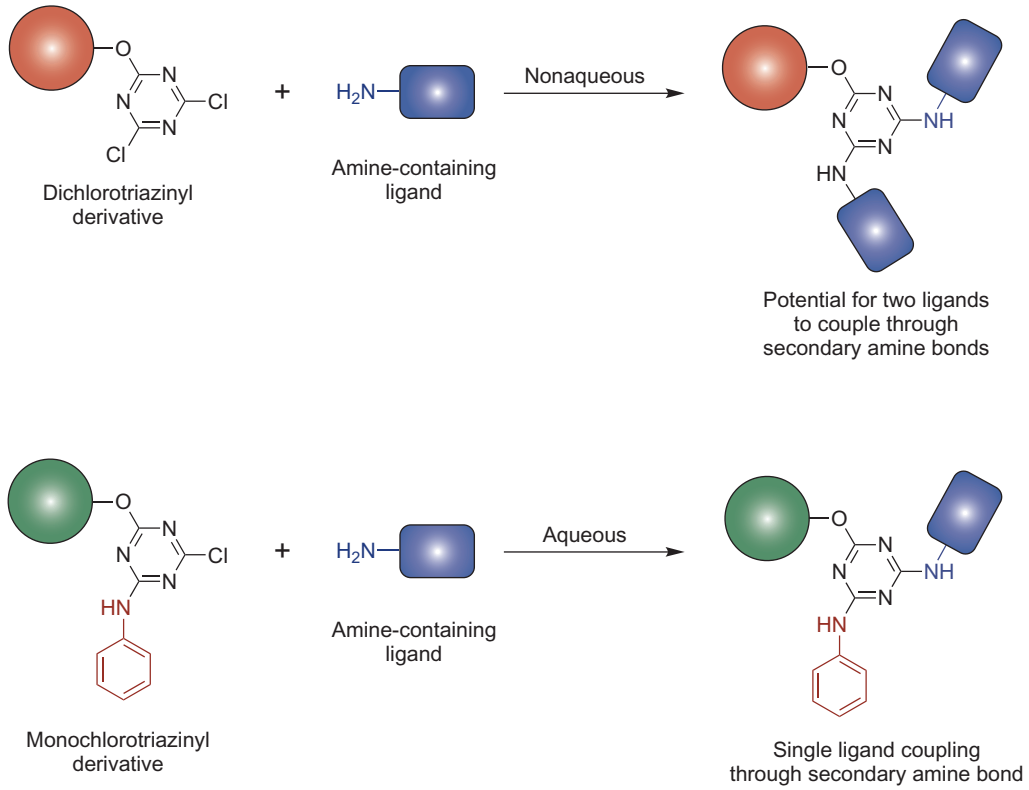

FIGURE 15.64 Coupling an amine-containing ligand to a TsT-activated support.

performance in its intended application. For organic solvent based reactions, add an organic base to the ligand solution, such as DIEA, to make a final concentration of 2-m*M*.

3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for at least 2 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. Longer reaction times may be done if appropriate to reach maximal yield of coupling.
4. Block unreacted active sites by the addition of ethanolamine (6.1 g) to the solution to make a 1-*M* solution. Mix for an additional 30 min.
5. Transfer the gel slurry to a sintered glass filter in the fume hood that is suspended in a suction filter flask and wash extensively (at least 10 bed volumes) with solvent to remove the remaining ligand and reaction byproducts. If the ligand is detectable, such as by using spectrophotometric methods, continue to wash the support until no further ligand is detected in the washings. Finally, drain the support of excess solvent by pulling a gentle vacuum on the filter flask while breaking up the support into small, finely divided pieces using a spatula, but be careful not to allow the matrix to dry out. Once the support is broken into small pieces, remove the vacuum and resuspend the gel in water with mixing. Continue to wash the support with water until all traces of solvent have been removed. Additional washes with 1-*M* NaCl as well as low and high pH conditions may be carried out as appropriate to remove any noncovalently adsorbed ligand. Finally, wash with water and store the affinity support as a 50% slurry in water containing a preservative at 4°C until used.

(B) Aqueous Coupling of Biomolecules to TsT-Activated Supports

1. Wash 100 ml of a TsT-activated support into water and coupling buffer by suctioning off excess acetone storage solution and resuspending the gel into water. This can be done by pulling a gentle vacuum on the filter flask to filter off solvent while breaking up the support into small, finely divided pieces using a spatula, while being careful not to allow the matrix to dry out. Once the support is broken into small pieces, remove the vacuum and resuspend the gel in water with mixing. Continue to wash the support with water for at least 5 to 10 bed volumes. Finally, wash the support with 2 to 3 bed volumes of coupling buffer (0.1-*M* sodium borate, pH 8.5, containing 0.15-*M* NaCl).
2. Dissolve the protein or other amine-containing macromolecule to be immobilized in coupling buffer at a concentration of 1 to 20 mg/ml, or for

small molecules, dissolve it at a concentration of 1 to 5 mg/ml. The optimal concentration of ligand that is used for the immobilization reaction should be determined experimentally to obtain the best performance of the affinity matrix after coupling. Avoid buffers or solution additives that contain amines, such as Tris, glycine, or imidazole, as these will compete with the ligand coupling reaction. Also avoid the presence of thiol-containing compounds such as DTT, because these will react with the chlorotriazine groups.

3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for at least 24 h at room temperature using an overhead paddle stirrer or by end-over-end rocking in a sealed container. The reaction may be performed at 4°C or at room temperature, depending on the stability of the ligand being immobilized; however, the coupling yield at 4°C is about 50% less than that at room temperature. For small-molecule reactions where the compound is thermally stable, the temperature may be increased to higher levels (i.e., as high as 45°C) to further increase the efficiency of the immobilization process.
4. Filter and wash the support with several bed volumes of water to remove most of the unreacted ligand and reaction byproducts. Transfer the support to a clean vessel and add 100 ml of 1-*M* ethanolamine, pH 9, with mixing to block the remaining active groups. Stir the reaction for 1 h at room temperature.
5. Filter and wash the affinity support to remove uncoupled ligand, blocking agent, and reaction byproducts using coupling buffer, water, 1-*M* NaCl, and again with water. Depending on the ligand being coupled, other wash solutions may be used to completely remove unreacted ligand, such as detergents, denaturants, and high or low pH conditions. Finally, store the affinity support in water containing a preservative at 4°C until use.

2.2. Thiol-Reactive Immobilization Methods

Although the majority of methods used to immobilize affinity ligands onto chromatography supports involve reactive groups that target amines, the use of site-directed chemistry that can target other functional groups such as thiols can have significant benefit in certain instances (Domen *et al.*, 1990). Thiols are typically present in proteins at more limited locations than amines and they can, therefore, be used to covalently link at selective sites within a macromolecule. Cystine disulfides in proteins also can be mildly reduced to provide thiol groups for coupling even if a protein in its native state does not have an available free thiol, such as in the reduction of disulfides within antibody hinge regions or in $F(ab')_2$ fragments (see Chapter 20). This strategy can result in the immobilization of proteins in areas away from binding sites or active centers, thus avoiding the blocking of these regions by being forced down toward the matrix during coupling instead of facing outward and available to interact with molecules in the mobile phase. Peptides can also be synthesized with a cysteine residue at one end of their amino acid sequences, thereby providing a functional handle to orient the immobilized peptide with the important binding end facing out from the support. Thiols can even be purposely added to proteins and molecules through the use of special modification reagents to facilitate subsequent coupling to a thiol-reactive support (see Chapter 2, Section 4.1).

The many choices available in thiol-specific immobilization reactions described in this section can provide important options in designing an affinity support with the best possible performance for a particular application. Some of the methods form permanent or stable linkages with thiol-containing molecules by creating thioether bonds. Other methods are capable of forming reversible linkages using disulfide bonds, which subsequently can be reduced to elute off the ligand from the support along with any interacting molecules. The following sections describe the most common methods used for support activation and coupling to thiol-containing ligands for affinity chromatography. The reader is also directed toward the various other sections within this book that describe bioconjugate reagents for use with thiols to better understand the chemistry of thiol reactivity and coupling.

Iodoacetyl and Bromoacetyl Activation

Haloacetyl compounds have been used for decades in the crosslinking, modification, and immobilization of thiol-containing molecules, especially for covalently linking to cysteine-containing proteins and peptides (Narayan *et al.*, 2004; Wilhelmsen *et al.*, 2004; Handlogten, et al., 2005; Kim and Hage, 2006a; Mallik *et al.*, 2007). The reactivity of this group has its origin in the electron-withdrawing properties of the carbonyl oxygen of the carboxylate (note that the iodine atom of iodoacetyl compounds has an electronegativity approximately equivalent to that of the carbon to which it is attached). This effect causes an electrophilic center of partial positive charge on the carbon atom attached to the halogen. Nucleophiles such as thiols containing an unshared pair of electrons can attack this carbon resulting in a potential nucleophilic substitution reaction, which causes displacement of the halogen with simultaneous formation of a thioether bond with the thiol-containing compound.

Iodoacetyl groups in particular have been used to immobilize affinity ligands on all types of solid phases,

including chromatography supports, nonporous particles, and planer surfaces for arrays (Camarero, 2006; Fu *et al.*, 2011). Once a support is activated to contain iodoacetyl groups it is relatively stable in aqueous solution, provided it is protected from light and reducing agents. Strong light exposure, especially sunlight, can cause the loss of the iodine atom (as HI) and rapidly eliminate coupling capacity. For this reason, activated supports should be stored in containers that prevent light transmittance to avoid this problem. Thiol-reducing agents can also react with the iodoacetyl groups and should be avoided, but even other reductants such as sodium cyanoborohydride, sodium borohydride, and phosphine reducing agents (e.g., TCEP) can liberate HI and destroy activity, as well.

Bromoacetyl groups can also can be used to create thiol-reactive support materials. All of the reactions described in this section relative to iodoacetyl groups and their synthesis apply to bromoacetyl chemistry, too. To use bromo- instead of iodo-derivatives, substitute bromoacetate for use of iodoacetate in the preparation of the activated support. The bromoacetyl group is more reactive than iodoacetyl, because the bromine atom is more electronegative than the iodine atom; however, in practice the two groups perform nearly identically in the immobilization of thiol-containing ligands onto chromatography supports. The iodoacetyl-activated supports are the most commonly cited in the literature for coupling thiol ligands.

Iodoacetyl groups can potentially react with any nucleophilic site in biomolecules or other ligands, including thiols, amines, and hydroxyl groups, depending on the conditions of the reaction. The product of the reaction is an alkylation of the ligand by the C2 carbon atom of the acetyl group, which forms thioether, secondary amine, or ether linkages with thiols, amines, or hydroxyls, respectively (Figure 15.65). Methionine thioether side chains are the most highly reactive toward alkylation and they can be modified even at acid pH conditions (pH 4.0) (Gundlach *et al.*, 1959). Reaction of an iodoacetyl group with methionine yields an unstable alkylation product, the carboxymethyl sulfonium salt of methionine, which subsequently can degrade by several routes into homocysteine, *S*-carboxymethyl homocysteine, or back to methionine (see Chapter 3, Section 2.1). Care should be taken using this method of coupling, therefore, if a methionine residue in a peptide or protein ligand represents a particularly important amino acid that must remain untouched by the immobilization process. Even if conditions are right to prevent amine or hydroxyl modification during the coupling of a thiol compound, the presence of methionine definitely may result in cross-reactions at this site.

Using iodo- or bromoacetyl-activated supports, thiols including cysteine will typically react under slightly alkaline conditions that involve the use of a buffer in the range of pH 8.0 to 8.5. In this range, amine reactivity will be very limited and hydroxyls will be virtually non-reactive. In fact, most protocols even make use of the amine-containing buffer Tris during the reaction, indicating that the specificity of the reaction toward cysteine thiols is very high. Increasing the alkalinity of the reaction can be used to purposely couple with amines (pH 10–12), while hydroxyls can be effectively targeted at pH > 12. Amine and hydroxyl group reactivity may also be accompanied by the covalent modification of one of the imidazole ring nitrogens of histidine as well as the phenolic hydroxyl group of tyrosine residues. Thus, iodoacetyl supports potentially are one of the few immobilization chemistries that can have multi-purpose immobilization selectivity—the others being epoxy, TsT, and vinyl sulfone, which are able to couple with a variety of nucleophilic functional groups depending on the conditions used during the reaction. However, the targeting of amines or hydroxyls in the presence of thiols is not possible, because thiols have greater reactivity and will always be modified under higher pH conditions (unless the thiols are protected beforehand). The greatest benefit of using iodoacetyl activation is the potential to chemoselectively target

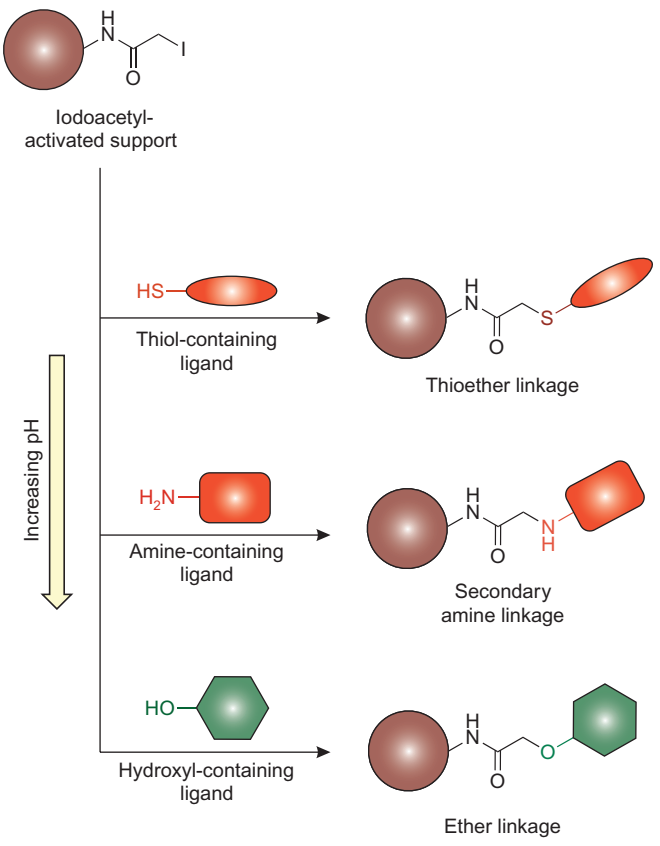

FIGURE 15.65 Reaction of an iodoacetyl-support with thiol-, amine-, and hydroxyl-containing supports.

only thiols (e.g., cysteines) at mild pH, thus leaving other functional groups alone.

Iodoacetyl supports are typically prepared from amine-containing matrices by coupling the carboxylate of iodoacetic acid to a terminal amine-containing spacer arm to form an amide bond. Thus, the initial step in the preparation of this support may be to modify an amine-reactive matrix with a diamine in large excess to form the terminal amino modifications suitable for reaction with iodoacetate. Many different diamine spacers can be used for this purpose, including diaminodipropylamine (DADPA), ethylene diamine (EDA; such as that used in the formation of MANAE supports), and the hydrophilic Jeffamine spacers containing short PEG groups (see the section on spacer arms, this chapter). The final coupling of the iodoacetate molecule onto the amino spacer can be performed using iodoacetic anhydride or NHS-iodoacetate, or through a carbodiimide (EDC) coupling procedure to attach the carboxylate to the amine through an amide bond. Mallik *et al.* (2007) prepared a thiol-reactive silica support using NHS–iodoacetate in the modification of an aminopropyl silane-coated silica particle (see Chapter 13, Section 2) to immobilize ligands for ultimate use in high-performance affinity chromatography (HPAC). The synthesis of a similar iodoacetate-agarose matrix made using the diamine spacer DADPA and attaching iodoacetate using EDC is described in the following protocol (Figure 15.66).

PREPARATION OF AN IODOACETYL-ACTIVATED SUPPORT

1. Prepare 100 ml of a DADPA-agarose support using periodate activation and diamine coupling through a reductive amination process as described elsewhere in this chapter in the section on the preparation of spacer arm derivatives. Wash the support with water and then with several bed volumes of 0.1-*M* MES buffer, pH 4.7 (coupling buffer). Drain to a wet cake, but do not allow the gel to dry.
2. Dissolve 12 g of iodoacetic acid into 100 ml of coupling buffer (makes a 0.645-*M* solution) and adjust the pH back to 4.7 with base. Protect the compound and the solution from light to prevent degradation of the iodoacetate. Note: Bromoacetic acid may be substituted for iodoacetic acid by adding an equal mole amount (8.96 g) to the reaction slurry.
3. Add the wet gel cake to the iodoacetate solution with stirring.
4. With stirring, slowly add 10 g of EDC to the slurry to dissolve. React for 2 h at room temperature with constant mixing using an overhead paddle stirrer or end-over-end rotation in a sealed container. Protect the slurry from light by wrapping the vessel in aluminum foil.
5. Filter off the excess reaction solution and wash the activated gel with water, 1-*M* NaCl, and water (at least 10 bed volumes each) to remove unreacted compound and reaction byproducts. Store the iodoacetyl–agarose support as a 50% slurry in water containing a preservative at 4°C until use. Protect the gel from light to avoid decomposition.

LIGAND COUPLING TO IODOACETYL-ACTIVATED SUPPORTS

The first method described below is a generalized protocol that can be used to immobilize thiol-containing ligands onto iodoacetyl-activated supports. Molecules containing free thiols are notoriously susceptible to

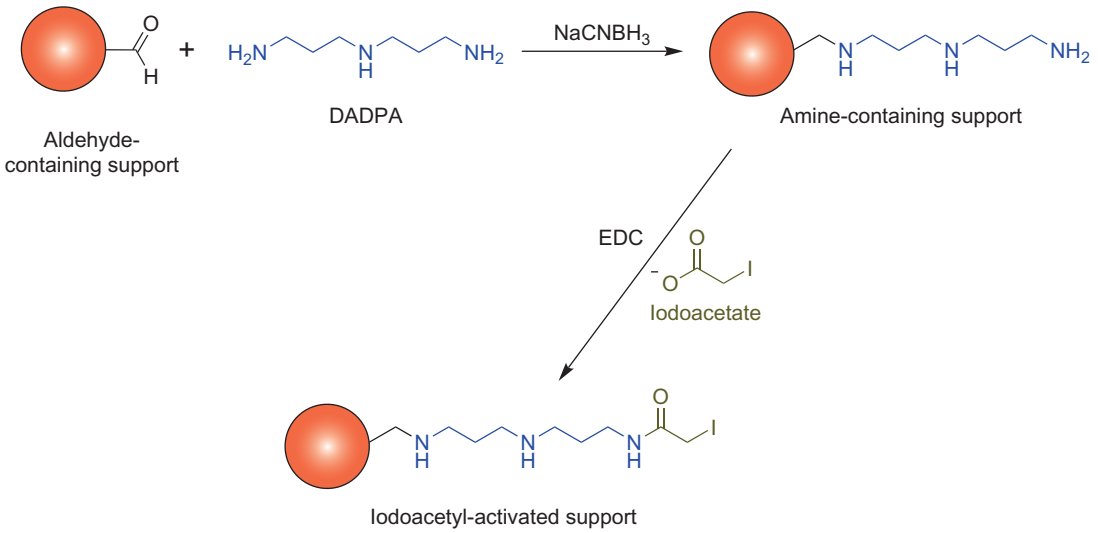

FIGURE 15.66 Synthesis of iodoacetyl–DADPA–agarose using reductive amination to link the diamine spacer followed by EDC coupling of iodoacetate onto the terminal amine group.

oxidation in solution. Cysteine-containing peptides should be dissolved in nitrogen-purged and vacuum-degassed buffer solutions containing EDTA (at least 5 to 10-m*M*) to avoid oxygen-catalyzed or metal-catalyzed oxidation of the thiols to disulfides. This oxidation process can take place very quickly in solution and result in virtually no coupling of ligand to the support material. In addition, after the reduction of protein disulfides to produce free thiols for coupling, the complete removal of the reducing agent is essential to prevent side reactions occurring with the iodoacetyl groups on the support.

The second procedure described below involves the conjugation of intact IgG or $F(ab')_2$ fragments to an iodoacetyl support after reduction of the disulfide linkages between the heavy chains (Figure 15.67). The immobilization of antibodies or antibody fragments through thiols can result in coupling to sites that are away from the antigen binding areas, thus potentially preserving activity better than when using amine-reactive strategies. Using intact antibodies, the reduction process will result in a number of free thiols being produced, the amount of which is dependent on the concentration of the reducing agent and the type of antibody. Often, antibodies are most susceptible to reduction at the disulfides in the hinge region between the heavy chains, but reduction may also occur between the heavy and light chains, which could result in disruption of the antigen binding site. High concentrations of reducing agents used with antibodies could result in the complete dissociation of the heavy and light chain fragments, and if this preparation is used during the immobilization reaction with an iodoacetyl support the result might be little to no specific binding activity after coupling. Therefore, controlling the amount of reductant added is important to the creation of thiols while not destroying the binding activity of the antibody toward antigen. After reduction, the amount of thiols present within the ligand to be immobilized can be determined using Ellman's reagent (see Chapter 2, Section 4.1).

(A) Coupling Thiol-Containing Ligands to Iodoacetyl-Activated Supports

1. Wash 10 ml of an iodoacetyl-activated support with water and then into coupling buffer using a sintered glass filter funnel suspended in a suction filter flask (coupling buffer: 50-m*M* Tris, 0.15-*M* NaCl, 10-m*M* EDTA, pH 8.5). The coupling buffer should be purged with nitrogen and degassed under vacuum to remove oxygen, which may oxidize the thiols and prevent coupling. Protect the activated resin and all solutions from light before and during the coupling reaction.

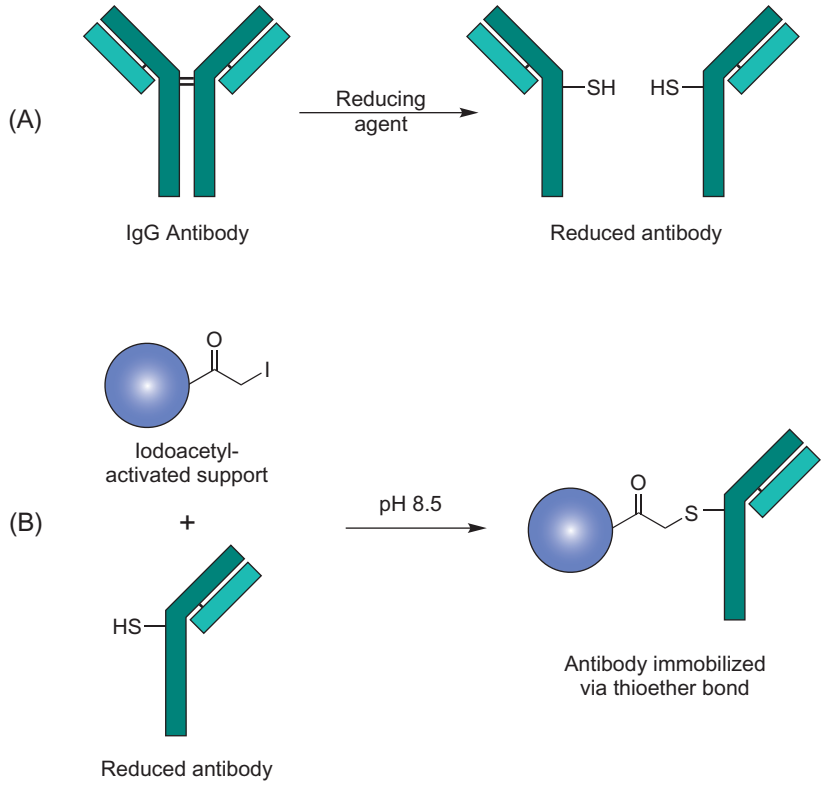

FIGURE 15.67 Reduction of antibody disulfides and coupling to an iodoacetyl-activated support.

2. Dissolve a thiol-containing ligand in 10 ml of coupling buffer at a concentration of at least 2 to 5 mg/ml. Determination of the optimal level of ligand concentration may be achieved experimentally by running a series of small reactions at different concentrations and determining which preparation performs best in the intended affinity chromatography application.
3. Add the ligand solution to the iodoacetyl-support and mix to thoroughly resuspend the resin in the solution. React for at least 1 h at room temperature (2–4 h at 4°C) with constant mixing.
4. Wash the gel with several bed volumes of coupling buffer to remove most of the excess uncoupled ligand. The amount of ligand not coupled may be determined by measuring the volume and concentration of the ligand in the pooled washes. This may be done using a protein assay or spectrophotometrically if the ligand has a characteristic spectral signature. The amount of ligand that has coupled to the matrix may then be determined by the difference. Drain the gel to a wet cake.
5. Block unreacted iodoacetyl active sites by adding to the gel 10 ml of a solution consisting of 50-m*M* cysteine (6.06 mg/ml) dissolved in coupling buffer. React for 30 min with stirring.
6. Wash the affinity resin thoroughly with water, 1-*M* NaCl, and again with water (at least 10 bed volumes each) to remove unreacted components. Store the support until use at 4°C as a 50% slurry in water containing a preservative.

(B) Coupling of Reduced IgG or F(ab')$_2$ Fragments to Iodoacetyl-Activated Supports

1. Dissolve 1 to 10 mg of an IgG antibody or F(ab')$_2$ fragment in 1 ml of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 5-m*M* EDTA, pH 6.0.
2. Add a reducing agent [such as DTT, 2-mercaptoethylamine (2-MEA), 2-mercaptoethanol (2-ME), or tris(carboxyethyl)phosphine (TCEP)] to the antibody solution to give a final concentration of at least 5-m*M*. Mix to dissolve and incubate for 1.5 h at 37°C. Note: Higher concentrations of the reducing agent are sometimes used (i.e., up to 50-m*M*), but the higher the concentration the more likely will be the reduction of disulfides between the heavy and light chains, which may disrupt the three-dimensional structure of the antibody and destroy antigen binding capability. Optimization of the reductant concentration may have to be done to ensure the best performance of the resultant immunoaffinity support.
3. Remove excess reducing agent from the antibody solution by desalting using size exclusion chromatography or by dialysis. During the chromatography or dialysis operation use coupling buffer consisting of 50-m*M* Tris, 0.15-*M* NaCl, 10-m*M* EDTA, pH 8.5, to equilibrate and elute protein through the gel filtration support or as the dialyzing solution. A gel filtration column should consist of at least 10 ml of a support having a molecular weight exclusion limit of no more than 5 to 10 kDa to ensure that the protein will come through in the void volume and be separated from the lower-molecular-weight reductant. A similarly sized dialysis membrane is appropriate. Complete removal of all reducing agent is essential to eliminate competition when coupling the reduced antibody to the iodoacetyl-activated support. Pool the fractions containing desalted protein peak from the gel filtration column or recover the dialyzed protein from the dialysis device. The solution may be concentrated if necessary using centrifugal concentrators to approximately 1 ml to maintain the desired concentration level of antibody in the coupling reaction.
4. Wash 1 ml of an iodoacetyl-activated support with water and then into coupling buffer by placing the resin into a drip column having a bottom porous frit and suspended in a test tube (coupling buffer: 50-m*M* Tris, 0.15-*M* NaCl, 10-m*M* EDTA, pH 8.5). If larger amounts of resin are used for the coupling reaction, then the use of a sintered glass filter funnel suspended in a suction filter flask is more appropriate for the washing steps. The coupling buffer should be purged with nitrogen and degassed under vacuum to remove oxygen, which may oxidize the thiols and prevent coupling. Protect the activated resin and all solutions from light before and during the coupling reaction.
5. Mix the washed iodoacetyl support with the reduced antibody solution and react in a sealed tube by gentle rotation for 1 h at room temperature. The tube should be wrapped in aluminum foil to prevent degradation of the iodoacetyl groups before the coupling reaction has occurred. If the antibody is sensitive to mixing, the tube can be rotated for the first 15 min and then allowed to incubate without continuous rotation. Every 5 min, gently resuspend the gel in the coupling solution to maintain a homogeneous slurry.
6. Wash the support with several bed volumes of coupling buffer to remove most of the not-coupled antibody. The washes may be analyzed *versus* the initial concentration of the antibody solution before coupling to determine the amount immobilized.
7. To block unreacted iodoacetyl groups, add to the washed resin 1 ml of 50-m*M* cysteine solution (6.06 mg/ml) prepared in coupling buffer. Mix and react for 30 min at room temperature.

8. Thoroughly wash the immunoaffinity support with coupling buffer, water, 1-*M* NaCl, and again with water to remove unreacted materials. Store the support until use at 4°C in water as a 50% slurry containing a preservative.

Maleimide Activation

Thiol-containing affinity ligands can be immobilized onto solid supports using maleimide-reactive groups. Maleimides long have been used in crosslinking and modification reagents to target thiols in cysteine-containing proteins for bioconjugation purposes (refer to the Index for many cross-references to this reactive group throughout this book). The specificity of the maleimide group toward thiols is excellent when reactions are performed at mildly basic pH. Side reactions might occur with amines if the pH is raised to a highly alkaline environment, but targeting thiols with maleimides is elegantly specific around physiological pH.

Maleimide groups can be formed on chromatography supports using an amine-containing spacer arm followed by reaction with a heterobifunctional crosslinker, which contains an amine-reactive NHS ester on one end and a maleimide group on the other end. Some examples of these reagents include sulfo-SMCC (Chapter 6, Section 1.3), sulfo-GMBS (Chapter 6, Section 7), or NHS–PEG_n–maleimide crosslinkers (Chapter 18, Section 1.2). An SMCC-based method was used to create maleimide groups on a silica support that had been modified with aminopropyl silane to form the requisite amino terminal spacers (Mallik *et al.*, 2007). EMCS-based linkers have also been described to immobilize affinity ligands containing thiols (Kim and Hage, 2006b). However, a superior alternative for modifying surfaces, particles, and chromatography supports with thiol-reactive maleimide groups is to use a PEG-based crosslinker, which can add hydrophilicity to the spacer group formed on the matrix and thus limit nonspecific binding by avoiding aliphatic linkers. Building hydrophilic amine-terminal spacers off of a glycidol-modified support (see section on periodate oxidation and reductive amination coupling, discussed previously) will also result in extremely biocompatible linkers, which can be used for modification with a maleimide heterobifunctional crosslinker. The reaction of NHS–PEG_4–maleimide with a MANAE–agarose amine-containing spacer arm prepared from a glycidol-modified precursor is shown in Figure 15.68. Other amine-terminal spacer groups may also be used for this purpose to create a thiol-reactive support. Similar chemical coupling strategies have been used successfully for immobilizing affinity ligands onto surfaces (Houseman *et al.*, 2003; Misra and Dwivedi, 2007).

The maleimide-reactive group undergoes rapid alkylation with a thiolate anion ($-S^-$) in the pH range of 5.5 to 8.5 and displays second-order reaction kinetics (Tournier *et al.*, 1998). Under these conditions, the major competing reaction is the potential of the maleimide ring to hydrolyze by opening to the maleamic acid derivative, which essentially inhibits effective coupling with thiols (see Chapter 19, Section 5). However, under standard coupling conditions the immobilization of a thiol ligand proceeds much faster than the rate of hydrolysis, yielding maximal density of ligand within 2 to 4 h at room temperature (Figure 15.69). The reaction of the blocked amino acid *N*-acetylcysteine with the maleimide group of sulfo-SMCC was found to be 50% complete within 20 min at pH 6.5 and totally complete within 10 min at pH 8.5 (Tournier *et al.*, 1998). Allowing reactions to go for a longer time for immobilization reactions onto porous chromatography supports is good practice, as the diffusion of large protein ligands

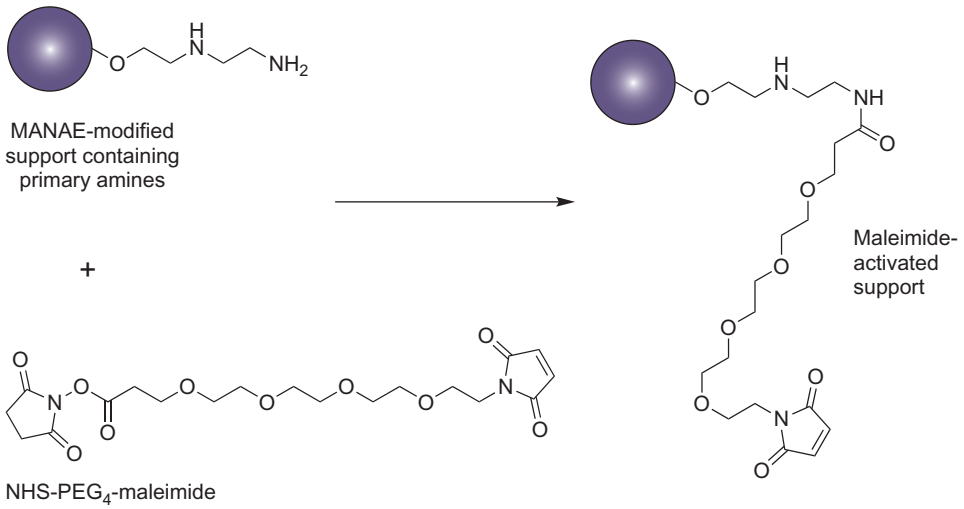

FIGURE 15.68 Preparation of maleimide-agarose by the reaction of NHS–PEG_4–maleimide with MANAE–agarose.

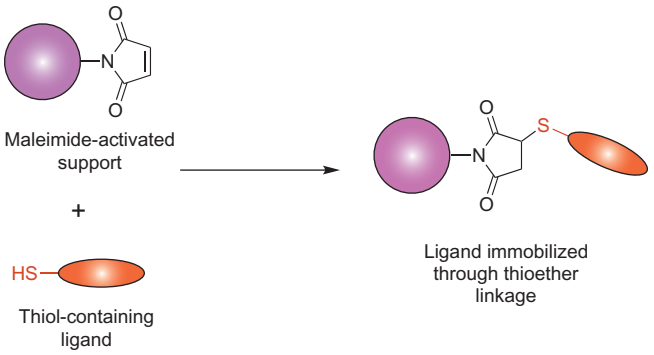

FIGURE 15.69 Coupling of thiol-containing ligands to a maleimide-activated support.

into the particles will increase the reaction times necessary to obtain optimal yields.

A survey of the literature on maleimide immobilization of thiol-containing affinity ligands indicates that this technique has mainly been used to activate and couple molecules to surfaces or nonporous particles (Hwang *et al.*, 2011; Cellet *et al.*, 2012). This is not a limitation of the maleimide group with respect to its utility, but a realization that the cost of materials to form a maleimide-reactive chromatography support may be prohibitive for large-scale use. The creation of other thiol-reactive supports, such as iodoacetyl, discussed previously, involves the use of reagents that are available in multi-gram quantities at relatively inexpensive price points. By contrast, maleimide crosslinkers used to form the support derivatives described in this section are much more expensive on a per-gram basis. Therefore, if small amounts of resin are being activated, this method is eminently appropriate; however, if quantities > 10 ml of support are to be prepared, then it might be better to consider another coupling method due to the price of the maleimide crosslinker.

PREPARATION OF A MALEIMIDE-ACTIVATED SUPPORT

The following protocol requires the use of an amine-containing chromatography support, which may be prepared by the methods discussed in the section on spacer arms elsewhere in this chapter.

Protocol

1. Wash 10 ml of an amine-containing support material (such as MANAE–agarose) with water to remove storage solutions and then with several bed volumes of 0.1-*M* sodium phosphate, pH 7.2 (activation buffer). Finally, suspend the support in an equal volume of activation buffer with mixing.
2. While mixing the suspended amine-containing gel, add 218 mg sulfo-SMCC (Thermo Scientific Pierce) (equivalent to about 50 µmoles/ml gel). Alternatively, an equivalent mole quantity of NHS–PEG_4–maleimide may be added instead of sulfo-SMCC to create a more hydrophilic support environment due to the presence of the PEG-based spacer arm.
3. React with constant mixing for 1 h at room temperature. The mixing may be done using an overhead stirring paddle or end-over-end rotation in a sealed container.
4. Quickly wash the activated support with several bed volumes of activation buffer, 1-*M* NaCl, and with water to remove unreacted crosslinker and reaction byproducts. Drain to a moist cake. To prevent hydrolysis of the maleimide groups, use the activated support immediately to immobilize a thiol-containing ligand according to the following protocol.

LIGAND COUPLING TO MALEIMIDE-ACTIVATED SUPPORTS

1. Prepare 10 ml of a ligand solution for immobilization by dissolving in coupling buffer (0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2) a protein containing one or more free cysteine thiols or a small molecule ligand having an available thiol at a concentration of 1 to 20 mg/ml for the protein or 2 to 5 mg/ml for the small ligand. Alternatively, the small molecule may be reacted with the support at a concentration of 50 to 100 µmoles/ml gel. The thiols on proteins may be generated by the use of a reducing agent to cleave disulfides (see the protocol described previously for coupling reduced antibodies to iodoacetyl-activated supports) or through the use of a thiolation modification reagent (see Chapter 2, Section 4.1).
2. Add 10 ml of the washed, maleimide-activated support prepared above to the ligand solution with stirring to resuspend the matrix. React at room temperature for at least 2 h with constant mixing using an overhead paddle stirrer or end-over-end mixing in a sealed container.
3. Wash the support with several bed volumes of coupling buffer to remove most of the not coupled ligand. Drain to a moist cake. The washes may be analyzed *versus* the initial concentration of the ligand in the coupling solution before the reaction was initiated to determine the amount immobilized.
4. To block unreacted maleimide groups, add to the washed resin 10 ml of 50-m*M* cysteine solution (6.06 mg/ml) prepared in coupling buffer. Mix and react for an additional 30 min at room temperature.
5. Thoroughly wash the affinity support with coupling buffer, water, 1-*M* NaCl, and again with water to remove unreacted materials. Store the support until use at 4°C in water as a 50% slurry containing a preservative.

Divinyl Sulfone Activation

Divinyl sulfone (DVS) is a highly reactive homobifunctional compound that can be used to activate hydroxylic matrices for coupling to a wide variety of affinity ligands (Porath, 1974). It has also been used as a crosslinking agent to increase the physical strength of hydroxylic supports and as a gelling agent to form large-scale crosslinks in polymers for industrial applications (Kriegel, 2006). Activation of an agarose support with DVS in large excess occurs under alkaline pH conditions with modification of the hydroxyls present on the support. This process results in the reaction of one side of the DVS molecule with an available hydroxyl group on the support, which proceeds through a Michael-type addition to the double bond. At the same time, the formation of reactive vinyl sulfone groups occurs due to the presence of the unreacted end of the molecules remaining free (Figure 15.70). If the reaction is performed with a large excess of DVS, it will occur with minimal crosslinking within the matrix, although closely spaced hydroxyl groups may indeed link together and increase the overall structural rigidity within a resin at the same time as activation occurs. The resultant vinyl sulfone reactive groups are stable for storage in aqueous solution as long as no nucleophiles are present in the storage solution. This simple activation process combined with the excellent hydrolytic stability of DVS-activated supports (at 4°C) makes this method of ligand coupling highly attractive, especially for immobilizing ligands containing thiols or hydroxyls.

Supports activated to contain vinyl sulfone groups can be used to immobilize ligands containing nucleophilic thiol, amino, or hydroxyl groups with good linkage stability (Lihme *et al.*, 1986). Ubrich *et al.* (1992) also found that DVS-mediated coupling resulted in one of the most stable affinity supports for the immobilization of antibodies. Highly activated supports typically can couple proteins at densities of up to 30 to 50 mg/ml gel, depending on the quantity of protein initially reacted. Small-molecule ligands can also be coupled at high mole densities. Thiol-containing ligands are the most reactive and are able to couple with the vinyl sulfone groups at a pH of 6 to 8, while forming thioether linkages of excellent stability. Amine-containing ligands may also be immobilized onto vinyl sulfone supports within the somewhat higher pH range of 8 to 10, which results in a secondary amine bond upon addition to the double bond. Finally, hydroxyl groups on ligands such as those on polysaccharides, carbohydrates, and glycans may be linked to vinyl sulfone supports at pH values > 10 to create ether bonds (Figure 15.71). The pH modulation of vinyl sulfone to react with a single nucleophile type is only limited by the presence of other more nucleophilic groups. In other words, an amine cannot be targeted in the presence of a thiol without coupling also taking place at the thiol site. Similarly, hydroxyl functionalities cannot be targeted for coupling in the presence of other amines or thiols, because the more nucleophilic groups will react preferentially or in addition to the hydroxyl.

The yield of protein coupling to a vinyl sulfone-activated matrix may be enhanced by the addition of relatively high concentrations of PEG added to the reaction medium (5–7% PEG for antibodies, 7–10% PEG for most other proteins; Mini-Leak protocol, Kem-en-tec). In addition, similar enhanced coupling rates and

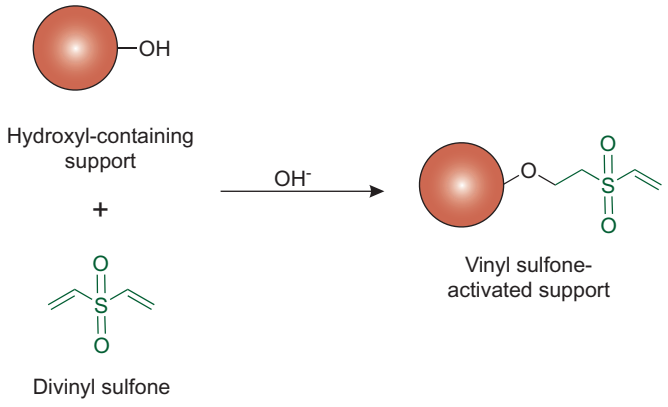

FIGURE 15.70 Activation of a hydroxylic support with divinyl sulfone.

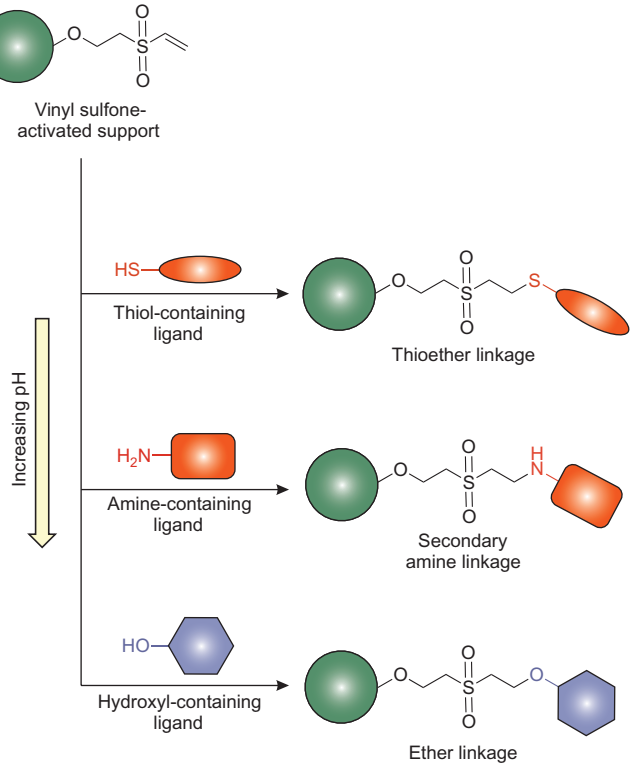

FIGURE 15.71 Reaction of vinyl sulfone-activated supports with thiol-, amine-, and hydroxyl-containing ligands.

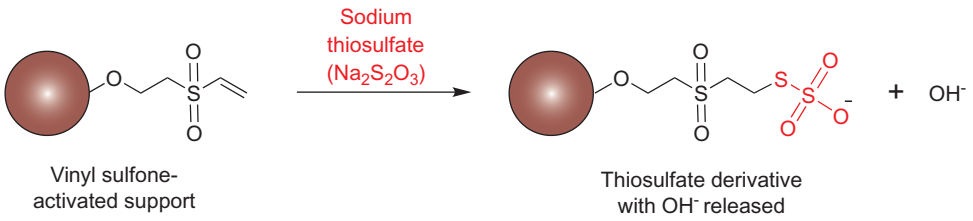

FIGURE 15.72 Reaction of sodium thiosulfate with vinyl sulfone to generate hydroxyl ions.

yields can be observed with the addition of a lyotropic salt (sodium sulfate, potassium sulfate, ammonium sulfate, or potassium phosphate, > 0.5-*M*). Both the PEG and high salt concentrations have the effect of pushing proteins out of solution and toward the surfaces of the activated support where they can more effectively react with the vinyl sulfone groups. This effect is also observed with azlactone-activated supports and with epoxide coupling reactions, described elsewhere in this chapter. Some optimization of the level of PEG or salt addition should be carried out to obtain the best rate of reaction for a given ligand to be immobilized.

The degree of vinyl sulfone-activated species within a chromatography support may be determined by reaction of a small sample of the gel with a large excess of sodium thiosulfate (Porath *et al.*, 1975; Lihme and Boenisch, 1996; Subramanian, 2000). The thiosulfate anion reacts with the vinyl groups and generates OH^- ions (Figure 15.72). Subsequent titration with HCl of the amount of hydroxide ions released provides a measurement of the quantity of vinyl sulfone groups originally present within the matrix.

Divinyl sulfone-activated supports are more reactive than epoxide-activated supports, but the abilities of both immobilization methods are similar in that they can be made to couple with thiols, amines, or hydroxyls simply by modulating the pH of the reaction. The resultant sulfone bridge created between the support and the ligand is stable under physiological conditions, but it can be purposely cleaved by exposure to highly alkaline conditions (see Chapter 9, Section 5). Retro-Michael cleavage of base labile sulfones can be accomplished by mixing the support as a 50% slurry in 0.1-*M* sodium carbonate (or sodium phosphate), pH 11.6, and heating the stirred gel suspension at 37°C for at least 2 h (Zarling *et al.*, 1980). Longer incubation periods may be required for complete reversal of immobilized ligands. The reversible nature of the support indicates that DVS-coupled affinity ligands should not be exposed to conditions exceeding pH 8.5 for long periods of time to avoid potential ligand leakage through cleavage of the sulfone linker arm. However, under normal use and storage conditions the sulfone linker arm is very stable and provides a robust affinity support suitable for long term use.

DVS-activated supports have often been used to immobilize a wide variety of biological molecules to solid supports (Pepper, 1994; Morales-Sanfrutos *et al.*, 2010), including to covalently link glycans onto surfaces (Cheng *et al.*, 2011), to activate biodegradable polymers for coupling bioactive molecules (Wang *et al.*, 2011), in the activation of silica particles for the coupling of thiol-containing affinity ligands (Ortega-Munoz, 2010), and in the preparation of reactive polymers (Lihme and Boenisch, 1996).

DVS activation is also critical in the preparation of thiophilic adsorbents that are used in the isolation of immunoglobulins. The principle of thiophilic interaction chromatography involves an affinity for certain regions within the Fc fragment of antibodies by a ligand consisting of a sulfone in proximity to a thioether group, with or without the addition of an aromatic group nearby in the structure (Porath *et al.*, 1985; Hutchens and Porath, 1986, 1987a,b; Belew *et al.*, 1987; Porath, 1987; Porath and Belew, 1987; Nopper *et al.*, 1989; Lihme and Heegaard, 1991; Knudsen *et al.*, 1992; Hardouin *et al.*, 2007). The interaction was discovered entirely by accident, as the affinity does not involve a biospecific interaction, but a synthetic ligand which likely binds through hydrophobic contacts with pockets within the Fc domains of immunoglobulins. A thiophilic affinity resin can be prepared simply by coupling 2-mercaptoethanol to a DVS-activated support according to the following protocols (Figure 15.73). The resultant support can be used to capture antibodies in the presence of high concentrations of a lyotropic salt (at least 0.5-*M* potassium sulfate), which serves to enhance hydrophobic interactions. Subsequent elution of bound antibody is carried out merely by elimination of the salt from the buffer, thus making this method extremely mild for purifying IgG antibodies. The capacity of this affinity support for human IgG can be as high as 20 mg/ml of thiophilic gel.

PREPARATION OF A DVS-ACTIVATED SUPPORT

The activation protocol described below should be done with caution, as divinyl sulfone is a highly reactive and toxic compound. All operations should be carried out in a fume hood and with the use of proper personal protective equipment.

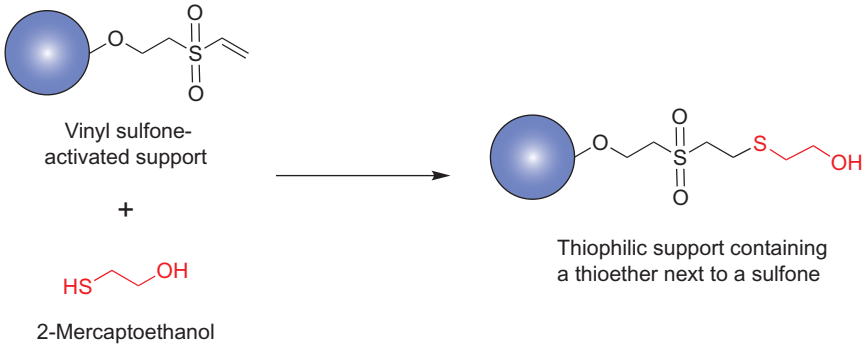

FIGURE 15.73 Preparation of a thiophilic adsorbent through coupling of 2-mercaptoethanol to DVS-activated supports.

Protocol

1. Wash 100 ml of a support material containing hydroxyl groups (such as agarose) with water (at least 5 bed volumes) to remove storage solutions and preservatives. Typically, a non-crosslinked agarose resin can be used for the activation, because crosslinking will occur during the activation step and create a more rigid matrix. However, other natural or synthetic polymeric, hydroxyl-containing supports or inorganic supports containing hydroxyl groups may be used as well, whether crosslinked or not. Use a sintered glass filter funnel suspended in a suction filter flask while pulling a gentle vacuum to facilitate the washing steps. After washing the gel, suction to a moist cake by removing excess water, but do not allow the support to dry.
2. Suspend the gel in 100 ml of 0.5-*M* sodium carbonate (no pH adjustment) and mix in a fume hood using an overhead paddle stirrer.
3. Add 10 ml of divinyl sulfone dropwise to the stirring gel slurry over a period of about 15 min.
4. Continue to react for 1 h at room temperature with constant mixing.
5. Wash the activated gel extensively with water to remove excess DVS (at least 20 bed volumes). Storage of the activated support may be achieved as a 50% slurry in water containing a preservative (e.g., 1,1,1-trichloro-2-methyl-2-propanol) at 4°C. Properly stored, the support should remain stable up to 2 years with minimal loss of vinyl sulfone coupling activity.

LIGAND COUPLING TO DVS-ACTIVATED SUPPORTS

The following ligand-coupling procedures describe the use of a DVS-activated support (10 ml) for the coupling of a thiol-, amine-, or hydroxyl-containing ligand. This may include the immobilization of proteins, carbohydrates, or other molecules that contain these functional groups. The immobilization through thiols may be performed in the presence of other amines or hydroxyl groups on the ligand; however, coupling through amines must be done while avoiding the presence of thiols, as they will preferentially react at a faster rate than amines. Similarly, the coupling of hydroxyls should be done while avoiding the presence of thiols or amines on the ligand.

(A) Coupling of Thiol-Containing Proteins or Ligands

1. Prepare 10 ml of a thiol-containing ligand solution by dissolving in coupling buffer (0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5) a protein containing one or more free cysteine thiols or a small molecule ligand having an available thiol at a concentration of 1 to 20 mg/ml for the protein or 2 to 5 mg/ml for the small ligand. Notes: The EDTA chelator is present to inhibit metal-catalyzed oxidation of the thiols to disulfides. Alternatively, a small molecule may be reacted with the support at a concentration of 50 to 100 µmoles/ml gel. The thiols on proteins may be generated by the use of a reducing agent to cleave disulfides (see the protocol described previously for coupling reduced antibodies to iodoacetyl-activated supports) or through the use of a thiolation modification reagent (see Chapter 2, Section 4.1). Complete removal of any thiol-containing reducing agents must be performed before attempting to immobilize the reduced protein to avoid competition during the coupling reaction. The coupling buffer may also be formulated to contain a lyotropic salt, such as sodium sulfate, at a concentration of at least 0.5-*M* to increase the rate of reaction when immobilizing proteins. Alternatively, the addition of PEG (MW 20 kDa) to the coupling buffer may be used for this purpose at a concentration of 5 to 7% for antibodies or 7 to 10% for most other proteins.
2. Wash 10 ml of the DVS-activated support prepared above with water to remove any preservatives from the storage solution and then wash with coupling buffer (at least 2 bed volumes). Drain to a wet cake.
3. Add the gel to the ligand solution with stirring (total slurry volume: 20 ml). React overnight at room

temperature or for at least 18 h with constant mixing using an overhead paddle stirrer or end-over-end mixing in a sealed container. The reaction may also be performed at 4°C for sensitive molecules or proteins, but the reaction time may have to be extended to obtain the same levels of coupling.
4. Wash the support with several bed volumes of coupling buffer (without the lyotropic salt or PEG present) to remove most of the not-coupled ligand. The washes may be analyzed *versus* the initial concentration of ligand in the coupling solution before the reaction was started to determine the amount that was immobilized. Continue to wash with several bed volumes of water and drain to a wet cake.
5. To block unreacted vinyl sulfone groups, add the washed resin to 10 ml of 0.1-*M* cysteine solution (12.12 mg/ml) prepared in 0.1-*M* sodium bicarbonate, pH 8.6. Alternatively, use a blocking solution consisting of 0.2-*M* ethanolamine prepared in the same buffer. Mix and react for an additional 2 h at room temperature. Note: Do not block the support with 2-mercaptoethanol, because coupling this molecule may result in the creation of a number of thiophilic interaction sites within the matrix, which could cause nonspecific binding with antibodies and other molecules, depending on the conditions of the affinity chromatography being done.
6. Thoroughly wash the affinity support with 0.1-*M* sodium phosphate, pH 7.5, water, 1-*M* NaCl, and again with water to remove unreacted materials. Store the support until use at 4°C in water as a 50% slurry containing a preservative.

(B) Coupling of Amine-Containing Proteins or Ligands

1. Prepare 10 ml of a amine-containing ligand solution by dissolving in coupling buffer (0.1-*M* sodium bicarbonate, pH 8.6) a protein containing one or more free amines or a small molecule ligand having an available amine at a concentration of 1 to 20 mg/ml for the protein or 2 to 5 mg/ml for the small ligand. Alternatively, the small molecule may be reacted with the support at a concentration of 50 to 100 µmoles/ml gel. Note: The coupling buffer may also be made up to contain a lyotropic salt, such as sodium sulfate, at a concentration of at least 0.5-*M* to increase the rate of reaction when immobilizing proteins. Alternatively, the addition of PEG (MW 20 kDa) to the coupling buffer may be used for this purpose at a concentration of 5 to 7% for antibodies or 7 to 10% for most other proteins.
2. Wash 10 ml of the DVS-activated support prepared as described previously with water to remove any preservatives from the storage solution and then wash with coupling buffer (at least 2 bed volumes). Drain to a wet cake.
3. Add the gel to the ligand solution with stirring to resuspend the matrix (total slurry volume: 20 ml). React overnight (for at least 18 h) at room temperature or at 4°C with constant mixing using an overhead paddle stirrer or end-over-end mixing in a sealed container.
4. Wash the support with several bed volumes of coupling buffer (without the lyotropic salt or PEG present) to remove most of the not-coupled ligand. The washes may be analyzed *versus* the initial concentration of ligand in the coupling solution to determine the amount immobilized. Continue to wash with several bed volumes of water and drain to a wet cake.
5. To block unreacted vinyl sulfone groups, add the washed resin cake to 10 ml of 0.2-*M* ethanolamine solution prepared in 0.1-*M* sodium bicarbonate, pH 8.6. Note: After the addition of ethanolamine to the buffer, adjust the pH back to 8.6 with 6-*N* HCl solution while maintaining the temperature near ambient using an ice bath if necessary. Mix and react for an additional 2 h at room temperature.
6. Thoroughly wash the affinity support with 0.1-*M* sodium bicarbonate, water, 1-*M* NaCl, and again with water to remove unreacted materials. Store the support until use at 4°C in water as a 50% slurry containing a preservative.

(C) Coupling of Carbohydrates or Hydroxyl-Containing Ligands

1. Prepare 10 ml of a hydroxyl-containing ligand solution (such as a carbohydrate, polysaccharide, or glycan) by dissolving it in coupling buffer (0.1-*M* sodium carbonate, pH 11.0) at a concentration of up to 100 mg/ml for mono- or disaccharides, or at least 1 to 20 mg/ml for larger polysaccharides or glycans. Alternatively, a hydroxyl-containing ligand may be reacted with the support at a concentration of 50 to 100 µmoles/ml gel. Notes: The more concentrated the ligand solution, the better will be the coupling yield of the reaction and ultimate density of ligand on the support. However, for the immobilization of carbohydrates to be used in the affinity capture of lectins or other carbohydrate binding proteins, it may be optimal to immobilize the ligand at lower than maximal densities. This is due to the fact that many lectins contain more than one binding site for a carbohydrate, and multi-site interactions on the affinity support will have a tendency to create strong avidity, which may be difficult to reverse for the efficient elution of interacting proteins. Thus, some degree of experimental optimization of ligand density may have to be performed to obtain the best

performance of the affinity support in its intended application.

2. Wash 10 ml of the DVS-activated support prepared previously with water to remove any preservatives from the storage solution and then wash with coupling buffer (at least 2 bed volumes). Drain to a wet cake.
3. Add the gel to the ligand solution with stirring (total slurry volume: 20 ml). React overnight at room temperature (for at least 18 h) or at 4°C with constant mixing using an overhead paddle stirrer or end-over-end mixing in a sealed container. Reactions done at 4°C may take extended time periods to reach the same level of coupling yield as those done at room temperature.
4. Wash the support with several bed volumes of coupling buffer to remove most of the not coupled ligand. The washes may be pooled and analyzed *versus* the initial concentration of ligand in the coupling solution before the reaction was initialized to determine the amount of ligand immobilized. Drain the gel to a wet cake.
5. To block unreacted vinyl sulfone groups, add the washed resin cake to 10 ml of 0.2-*M* ethanolamine solution prepared in 0.1-*M* sodium carbonate, pH 11.0. (Note: After the addition of ethanolamine to the buffer, adjust the pH back to 11.0 with 6-*N* HCl, if necessary. Mix and react for an additional 2 h at room temperature.
6. Thoroughly wash the affinity support with 0.1-*M* sodium carbonate, water, 1-*M* NaCl, and again with water to remove unreacted materials. Store the support until use at 4°C in water as a 50% slurry containing a preservative.

(D) Coupling of 2-Mercaptoethanol to Make a Thiophilic Resin

The following protocol represents one of several methods available to form a thiophilic affinity support for the purification of immunoglobulins and other proteins able to interact with the ligand.

1. Wash 10 ml of the DVS-activated support prepared previously with water to remove any preservatives from the storage solution and then wash with at least 2 bed volumes of coupling buffer (0.1-*M* sodium carbonate, pH 9.0). Drain to a wet cake.
2. In a well-ventilated fume hood, suspend the washed activated support in 9 ml of coupling buffer and add 1 ml of 2-mercaptoethanol (stench!) with stirring.
3. React overnight (at least 18 h) at room temperature with constant mixing. For small volumes of gel, mixing may be accomplished by end-over-end rotation in a sealed container. For larger volumes of gel the use of an overhead paddle stirrer is appropriate; however, due to the unpleasant odor of 2-mercaptoethanol a sealed round-bottom flask should be used for the gel slurry during mixing operations.
4. Wash the resin thoroughly in the fume hood with coupling buffer, 1-*M* NaCl, and water. Continue the washing until no odor is detectable from 2-mercaptoethanol. Store the thiophilic support until use at 4°C in water as a 50% slurry containing a preservative.

Pyridyl Disulfide Activation

Pyridyl disulfide groups can react with thiol-containing molecules by disulfide exchange to form new mixed disulfide linkages. This group long has been used as a thiol-reactive end in crosslinking reagents and protein modification agents, such as the popular heterobifunctional compound SPDP (Chapter 6, Section 1.1). Pyridyl disulfide groups also can be formed on chromatography supports to immobilize thiol-containing ligands for affinity separations through a simple reaction process (Cuatrecasas, 1970; Egorov *et al.*, 1975; Carlsson *et al.*, 1976; Ngo, 1989). The similar reagents 4,4′-dipyridyl disulfide (Grassetti and Murray, 1967) or 2,2′-dipyridyl disulfide (Brocklehurst *et al.*, 1973) can be used as activation agents to form reactive pyridyl disulfide groups on resins. Reaction of these compounds in excess with a thiol-containing support material results in the formation of pyridyl disulfide groups and activation of the support for disulfide exchange reactions with a thiol-containing ligand (Figure 15.74). The requirement for activation using these reagents is to first form free thiol groups on a support using spacer arms that terminate in thiol groups. One method of creating such a thiol-containing matrix is to couple the *bis*-thiol compound DTT to an epoxy-activated support (see the section Epoxide Activation, this chapter). Another potential approach to forming terminal thiol groups is to modify an amine-containing support with a thiolation reagent

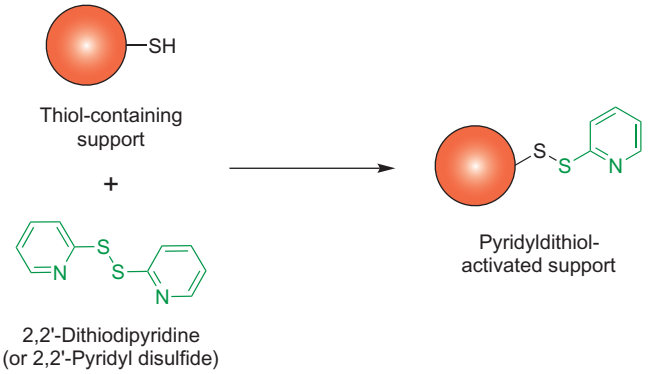

FIGURE 15.74 Activation of a thiol-containing support with 2,2′-pyridyl disulfide.

such as SATA, Traut's reagent, or homocysteine thiolactone (Chapter 2, Section 4.1), which form free or protected thiols upon reaction with the amines.

Amine-containing supports may also be modified with heterobifunctional crosslinking agents to form the pyridyl disulfide reactive groups directly from an amine-terminal spacer (Brogan and Schoenfisch, 2005). In this case, reaction of the terminal amines with the crosslinking reagent SPDP (Chapter 6, Section 1.1) through its NHS ester end creates amide bond linkages with the amines on the support, which then forms short spacer arms that terminate in pyridyl disulfide groups. An even better option is to use an NHS–PEG$_n$–pyridyl disulfide crosslinker, which has a hydrophilic spacer arm in its construction to create a matrix having low nonspecific binding characteristics (Chapter 18, Section 1.2) (Figure 15.75). This activation strategy may be the most straightforward, but it also is likely the most expensive due to the potential cost of the crosslinking reagent. For making small amounts of support material (i.e., <10 ml) the use of a pyridyl disulfide-containing crosslinker is cost effective and a simple route to production of the activated support. It also works well for activation of surfaces or small nonporous particles. For making larger quantities of resin materials, however, it may be best to use the methods that employ the dipyridyl disulfide activation reagents, because these compounds are much less expensive.

Perhaps the simplest method of introducing pyridyl disulfide groups into a chromatography support is to use the reagent PDEA, which is 2-(2-pyridinyldithio) ethaneamine. This small compound has an amine on one end and the thiol-reactive group on the other end. An amine-reactive chromatography support may be used to couple this reagent in high yield, thus forming the pyridyldithiol groups in a single step. Figure 15.76 illustrates the coupling of PDEA to a succinimidyl-carbonate-activated support, which reacts with amines within the pH range of 7 to 9 to give carbamate linkages (see the associated section, this chapter). Renberg *et al.* (2005) used PDEA to modify a sensor chip for the immobilization of thiol-containing Affibodies, which

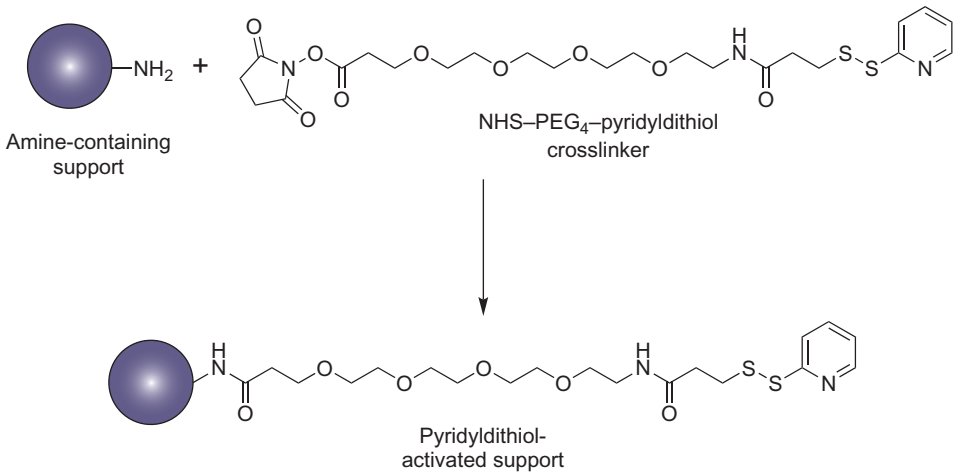

FIGURE 15.75 Use of NHS–PEG$_n$–pyridyl disulfide to create pyridyl disulfide groups from an amine-containing support.

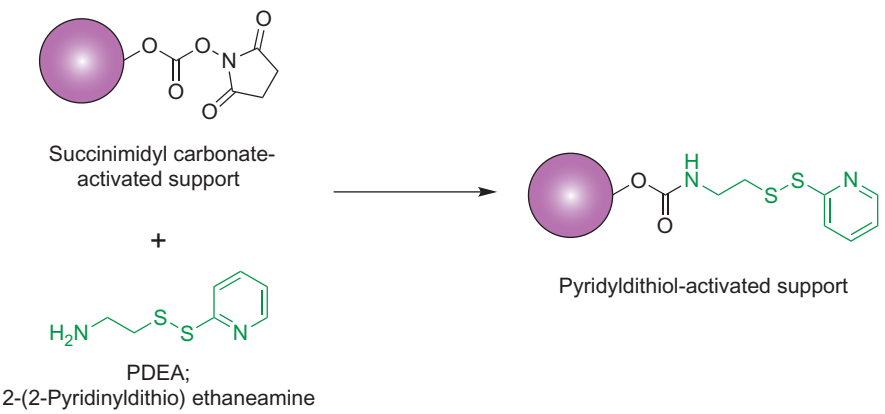

FIGURE 15.76 Use of PDEA to form pyridyl disulfide groups on an amine-reactive support.

are synthetic peptides having antibody-like binding properties toward antigens. The use of PDEA is also a recommended method of coupling thiol affinity ligands to a Biacore sensor chip, because the chip can be regenerated after use. PDEA-modified agarose supports have also been used to immobilize enzymes for use a bioreactors (Mansfeld and Ulbrich-Hofmann, 2000). The amino group of PDEA was coupled to CNBr-activated agarose or through an aminocaproic acid spacer using the EDC/NHS coupling reaction to yield the final thiol-reactive derivative (Chapter 4, Section 1).

Once pyridyl disulfide groups are formed on a support, they are stable for long-term storage in aqueous solution provided no reducing or oxidizing agents are present. The reaction of these groups with thiol-containing affinity ligands results in the formation of reversible disulfide bonds with release of the chromogenic leaving group pyridine-2-thione (Figure 15.77). Once the leaving group is displaced by a thiol ligand, it cannot go back and again react with the disulfide groups formed on the matrix, because the thione double bond makes the sulfur unreactive toward disulfide exchange. The release of this group also can be used to estimate the degree of coupling by measurement of its absorbance at 343 nm, provided the ligand does not absorb in this region. The reaction of a thiol-containing ligand with the pyridyl disulfide groups on the support will occur within the pH range of 4 to 8, with optimal reaction kinetics observed at pH 7 to 8 (Carlsson *et al.*, 1978).

Pyridyl disulfide immobilization is an alternative to the permanent coupling methods discussed previously for thiol ligands in that a coupled molecule can be subsequently removed from the support by treatment with a disulfide reducing agent. Disulfide immobilized ligands may be cleaved from the support by incubation with 25- to 50-m*M* DTT for 2 h at room temperature. This feature builds the potential for reversible covalent capture and release of ligand-target molecule interacting pairs under mild chromatography conditions. Therefore, this may be a valuable technique for co-immunoprecipitation (co-IP) assays in the study of protein interactions, because it allows for the isolation of these proteins under non-denaturing conditions. After a bound ligand is released, the support once again contains free thiol groups that then can be re-activated to form pyridyl disulfide groups for another immobilization reaction, thus allowing complete reusability of the support.

Pyridyl disulfide immobilization has also been used to couple thiol-containing antibodies, antibody fragments, proteins, and other molecules to polymers and solid phases of all types. For instance, Iwata *et al.* (2007) used pyridyl disulfide groups on polymer brushes to immobilize Fab′ fragments containing thiol groups

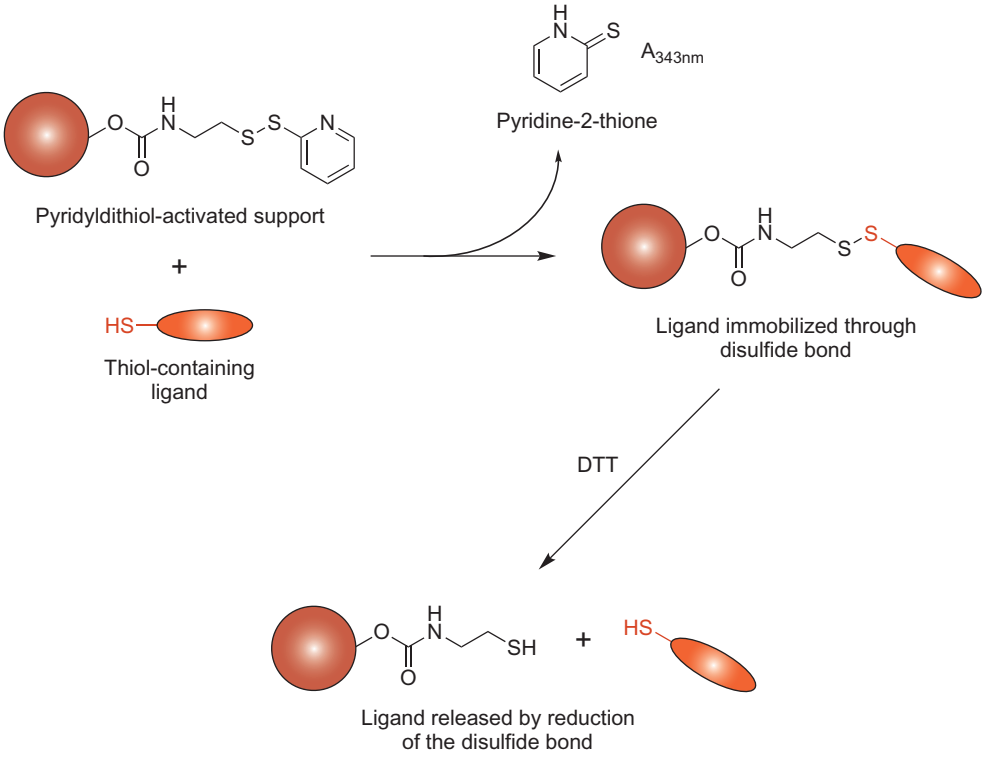

FIGURE 15.77 Coupling a thiol-containing ligand to a pyridyl disulfide-activated support with subsequent removal by treatment with a reducing agent.

within their hinge region. Vázquez-Dorbatt *et al.* (2009) formed these active groups within a glycopolymer by reaction of a pyridyl disulfide-containing initiator using atom transfer radical polymerization (ATRP) to create a copolymer matrix that could immobilize double-stranded siRNA, which had been previously modified to contain a terminal thiol group. Metal surfaces have also been activated with pyridyldithiol groups to allow affinity ligands to be coupled for molecular recognition force microscopy measurements (Brogan and Schoenfisch, 2005). In addition, a pyridyl disulfide-activated support can be used for the proteomics study of cysteine-containing peptides by reversible capture and elution with subsequent analysis by mass spec (Shen *et al.*, 2003).

PREPARATION OF A PYRIDYL DISULFIDE-ACTIVATED SUPPORT

The following methods for the preparation of a pyridyldithiol support represent different options for building this reactive group onto various base supports. The same general methods may be used to activate particles or surfaces with excellent results. The level of reactive pyridyl disulfide groups formed on a support may be controlled by adjusting the amount of functional groups initially created on the support, which are subsequently modified to create the reactive groups. The following methods use either amine- or thiol-terminal spacer arms on a support to form the final reactive pyridyl disulfides.

(A) Activation using 2,2′-Dipyridyl Disulfide

This protocol will work well using either 2,2′-dipyridyl disulfide or 4,4′-dipyridyl disulfide. These compounds may be obtained commercially (Acros, Aldrich) or synthesized from the corresponding mercaptopyridine precursor according to the method presented in Hermanson *et al.* (1992).

1. Prepare 10 ml of a support containing a thiol-terminal spacer using the methods described within the section on spacer arms in this chapter. The support should contain 10 to 50 µmoles –SH groups/ml of gel. Wash the support with water to remove storage solution components, if necessary, and drain to a wet cake.
2. In the fume hood, prepare 10 ml of an acetone:water (1:1, v/v) solution containing 1 g of 2,2′-dipyridyl disulfide dissolved into it.
3. Add the gel to the 2,2′-dipyridyl disulfide solution with stirring and react at room temperature for 30 min with constant mixing in the fume hood. For small amounts of gel, mixing may be accomplished by end-over-end rocking in a sealed container. If preparing larger quantities of activated gel, use an overhead paddle stirrer. During the course of the reaction, the release of pyridyl-2-thione molecules will turn the solution a yellow color.
4. Wash the activated gel with at least 10 bed volumes of acetone:water (1:1) to remove excess reactants and reaction byproducts. Continue to wash thoroughly with water to remove the last traces of acetone. Finally, wash the support with 1-m*M* EDTA (at neutral pH) to protect against metal-catalyzed oxidation. Store the pyridyl disulfide-activated support at 4°C as a 50% slurry in water containing 1-m*M* EDTA and a preservative until use.

(B) Activation using NHS–PEGn–Pyridyl Disulfide Crosslinkers

PEG-containing heterobifunctional crosslinkers containing an amine-reactive NHS ester on one end and a pyridyl disulfide group on the other end may be used to form thiol-reactive groups by modification of amine-containing supports according to the following protocol. Some optimization of the amount of crosslinker addition may have to be carried out to obtain the best density of pyridyldithiol groups on the support for a specific application. Refer to Chapter 18 for additional information on discrete PEG-based reagents. Other pyridyl disulfide-containing crosslinkers may also be used to activate an amine-support, such as SPDP or SMPT (Chapter 6, Sections 1.1 and 1.2).

1. Prepare 10 ml of a support containing an amine-terminal spacer using the methods described in the section on spacer arms in this chapter. The support should contain 10 to 50 µmoles $–NH_2$ groups per ml of gel. Wash the support with water to remove storage solution components, if necessary, and drain to a wet cake.
2. In a fume hood, dissolve 0.56 g SPDP–$dPEG_4$–NHS ester (also called PEG_4–SPDP) (Quanta Biodesign or Thermo Fisher) in 2 ml of dry DMSO, DMF, or DMAC solvent. This amount will provide 100 µmoles of crosslinker per milliliter of gel during the reaction.
3. Add the moist gel cake from step 1 to 8 ml of reaction buffer (0.1-*M* sodium phosphate, pH 7.5) and mix to resuspend the beads.
4. With stirring, add the 2 ml of dissolved crosslinker prepared in step 2 to the stirring support slurry prepared in step 3.
5. React with constant mixing at room temperature for 1 h. Mixing may be done using an overhead paddle stirrer or by using end-over-end rocking in a sealed container.
6. Wash the activated gel thoroughly with water, 1-*M* NaCl, and water to remove excess reactants and reaction byproducts. Finally, wash the support with 1-m*M* EDTA (at neutral pH) to protect against metal-catalyzed oxidation of the disulfide groups. Store the pyridyl disulfide-activated support at 4°C as a

50% slurry in water containing 1-m*M* EDTA and a preservative until use.

(C) Activation using PDEA

The following protocol can be used to create reactive pyridyl disulfide groups on an amine-reactive support. The procedure uses the compound PDEA, which is 2-(2-pyridinyldithio)ethaneamine, containing a free primary amine on one end and a pyridyldithiol group on the other end. PDEA may be obtained from GE Healthcare or synthesized by the reaction of 2 equivalents of 2,2′-dipyridyl disulfide (Aldrich) with 1 equivalent of cysteamine (or 2-mercaptoethylamine) in methanol according to the procedure of Li *et al.* (2008). The preparation of an amine-reactive support can be accomplished using any of the protocols previously described in this chapter; however, do not use an aldehyde-containing support to couple PDEA through reductive amination, because the presence of a reducing agent also will reduce the pyridyl disulfide groups and render the support inactive.

1. Prepare 10 ml of an amine-reactive support material according to the methods described in this chapter (e.g., CDI or an NHS ester-activated agarose). If the support is stabilized in an organic solvent (e.g., acetone), just before use filter off the excess solution using a sintered glass filter suspended in a vacuum filter flask within a fume hood. Draw a gentle vacuum until the excess solvent stops dripping from the filter while at the same time breaking up the support into finely divided pieces using a spatula, but do not allow it to dry. Release the vacuum.
2. In a fume hood, prepare a 20-m*M* PDEA solution in the appropriate solvent for coupling to the amine-reactive support of choice. For instance, if using a CDI- or NHS ester-activated support, to obtain maximal coupling yields dissolve 44 mg of PDEA in 10 ml of nonaqueous solvent, such as DMSO or DMF. Add to this solution, 2 mole equivalents (over the amount of PDEA added) of an organic base such as DIEA, TEA, or DMAP to catalyze the reaction by accepting the protons that are generated during the course of the reaction. Note: PDEA may also be coupled to amine-reactive supports in aqueous solution. The buffer composition and pH should be determined based on the suggested methods associated with the amine-reactive chemistries described earlier in this chapter. For aqueous coupling, mix the finely divided pieces of activated gel from step 1 with the PDEA buffer solution. The PDEA concentration may be increased for aqueous coupling to account for potential hydrolysis of reactive groups on the support. For instance, PDEA may be dissolved at 80-m*M* concentration in 50-m*M* sodium borate, pH 8.5, for amine-reactive immobilization methods compatible with this environment (i.e., for use with CDI- or NHS ester-activated supports).
3. With stirring and in the fume hood, mix the activated support material with the PDEA solution to resuspend it as a uniform slurry.
4. React with mixing for 1 h at room temperature using an overhead paddle stirrer or end-over-end rocking in a sealed container.
5. Wash the thiol-reactive support with solvent to remove excess reactants (at least 10–20 bed volumes). Wash the support into water by using sequentially increasing concentrations of water-in-solvent (e.g., 30% water, 70% water) until 100% water washes are used to completely remove the solvent. Note: If an aqueous reaction was done, then instead of washing with solvent wash with water, 1-*M* NaCl, and water to remove excess reactants. Finally, wash the support with 1-m*M* EDTA (at neutral pH) to protect against metal-catalyzed oxidation during storage. Store the pyridyl disulfide-activated support at 4°C as a 50% slurry in water containing 1-m*M* EDTA and a preservative until use.

LIGAND COUPLING TO PYRIDYL DISULFIDE-ACTIVATED SUPPORTS

The coupling of thiol-containing ligands to pyridyl-disulfide-activated supports can be performed over a broad pH range of approximately pH 4 to 8 with excellent results. The following immobilization protocols are generalized methods for coupling cysteine-containing proteins, peptides, or other thiol-containing molecules. The methods may also be used with proteins modified to contain –SH groups through the use of thiolation reagents (Chapter 2, Section 4.1). Some optimization may have to be carried out to determine a ligand density that is best for a particular affinity chromatography application. Preparing a series of small batches using different concentrations of ligand in each reaction medium will produce a range of ligand densities on the support for evaluation. In addition, after ligand coupling do not attempt to block excess reactive groups with a thiol-containing compound such as cysteine, as this may also cleave off any immobilized ligands.

(A) Coupling of Reduced IgG or F(ab′)$_2$ Fragments

1. Dissolve an IgG antibody or F(ab′)$_2$ fragment at a concentration of 1 to 10 mg/ml in 1 ml of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5 (coupling buffer). The coupling buffer should be purged with nitrogen and degassed under vacuum to remove oxygen, which may oxidize the thiols and prevent coupling.

2. Add a reducing agent, such as DTT, 2-mercaptoethylamine (2-MEA), 2-mercaptoethanol (2-ME), or tris(carboxyethyl)phosphine (TCEP), to the antibody solution to give a final concentration of at least 5-m*M*. A highly concentrated stock solution of the reducing agent first may be prepared in coupling buffer and then a small aliquot of that solution added to the antibody to obtain the final desired concentration. Mix to dissolve and incubate for 1.5 h at 37°C. Note: Higher concentrations of the reducing agent may be used (typically ≤50-m*M*), but the higher the concentration, the more likely the reduction of disulfides between the heavy and light chains, which may disrupt the three-dimensional structure of the antibody and destroy antigen binding capability. Optimization of the reductant concentration may have to be done to ensure the best performance of the resultant immunoaffinity support. An alternative to the use of a reducing agent to generate free thiols is to use a thiolation reagent to first modify the amines on an antibody to contain thiols. Various procedures on the use of thiolation reagents with proteins and antibodies can be found elsewhere in this book (Chapter 2, Section 4.1).
3. Remove excess reducing agent from the antibody solution by desalting using size exclusion chromatography or by dialysis. During the chromatography or dialysis operation, use coupling buffer to equilibrate and elute the protein through the gel filtration support or as the dialyzing solution. To desalt the 1-ml sample size, a gel filtration column should consist of at least 10 ml of a support having a molecular weight exclusion limit of no more than 5 to 10 kDa to ensure that the protein will come through first in the void volume and be separated from the salt peak containing the reducing agent. A similarly sized dialysis membrane having a size exclusion limit of 5 to 10 kDa also is appropriate. Dialyze the antibody with numerous changes of the outside dialysis solution to ensure that the concentration of the reducing agent is decreased down to levels far below that of the reduced antibody. Complete removal of the reducing agent is essential to eliminate competition when coupling the reduced antibody to the pyridyl disulfide-activated support. Pool the fractions containing desalted protein from the gel filtration column or recover the dialyzed protein from the dialysis device. The solution may be concentrated if necessary using a centrifugal concentrator to approximately 1 ml to maintain the desired concentration level of antibody in the coupling reaction.
4. Wash 1 ml of a pyridyl disulfide-activated support with several bed volumes of water to remove storage solution components and then with two bed volumes of coupling buffer. Washing may be performed using spin columns or by using a small drip column. Drain to a moist cake.
5. Mix the washed pyridyl disulfide-activated gel with the reduced antibody solution and stir at room temperature (or 4°C) overnight or for at least 18 h. Mixing may be achieved by end-over-end rocking in a sealed container. If the antibody is sensitive to extensive stirring or rocking, the mixture may be mixed for 2 h and then left to sit with periodic resuspension and mixing every hour or so to maintain a somewhat homogeneous mixture of ligand throughout the resin.
6. Wash the support with several bed volumes of coupling buffer to remove most of the not-coupled antibody. The washes may be analyzed *versus* the initial concentration of the antibody solution before coupling to determine the amount immobilized.
7. Thoroughly wash the immunoaffinity support with coupling buffer, water, 1-*M* NaCl, and again with water to remove unreacted materials. Store the support until use at 4°C in water as a 50% slurry containing a preservative.

(B) Coupling Thiol-Containing Small Ligands

1. Wash 10 ml of a pyridyl disulfide-activated support with water and then place into coupling buffer using a sintered glass filter funnel suspended in a suction filter flask (coupling buffer: 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5). The coupling buffer should be purged with nitrogen and degassed under vacuum to remove oxygen, which may oxidize the thiols and prevent coupling.
2. Dissolve a thiol-containing ligand (such as a cysteine-containing peptide) in 10 ml of coupling buffer at a concentration of at least 2 to 5 mg/ml. Determination of the optimal level of ligand concentration may be done experimentally by running a series of small reactions at different concentrations and determining which preparation performs best in the intended affinity chromatography application.
3. Add the ligand solution to the washed pyridyl disulfide-activated resin and mix to thoroughly resuspend the support in the solution. React overnight or for at least 18 h at room temperature (or 4°C) with constant mixing.
4. Wash the gel with several bed volumes of coupling buffer to remove most of the excess uncoupled ligand. The amount of ligand not coupled may be determined by measuring the volume and concentration of the ligand in the pooled washes. This may be done using a protein assay or spectrophotometrically if the ligand has a characteristic spectral signature. The amount

of ligand that coupled to the matrix then may be determined by difference. Drain the gel to a wet cake.

5. Wash the affinity resin thoroughly with water, 1-*M* NaCl, and again with water (at least 10 bed volumes each) to remove unreacted components. Store the support until use at 4°C as a 50% slurry in water containing a preservative.

TNB–Thiol Activation

Ellman's reagent (5,5′-dithiobis(2-nitrobenzoic acid), or DTNB, long has been used as a chromogenic agent for the determination of free thiol groups, especially cysteine residues in proteins (Chapter 2, Section 4.1) (Ellman, 1958; Riddles *et al.*, 1979, 1983; Watabe *et al.*, 1982). The compound reacts with thiol groups in a disulfide exchange process to generate the chromogenic leaving group 5-thio-2-nitrobenzoic acid (TNB). The yellow color generated by the TNB anion at 412 nm can be used to quantify the amount of thiol groups present ($\varepsilon = 14{,}150$ at pH 8.0).

Ellman's reagent also can be used to create thiol-reactive groups on affinity supports for the coupling of sulfhydryl-containing ligands (Jayabaskaran *et al.*, 1987). Much like the reaction of 2,2′-dipyridyl disulfide discussed in the previous section, DTNB can be used to activate thiol-containing chromatography supports to contain reactive TNB–thiol groups (Figure 15.78). The TNB–thiol groups then can be used to immobilize thiol-containing proteins or other ligands through a disulfide exchange process leading to the formation of a disulfide linkage with the affinity ligand (Figure 15.79). The use of Ellman's reagent in this process provides advantages over the pyridyl disulfide chemistry in that the reactions of the TNB group can be followed visually and spectrophotometrically. The activation of a thiol-containing support proceeds with loss of one chromogenic TNB group per thiol, so the reaction can be quantified by measuring the amount of color released during the process. In addition, the immobilization of a thiol-containing protein or molecule can be quantified through the number of TNB groups generated during the coupling reaction.

The requirement for production of a TNB-activated support is to first prepare a spacer arm derivative that terminates in a thiol group. This can be done using the techniques discussed in this chapter on the preparation of spacer arm derivatives. Perhaps one of the easiest routes to accomplish this process is to use an amine-containing support (such as DADPA–agarose or MANEA–agarose) and modify it with Traut's reagent to spontaneously form a small spacer arm, which opens up to a free thiol on its terminus (Chapter 2, Section 4.1). This intermediate can then be immediately reacted with DTNB to create the activated TNB–thiol support (Figure 15.80).

PREPARATION OF A TNB–THIOL-ACTIVATED SUPPORT

The following protocol requires the prior preparation of an amine-containing support for the initial modification with a thiolation reagent to create thiols (see section on spacer arms in this chapter).

1. Wash 100 ml of an amine-containing support (such as DADPA–agarose or MANEA–agarose) with water to remove any storage components (at least 3 bed volumes) and then with 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 8.0 (modification buffer). Use a sintered filter funnel suspended in a suction filter flask to facilitate the washing steps, while applying a gentle vacuum between each wash solution addition to accelerate flow through the resin. Drain to a wet cake.

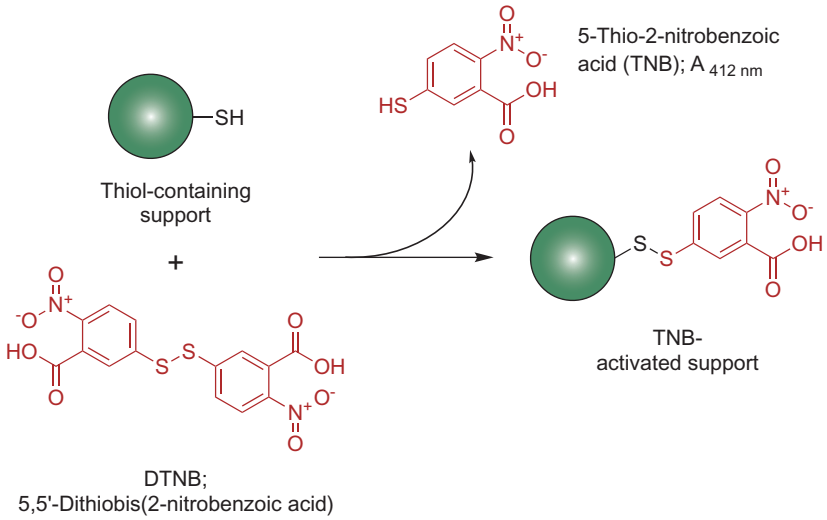

FIGURE 15.78 Activation of a thiol-containing matrix with DTNB.

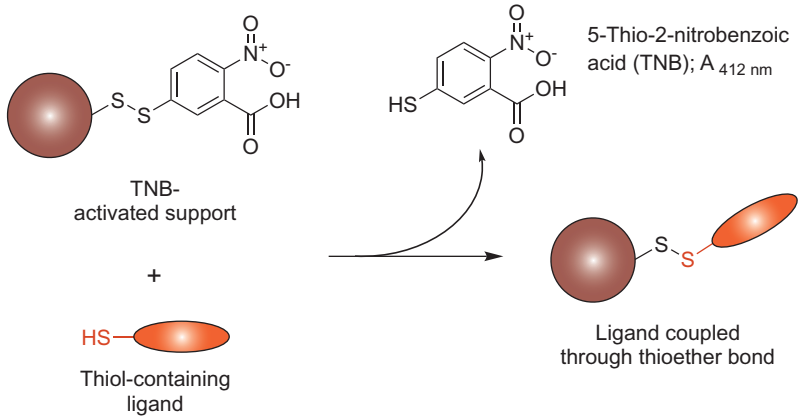

FIGURE 15.79 Coupling of a thiol-containing ligand to a TNB-thiol-activated support.

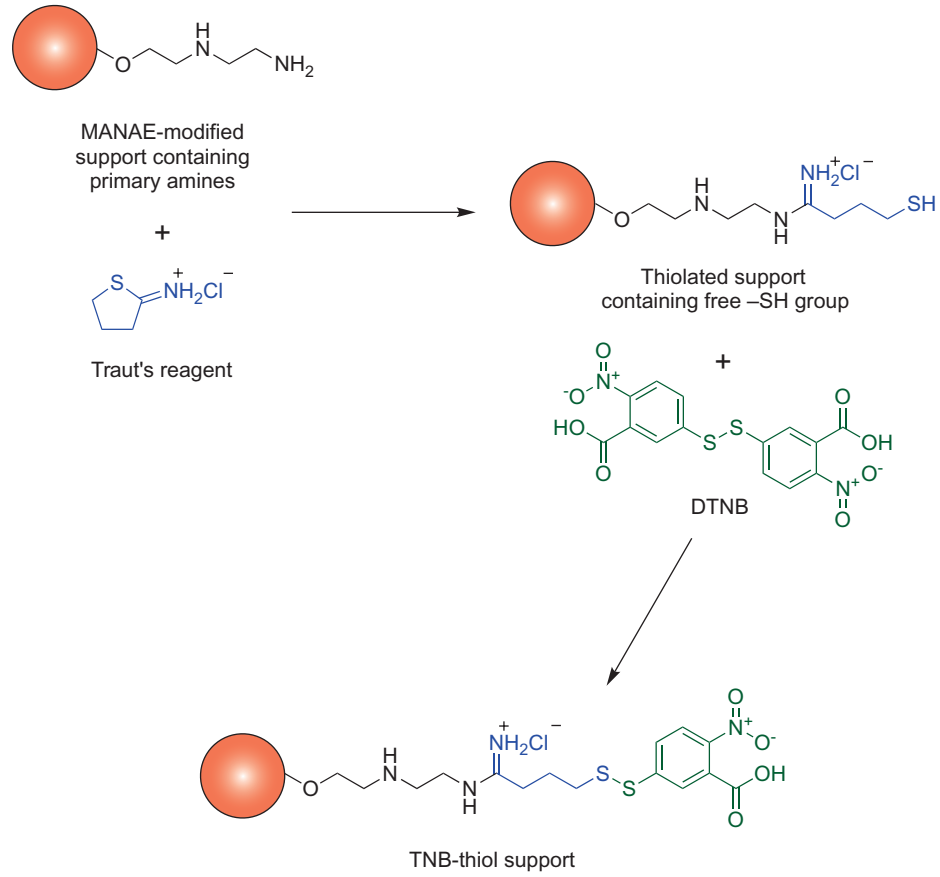

FIGURE 15.80 Reaction of Traut's reagent with MANEA–agarose and activation with DTNB.

2. Prepare 100 ml of a 20-m*M* 2-iminothiolane (Traut's reagent) solution in modification buffer and add the gel cake to it with stirring.
3. React for 1 h at room temperature with constant stirring using an overhead paddle stirrer or end-over-end rocking in a sealed container.
4. Quickly wash the support with several bed volumes of modification buffer to remove most of the reactant and then drain to a wet cake. Note: Do not store the thiolated support at this stage, because 2-iminothiolane modified species may undergo a recyclization reaction to an inactive state with the thiol group unavailable for further modification (refer to other sections on Traut's reagent within this book for additional information).

5. Prepare 100 ml of a 20-m*M* DTNB (Ellman's reagent) solution in modification buffer and add the gel cake to it with stirring.
6. React for 1 h at room temperature with constant mixing. During the reaction, the chromophoric TNB anion will be released and generates a yellow color within the gel slurry. This is indicative of a successful activation process.
7. Drain the activated gel of excess reaction solution and wash with an additional 2 bed volumes of modification buffer. These initial washes may be collected and pooled to determine the activation level of the support by measuring the absorbance of the released TNB anion at 412 nm (ε = 14,150 at pH 8.0). Continue to wash the activated support thoroughly with water, 1-*M* NaCl, and water to remove excess reactants and reaction byproducts. Finally, wash the support with 1-m*M* EDTA (at neutral pH) to protect against metal-catalyzed oxidation of the disulfide groups. Store the TNB–thiol-activated support at 4°C as a 50% slurry in water containing 1-m*M* EDTA and a preservative until use.

LIGAND COUPLING TO TNB–THIOL-ACTIVATED SUPPORTS

The following protocols describe the immobilization of a thiol-containing reduced antibody or a thiol-containing small ligand (such as a peptide containing a cysteine group) to a TNB–thiol-activated resin. The methods may also be used with proteins that have been modified to contain –SH groups through the use of thiolation reagents (Chapter 2, Section 4.1). Some optimization may have to be done to determine a ligand density that is best for a particular affinity chromatography application. Preparing a series of small batches using different concentrations of ligand in each reaction medium will produce a range of ligand densities on the support for evaluation. In addition, after ligand coupling do not attempt to block excess reactive groups with a thiol-containing compound such as cysteine, as this may also cleave off any immobilized ligands.

(A) Coupling of Reduced IgG or F(ab')$_2$ Fragments

1. Dissolve an IgG antibody or F(ab')$_2$ fragment at a concentration of 1 to 10 mg/ml in 1 ml of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 8.0 (coupling buffer). The coupling buffer should be purged with nitrogen and degassed under vacuum to remove oxygen, which may oxidize the thiols and prevent coupling.
2. Add a reducing agent, such as DTT, 2-mercaptoethylamine (2-MEA), 2-mercaptoethanol (2-ME), or tris(carboxyethyl)phosphine (TCEP), to the antibody solution to give a final concentration of at least 5-m*M*. A highly concentrated stock solution of the reducing agent may first be prepared in coupling buffer and then a small aliquot of that solution added to the antibody to obtain the final desired concentration. Mix to dissolve and incubate for 1.5 h at 37°C. Note: Higher concentrations of the reducing agent may be used (typically ≤50-m*M*), but the higher the concentration the more likely will be the reduction of disulfides between the heavy and light chains, which may disrupt the three-dimensional structure of the antibody and destroy antigen binding capability. Optimization of the reductant concentration may have to be done to ensure the best performance of the resultant immunoaffinity support. An alternative to the use of a reducing agent to generate free thiols is to use a thiolation reagent to modify the amines on an antibody to contain thiols. Various procedures on the use of thiolation reagents with proteins and antibodies can be found elsewhere in this book (Chapter 20, Section 1.1).
3. Remove excess reducing agent from the antibody solution by desalting using size exclusion chromatography or by dialysis. During the chromatography or dialysis operation, use coupling buffer to equilibrate and elute the protein through the gel filtration support or as the dialyzing solution. To desalt the 1-ml sample size, a gel filtration column should consist of at least 10 ml of a support having a molecular weight exclusion limit of no more than 5 to 10 kDa to ensure that the protein will come through first in the void volume and be separated from the salt peak containing the reducing agent. A similarly sized dialysis membrane having a size exclusion limit of 5 to 10 kDa is also appropriate. Dialyze the antibody with numerous changes of the outside dialysis solution to ensure a decrease in the concentration of the reducing agent down to levels far below that of the reduced antibody. Complete removal of the reducing agent is essential to eliminate competition when coupling the reduced antibody to the TNB–thiol-activated support. Pool the fractions containing desalted protein from the gel filtration column or recover the dialyzed protein from the dialysis device. The solution may be concentrated if necessary using a centrifugal concentrator to approximately 1 ml to maintain the desired concentration level of antibody in the coupling reaction.
4. Wash 1 ml of a TNB–thiol-activated support with several bed volumes of water to remove storage solution components and then wash with two bed volumes of coupling buffer. Washing may be carried out using spin columns or by using a small drip column. Drain to a moist cake.

5. Mix the washed TNB–thiol-activated gel with the reduced antibody solution and stir at room temperature (or 4°C) for 2 to 4 h. Mixing may be carried out by end-over-end rocking in a sealed container (which can consist of the sealed column used for washing). If the antibody is sensitive to extensive stirring or rocking, the mixture may be mixed for 2 h and then left to sit with only periodic resuspension and mixing every 30 min or so to maintain a somewhat homogeneous mixture of ligand throughout the resin.
6. Wash the support with several bed volumes of coupling buffer to remove most of the not-coupled antibody. The washes may be analyzed *versus* the initial concentration of the antibody solution before coupling to determine the amount immobilized by difference. During the course of the reaction, TNB groups will also be released as the thiol-containing antibody has coupled; therefore, measurement of the absorbance of this anion at 412 nm can provide an accurate determination of the amount of ligand coupled.
7. Thoroughly wash the immunoaffinity support with coupling buffer, water, 1-*M* NaCl, and again with water to remove unreacted materials. Store the support until use at 4°C in water as a 50% slurry containing a preservative.

(B) Coupling Thiol-Containing Small Ligands

1. Wash 10 ml of a TNB–thiol-activated support with water and then add into coupling buffer using a sintered glass filter funnel suspended in a suction filter flask (coupling buffer: 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 8.0). The coupling buffer should be purged with nitrogen and degassed under vacuum to remove oxygen, which may oxidize the thiols and prevent coupling.
2. Dissolve a thiol-containing ligand (such as a cysteine-containing peptide) in 10 ml of coupling buffer at a concentration of at least 2 to 5 mg/ml. Determination of the optimal level of ligand concentration may be achieved experimentally by running a series of small reactions at different concentrations and determining which preparation performs best in the intended affinity chromatography application.
3. Add the ligand solution to the washed TNB–thiol-activated resin and mix to thoroughly suspend the support in the solution. React for 2 to 4 h at room temperature (or 4°C) with constant mixing.
4. Wash the gel with several bed volumes of coupling buffer to remove most of the excess uncoupled ligand. The amount of ligand not coupled may be determined by measuring the volume and concentration of the ligand in the pooled washes. This may be done using a protein assay or spectrophotometrically if the ligand has a characteristic spectral signature. The amount of ligand that coupled to the matrix may then be determined by the difference. Alternatively, monitoring the amount of the TNB anion released during the coupling reaction through its absorbance at 412 nm can provide an indirect, but accurate measurement of the degree of ligand coupling. Drain the gel to a wet cake.
5. Wash the affinity resin thoroughly with water, 1-*M* NaCl, and again with water (at least 10 bed volumes each) to remove unreacted components. Store the support until use at 4°C as a 50% slurry in water containing a preservative.

2.3. Hydroxyl-Reactive Immobilization Methods

This section describes the immobilization of hydroxyl-containing ligands to chromatography supports. Activated supports that are able to couple effectively with hydroxyl-containing ligands must be able to react with the hydroxyl groups while avoiding substantial inactivation by hydrolysis in aqueous solution. The following activation methods perform particularly well in this regard for coupling sugars, carbohydrates, polysaccharides, glycans, and other molecules containing one or more hydroxyl groups. One should keep in mind that in addition to these methods meant to first activate the matrix and then attach the ligand, hydroxyl-containing ligands could also be initially activated in solution with any of the activating reagents described in this chapter suitable for hydroxyls and then in a reverse manner reacted with a support material that contained the appropriate functional group for coupling to the activated ligand intermediate. In other words, a hydroxyl-containing molecule might be activated in organic solution with a limiting mole quantity of DSC, for example (see previous section on DSC activation, this chapter), and then the resultant NHS carbonate reactive group formed on the ligand could be coupled to an amine-containing support material to form a carbamate linkage. This strategy of reversing the normal sequence of support activation followed by ligand coupling to be instead ligand activation followed by coupling to a support can be performed with many organic-soluble small molecules containing a hydroxyl group. This alternative strategy therefore may open up many more options for designing a reaction sequence leading to the desired immobilized ligand.

Epoxide Activation

An epoxide group is a small three-member heterocyclic ring containing two carbon atoms and one oxygen. The combination of ring strain and the electron withdrawing effects of the oxygen atom cause the carbon

atoms to carry a partial positive charge and therefore be good sites for potential nucleophilic attack. An epoxide reacts with a nucleophile through a ring opening process, which yields a bond to the nucleophilic group on one carbon and the formation of a hydroxyl group on the adjacent carbon as the epoxy ring opens. For epoxides that exist on terminal carbon atoms, the reaction with a nucleophile causes covalent linkage with the primary carbon atom and hydroxyl formation on the adjacent secondary carbon atom.

Depending on the pH and conditions of the reaction medium, epoxides can be made to react effectively with thiols, amines, or hydroxyl (even phenolic) groups (Figure 15.81). Similar to the relative reactivity of vinyl sulfone-activated supports described previously, epoxides efficiently react with thiols in the pH range of 7.5 to 8.5, amines react within the range

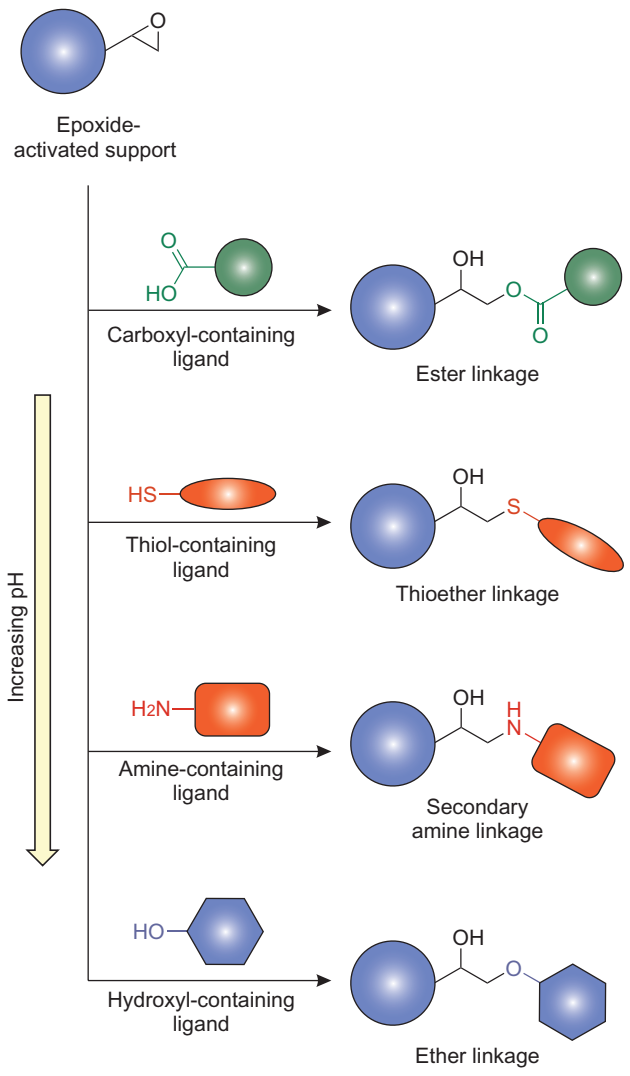

FIGURE 15.81 Reaction of an epoxide support with a thiol-, amine-, hydroxyl-, or carboxylate-containing compound.

of pH 9 to 11 (Ghazi *et al.*, 2005), and hydroxyl groups react at highly alkaline pH values (pH > 11). The reactions may be accelerated with heating (i.e., ≥37°C), which often is done during the activation of a hydroxyl-containing support with a *bis*-epoxide compound and during subsequent coupling reactions with carbohydrate hydroxyl groups. Epoxy groups also are known to react under certain conditions with carboxylic acids to form ester linkages. This reaction is important in many polymer resins that are designed to crosslink and form coatings, adhesives, moldings, and other synthetic solids for industrial and commercial applications (Blank *et al.*, 2001). Epoxy ester formation has also been investigated with amino acids as a mechanism in the preparation of crosslinked collagen-based materials, and it has found to occur best at slightly acidic pH (Zeeman, 1998). However, the reaction rate of carboxylate groups with epoxides is much slower than that of the reactions with thiols, amines, or hydroxyl groups under the recommended pH conditions described in this section. It is likely that if ester formation occurs with biological ligands that it is a minor product compared to the reactions commonly used with epoxy-activated supports.

Homobifunctional epoxide crosslinker compounds (bisoxiranes) are often used to activate hydroxyl-containing chromatography supports to result in the production of reactive epoxy groups for the immobilization of hydroxylic ligands. Perhaps the reagent most commonly used for this purpose is 1,4-butanediol diglycidyl ether (Sundberg and Porath, 1974), which contains a relatively hydrophilic 12-atom spacer group with epoxides at each end. At alkaline pH and in large excess, one end of this compound can be made to react with the hydroxyls on a matrix to create an ether linkage while forming a hydrophilic spacer which terminates in the second epoxide group for subsequent ligand immobilization (Figure 15.82).

The coupling of protein affinity ligands onto epoxide-activated supports can be significantly enhanced by the addition of certain salts to the reaction medium (Murthy and Moudgal, 1986; Wheatley and Schmidt, Jr., 1993, 1999). In particular, salts that increase the interactions of hydrophobic molecules in aqueous solution appear to promote protein adsorption onto the activated support prior to covalently reacting with the epoxy groups. Lyotropic salts such as sodium or potassium sulfate, sodium or potassium phosphate, and even ammonium sulfate can be used to drive soluble proteins toward the surface of the particles by a salting out effect, thus forcing them into proximity with the reactive groups. Surprisingly, even the presence of ammonium ions in ammonium sulfate salts does not interfere with the reaction with amines on proteins. Using ammonium sulfate concentrations of 0.4 to 2.5-*M*, most proteins will couple to the epoxide support in

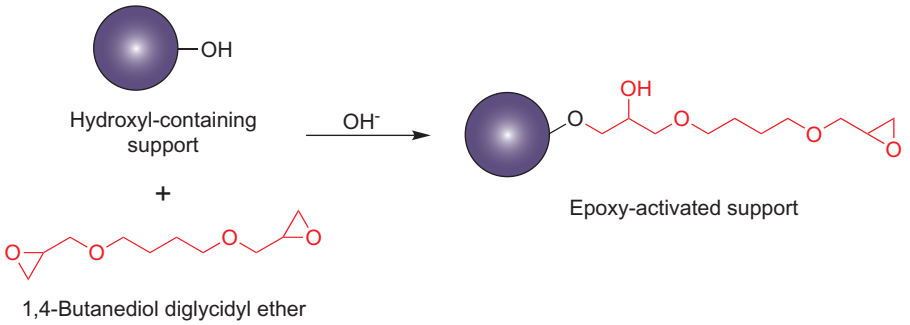

FIGURE 15.82 Activation of hydroxylic supports with 1,4-butanediol diglycidyl ether.

yields of 95 to 100% in 20 h at room temperature. The other activated support that has this tendency to be enhanced for coupling proteins when in the presence of a lyotropic agent is the azlactone activation chemistry, described previously in this chapter. Presumably, the lyotropic-induced deposition of proteins onto the epoxide-activated surface occurs first, followed by the nucleophilic attack of protein amines onto the carbon of the epoxide ring, which causes covalent coupling.

Even the immobilization of some small affinity ligands onto epoxide-activated supports can be enhanced by the addition of a lyotropic salt to the coupling reaction. Bauer-Arnaz *et al.* (1998) found that various *S*-alkyl glutathione derivatives could be coupled in approximately twice the yield if a high concentration of potassium phosphate (2-*M*) was present in the reaction buffer. In this case, the coupling reaction was performed at pH 10.5, which indicates that even amine-containing small ligand coupling can be enhanced with salt if the compound structure contains hydrophobic regions that can interact with the activated support prior to covalent binding.

Mateo *et al.* (2002) developed salt-induced immobilization methods using the epoxide-activated support Sepabeads-EP. The coupling and stabilization of the enzyme penicillin G acylase (PGA) from *E. coli* was accomplished using an initially high concentration of sodium phosphate buffer (1-*M*) at pH 7. The effect of the salt to push the enzyme molecules toward the matrix surface near the epoxide active groups resulted in efficient immobilization even at neutral pH. Although the reaction took 24 h to go to completion, the result was an increase of around 10,000-fold in stabilization of the enzyme compared to the soluble form.

Grazú *et al.* (2003) used an interesting combination of thiol/disulfide exchange coupling and epoxide reactions for enzyme immobilization to enhance the yield of epoxy coupling without the use of a lyotropic salt (see previous sections on pyridyl disulfide and TNB–thiol activation, this chapter). On a highly activated epoxide support, they reacted a limited amount of DTT with it to obtain a partially thiolated matrix, which contained both thiol and epoxide groups. Next, an enzyme was thiolated with SPDP followed by reduction and the thiols on the support were activated using 2,2′-dipyridyl disulfide to provide reactive pyridyldithiol groups. Mixture of the thiolated enzyme with the activated support resulted in the rapid formation of disulfide linkages with the thiol groups created on the protein followed by continued reaction with the epoxide groups to give a multi-point attachment with each enzyme.

Epoxy activation and coupling has been extensively used to couple metal chelating compounds to particles of all types for immobilized metal affinity chromatography (IMAC) applications (Novotna *et al.*, 2010). Often, an organic chelating molecule contains a secondary amine, such as in the example of iminodiacetic acid, which can be effectively coupled to a chromatography support by reaction with an epoxide (Figure 15.83). In addition, the coupling of glutathione is often done using epoxy-activated supports, because the most effective site of immobilization on the molecule is through its thiol group, which allows the ligand to interact with glutathione-*S*-transferase (GST) fusion proteins to capture and purify them after recombinant expression (Simons and Vander Jagt, 1977; Smith and Johnson, 1988; Stahl *et al.*, 2003).

Due to the versatility of epoxy-activated supports in coupling thiol-, amine-, or hydroxyl-containing ligands, the method has become a popular choice for immobilizing a wide range of affinity molecules. In addition, the activated support is extremely stable to hydrolysis even when stored in aqueous solution (neutral pH) for extended periods. The activation of chromatography supports, nonporous particles, and surfaces with the compound 1,4-butanediol diglycidyl ether creates a long spacer arm linking any potential ligand, which is also hydrophilic enough to minimize nonspecific binding.

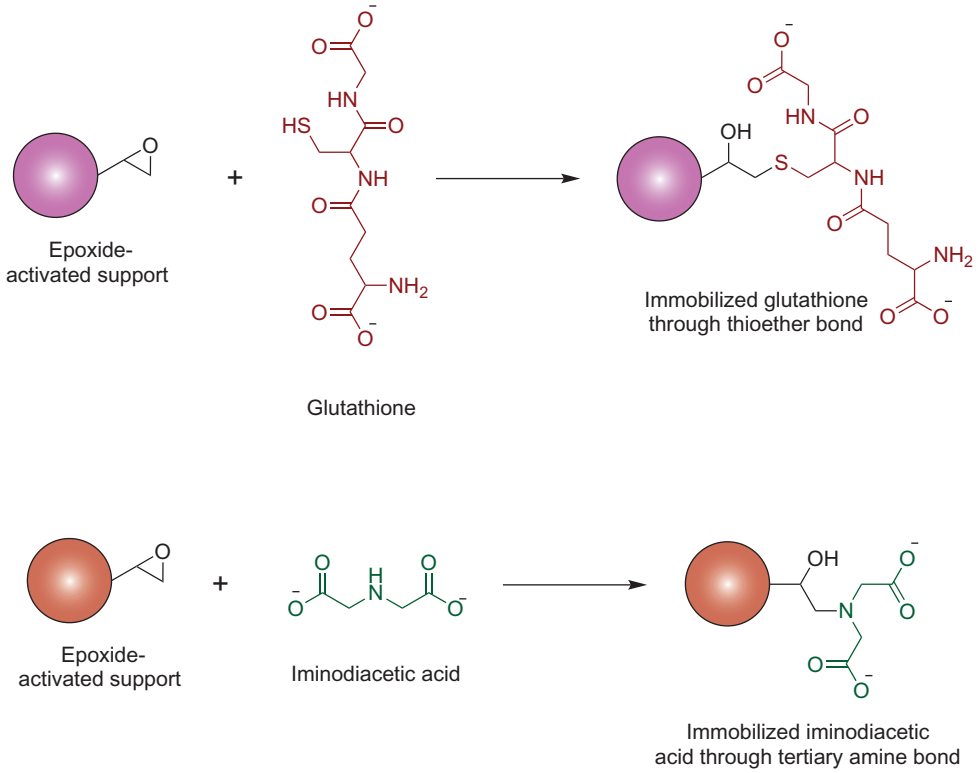

FIGURE 15.83 Immobilization of iminodiacetic acid and glutathione on epoxy-activated supports.

PREPARATION OF AN EPOXY-ACTIVATED SUPPORT

The following protocol describes the activation of a hydroxyl-containing support with the bis-epoxide compound 1,4-butanediol diglycidyl ether under highly alkaline conditions. All operations should be done in a fume hood while wearing the appropriate personal protective equipment. Avoid contact with all solutions and avoid breathing vapors of the epoxide compound or the solvents used during the operations.

1. Wash 100 ml of a hydroxyl-containing support material (i.e., Sepharose (agarose), Toyopearl, or Trisacryl) with several bed volumes of water to remove storage solution and preservatives. The washing may be done using a sintered glass filter funnel suspended in a suction filter flask. Pull a gentle vacuum on the flask to facilitate the removal of the solutions from the gel after each addition of wash. Drain to a moist cake. Note: When activating agarose supports with a *bis*-epoxy compound, it is common to start with a non-crosslinked support (e.g., 4% agarose), because reactions with both ends of the epoxide will occur to some extent and form a crosslinked matrix.
2. Suspend the gel in 75 ml of 0.6-*N* NaOH (caustic!) containing 150 mg of sodium borohydride dissolved into it. Transfer the gel suspension into a three-necked, round-bottom flask and stir using an overhead paddle stirrer in the fume hood. Place the round-bottom flask in an open container into which water can be added to control the temperature of the reaction. Put a thermometer into one of the three necks of the flask to monitor the temperature throughout the activation reaction. Add water at room temperature to the surrounding bath up to the level of the inner gel slurry and have ice on hand if necessary to control any exothermic tendencies.
3. Slowly add to the stirring gel suspension 75 ml of 1,4-butanediol diglycidyl ether over a period of about 20 min. Monitor the temperature and add ice to the surrounding water bath if required to maintain a constant ambient temperature of about 20 to 25°C. There may be an exothermic temperature spike during the early stages of the reaction; however, do not cool the reaction below the recommended temperature range, as it will slow the activation process.
4. Stir the reaction for 8 to 10 h or overnight at room temperature.
5. Transfer the gel slurry to the filter funnel and wash with 4 bed volumes of water to remove the NaOH solution and the borohydride. The excess epoxide

compound is more difficult to remove using only water washes. For this reason, sequentially wash the gel with increasing concentrations of acetone (or ethanol) (e.g., 30%, 70%) until 100% solvent is used. Continue to wash with 100% solvent for at least 10 bed volumes to remove the remaining traces of excess epoxide. Next, sequentially wash back into water by reversing the concentrations of solvent used previously. Finally, wash with 10 bed volumes of water to remove the last traces of solvent. Store the epoxy-activated support at 4°C as a 50% slurry in water and containing a preservative until use.

LIGAND COUPLING TO EPOXY-ACTIVATED SUPPORTS

The following protocols represent some common methods of coupling ligands to epoxy-activated supports. In the first example, a disaccharide (lactose) is immobilized through its hydroxyl groups onto epoxy-activated agarose at high pH. Other sugars or carbohydrates, including polysaccharides and glycans, may be coupled using similar procedures. In the second example, a protein is immobilized onto an epoxy-activated support at near physiological pH using a buffer containing a lyotropic agent to push the protein molecules into close proximity with the reactive groups, and thus facilitate efficient coupling while avoiding higher pH conditions to drive the reaction.

(A) Coupling of Carbohydrates

1. Wash 100 ml of an epoxy-activated support with several bed volumes of water to remove any storage solution and preservatives. Use a sintered glass filter funnel suspended in a vacuum filtration flask to facilitate the washing steps. Drain the gel to a moist cake.
2. Prepare a lactose ligand solution by dissolving 15 g of lactose in 100 ml of 0.1-*N* NaOH (makes a 0.438-*M* solution). Use care in handling the caustic NaOH solution and use the appropriate personal protective equipment during all operations.
3. Add the washed gel cake to the ligand solution with stirring and transfer the reaction slurry to a three-necked, round-bottom flask. Put the flask in a heating mantle and use an overhead paddle stirrer to mix the resin during the reaction. Add a thermometer to one of the openings in the flask and heat the reaction mixture with constant stirring to 40°C.
4. Stir the reaction for 24 h at 40°C.
5. Wash the support with several bed volumes of water to remove most of the reaction medium and then wash with 0.1-*M* sodium bicarbonate, pH 8.0, followed by an extensive water wash to remove the last traces of buffer and reactants. The immobilized lactose support can be stored until use at 4°C as a 50% slurry in water containing a preservative.

(b) Coupling of Proteins

Proteins containing cysteine thiol groups or amines may be immobilized onto epoxy-activated supports in the pH range of 7.0 to 11, with pH 7.5 to 8.5 being most effective for –SH groups and pH 9 to 11 optimal for lysine or N-terminal amines (Ghazi *et al.*, 2005). However, if a lyotropic salt is added to the reaction medium, then protein coupling to amines can be made to occur with excellent yield at pH 7.0 to 8.0, which is much more amenable to maintain protein stability. The following protocol describes the immobilization of a protein at mildly alkaline pH using the lyotropic salt sodium sulfate. Some optimization of the level of salt concentration in the reaction medium may have to be carried out for certain proteins to prevent precipitation while still promoting the best possible matrix-protein interactions leading to efficient reaction rates.

1. Wash 10 ml of an epoxy-activated support with several bed volumes of water to remove any storage solution and preservatives. Use a small sintered glass filter funnel suspended in a vacuum filtration flask to facilitate the washing steps. Drain the gel to a moist cake.
2. Prepare 10 ml of a protein ligand solution at a concentration of 1–20 mg/ml in coupling buffer. The coupling buffer may be formulated as 0.1-*M* sodium phosphate, pH 7.5, containing 0.5-*M* sodium sulfate as the lyotropic agent. Other lyotropic salts may also be used. For example, an alternative coupling buffer composition that was used with success by Mateo *et al.* (2002) to immobilize enzymes consisted of 1-*M* sodium phosphate, pH 7.0, in which the sodium phosphate functioned both as a buffer for pH stabilization and as the lyotropic agent. Despite the effect of a lyotropic agent to drive protein molecules toward the surface for reaction, some proteins may still require a higher-pH environment to efficiently couple. An alternative higher pH buffer is 0.1-*M* sodium carbonate, pH 9.0, containing 0.5-*M* sodium sulfate.
3. Add the washed epoxy-activated resin to the ligand solution with stirring.
4. React with constant mixing for at least 24 h at room temperature. Mixing may be done using an overhead paddle stirrer or by end-over-end rocking in a sealed container. Some proteins may require longer reaction times to reach maximal coupling yields for attachment to the support.
5. Wash the support with several bed volumes of coupling buffer and collect the washes. The amount of protein coupled may be determined by the difference between the initial amount of protein added to the reaction mixture and the total amount left in the not-coupled washings. Drain the support to a wet cake.
6. Block unreacted epoxide groups on the support using a small molecule containing a nucleophilic

group that will readily react with the leftover active sites. For instance, cysteine, ethanolamine, or glycine may be used for this purpose. Cysteine blocking will proceed faster than amine-containing blockers and at lower pH values, because of the increased reaction rate of epoxides with the highly nucleophilic thiol groups. However, avoid using thiol-containing compounds that are also strong disulfide reducing agents, such as DTT or 2-mercaptoethanol, if the protein that was immobilized is sensitive to reduction. Cysteine is much milder in this regard and can be used as a blocker without detrimentally affecting most proteins. Prepare at least a 0.1-*M* solution of the blocking agent in coupling buffer and mix with the washed resin.

7. React 2 to 4 h with mixing (for a thiol-containing blocking agent, such as cysteine) or for 24 h (if using an amine-containing blocking agent).
8. Wash the support with 10 bed volumes of coupling buffer without the lyotropic agent present (e.g., 0.1-*M* sodium phosphate, pH 7.5). Continue to wash with water, 1-*M* NaCl, and again with water to remove the last traces of all reactants and coupling buffer components. The immobilized protein can be stored until use at 4°C as a 50% slurry in water containing a preservative.

Divinyl Sulfone Activation

Divinyl sulfone (DVS) is a small bifunctional compound that can be used to activate hydroxyl-containing supports for the immobilization of hydroxyl-containing ligands, such as sugars, carbohydrates, polysaccharides, glycans, and small organic molecules containing an available –OH group. The chemistry of DVS activation and coupling is discussed in great detail in a previous section in this chapter, including a protocol for the coupling of hydroxylic ligands; see Thiol-Reactive Immobilization Methods for an overview and protocols for ligand immobilization.

Trichloro-s-Triazine Activation

The activation of hydroxyl-containing supports with trichloro-*s*-triazine (TsT) was presented in detail in the section on Amine-Reactive Immobilization Methods discussed earlier in this chapter. The cyanuric chloride reactive groups on a TsT-activated support can be used to immobilize thiol-, amine-, or hydroxyl-containing ligands with high efficiency. The coupling of hydroxyl-containing sugars, carbohydrates, polysaccharides, glycans, or other organic ligands containing hydroxyls can be done using a high pH environment (pH > 11), essentially using the same conditions that are recommended for the coupling of triazinyl dyes to hydroxyl matrices (Hermanson *et al.*, 1992; Chamani *et al.*, 2011).

LIGAND COUPLING TO TsT-ACTIVATED SUPPORTS

The following protocol assumes that 100 ml of a TsT-activated support has been prepared as described previously in the section on Amine-Reactive Immobilization Methods.

1. Prepare 100 ml of a hydroxyl-containing ligand solution in 0.5-*M* sodium carbonate (no pH adjustment necessary) by dissolving the ligand at a concentration range of 0.1 to 0.5-*M* (for a small sugar molecule or disaccharide) or about 5 to 10 mg/ml (for larger polysaccharide or glycan ligands). Notes: The optimal concentration of a carbohydrate in the immobilization reaction may have to be determined by experimentation to obtain the best ligand loading for acceptable performance in the intended affinity chromatography application. For example, immobilized sugars used in the purification of lectins often are coupled at relatively low ligand levels (below the maximal coupling capacity of the gel), because a lower ligand density avoids the potential for multi-site binding with a lectin, which may result in high avidity interactions followed by difficulty in eluting the bound proteins from the support.
2. Wash 100 ml of a TsT-activated support into water and coupling buffer by suctioning off excess acetone storage solution and resuspending the gel into water. This can be done by pulling a gentle vacuum on the filter flask to filter off solvent while breaking up the support into small, finely divided pieces using a spatula, at the same time as being careful not to allow the matrix to dry out. Once the support is broken into small pieces, remove the vacuum and resuspend the gel in water with mixing. Continue to wash the support with water for at least 5 to 10 bed volumes to remove the solvent. Finally, wash the support with 2 to 3 bed volumes of coupling buffer (0.5-*M* sodium carbonate, no pH adjustment).
3. Add the washed gel cake to the ligand solution with stirring and transfer the reaction slurry to a three-necked, round-bottom flask. Put the flask in a heating mantle and use an overhead paddle stirrer to mix the resin during the reaction. Add a thermometer to one of the openings in the flask and heat the reaction mixture with stirring to 40°C. After 2 h of mixing, increase the temperature to 60°C with continued stirring.
4. Mix the reaction for 24 h at 60°C.
5. Wash the support with several bed volumes of water to remove most of the reaction medium and then wash with 0.1-*M* sodium bicarbonate, pH 8.0, followed by an extensive water wash to remove the last traces of buffer and reactants. The immobilized carbohydrate support can be stored until use at 4°C as a 50% slurry in water containing a preservative.

2.4. Carbonyl-Reactive Immobilization Methods

Chromatography supports can be modified with reactive groups to specifically couple to carbonyls on affinity ligands or proteins and form stable covalent bonds. These carbonyl groups may consist of aldehydes, ketones, or sometimes even carboxylates on ligands that can be targeted under the right conditions to covalently link with certain reactive groups present on support materials. The following sections describe the principal methods of activating a support to couple with carbonyl-containing ligands. The reactive intermediates prepared in this section are somewhat unique, however, in that they typically do not spontaneously form covalent bonds with the functional groups encountered on most biomolecules. The hydrazide, aminooxy, and amine derivatives of supports described in this section will not immediately react with large complex macromolecules like proteins, nucleic acids, lipids, and most polysaccharides found within cells or living organisms. In this regard, they have more selective reactivity than most of the other electrophilic active groups described in this chapter for the immobilization of biomolecules. However, given the right circumstances where a ligand contains an aldehyde, ketone, or in some instances a carboxylate, the creation of these active intermediates can facilitate site-directed coupling to discrete locations on molecules that some of the other methods cannot accomplish.

Hydrazide or Hydrazine Supports for Coupling Aldehydes, Ketones, or Carboxylates

A hydrazine or hydrazide group is able to react with an aldehyde or ketone to form a dehydration product, called a hydrazone, which is a type of Schiff base having a double bond between the carbon atom of the original carbonyl group and the terminal hydrazino nitrogen. This product represents a more stable Schiff base than that formed between an amine and a carbonyl group (standard imine), because a hydrazone is less susceptible to hydrolysis back to the starting materials. In many cases, the hydrazone bond created with a carbonyl-containing ligand is strong enough not to need reduction with sodium cyanoborohydride to stabilize the linkage, as opposed to amino Schiff bases which almost always require reduction to prevent leakage. The hydrazone electrons can delocalize due to the electronegativity of the hydrazide carbonyl oxygen and therefore it stabilizes the bond much better than the linkage between an amine and an aldehyde group. Particularly, if there is a potential for more than one hydrazone attachment point with a ligand, such as in the immobilization of glycoconjugates, the likelihood of ligand leakage becomes negligible. In certain cases, however, hydrazone bonds should be reduced to prevent the possibility of slow ligand leaching over time. This is especially true if the point of attachment between the support and the ligand consists of only a single hydrazone bond.

The use of hydrazides or hydrazines created on a chromatography matrix to immobilize carbonyl-containing ligands was developed specifically to couple glycoproteins through their carbohydrates (O'Shannessy *et al.*, 1984; Bayer *et al.*, 1987; Hoffman and O'Shannessy, 1988; O'Shannessy and Wilchek, 1990). Limited oxidation of carbohydrates or glycans using sodium periodate can create aldehydes on either sialic acid groups alone or on any sugar of the glycan possessing adjacent hydroxyl groups (diols) (see Chapter 2, Section 2). Oxidized glycoproteins then may be reacted with a hydrazide-containing support to immobilize the proteins through hydrazone linkages, which only target the glycan portions of the molecules. This site-directed coupling method through the carbohydrate portion often aids in preserving active sites or binding regions within proteins. This can lead to better preservation of enzyme activity or better binding performance to a target molecule than using more random coupling methods like amine-reactive chemistries, which attach through lysine or N-terminal amines in many locations across the protein surface (Domen *et al.*, 1990).

Glycosylated antibodies, for instance, can be immobilized onto a hydrazide-containing support after mild periodate oxidation of the carbohydrate, which is usually located between the heavy chains within the Fc region. (Note: Some carbohydrate may be present on the Fab fragments near the antigen binding area in certain antibody types.) The use of hydrazone-mediated coupling might be used to avoid an attachment of the antibody to the support near the antigen binding regions. The kinetics of periodate oxidation with antibodies to generate aldehydes was investigated by Hage *et al.* (1997) and found to involve two distinct populations of oxidizable groups—one group that oxidized quickly within 5 to 10 min (likely sialic acid residues) and another group that took several hours to completely oxidize. The oxidation of rabbit polyclonal IgG with 10-m*M* periodate resulted in the production of approximately one aldehyde per immunoglobulin molecule after 10 min at 25°C, two aldehydes after 30 min, and about three aldehydes after 60 min. The rate of periodate oxidation of antibody carbohydrate also was found to be dependent on the pH of the reaction. From pH 3 to 7, the oxidation was found to decrease as the pH increased (Wolfe and Hage, 1995). After 30 min of oxidation at room temperature, two aldehydes were formed at pH 5 to 6, three were created at pH 4, and six resulted from the reaction at pH 3. Over-oxidation by extending the length of the periodate incubation procedure or by using concentrations of periodate exceeding

50-m*M* should be avoided to prevent damage to the avidity or immunoreactivity of antibodies (Abraham *et al.*, 1991). Normally, periodate oxidation reactions are not done for longer than about 15 to 30 min, depending on the sensitivity of the protein being treated. Treatment of antibodies with periodate at low concentrations for 30 min is thus sufficient to provide aldehydes on each antibody for efficient coupling while avoiding the damaging effects of over-oxidation.

Small-molecule aldehydes or ketones may also react with a hydrazide-activated support and end up being immobilized through hydrazone linkages. The reducing ends of sugars, carbohydrates, or even glycans that have been cleaved off of glycoproteins can be selectively immobilized through this process. The reducing ends of carbohydrates typically react with the hydrazide support at a slower rate due to the small amount of time most reducing sugars are in the open aldehyde form in solution as opposed to the cyclic hemiacetal form. Some biological small aldehyde- or ketone-containing molecules that may be present in some samples such as pyridoxal, glyceraldehyde, acetaldehyde, pyruvate, α-ketoglutarate, acetone, and retinal can also couple to the support quite effectively and block some of the hydrazides to further coupling to a glycoprotein. For this reason, exposure of a hydrazide-containing matrix to crude biological samples should be avoided. In addition, never wash a hydrazide support with acetone or any other organic solvent containing a ketone, because the support will become inactivated.

Hydrazide-containing supports can be prepared by the coupling of a *bis*-hydrazide compound to a matrix using at least two reaction strategies. A *bis*-hydrazide such as adipic dihydrazide or carbohydrazide can be added in large excess to the appropriately prepared matrix to form spacer arms, which then terminate in free hydrazide groups. This process can be done through direct coupling to an amine-reactive support or through the intermediary use of a carboxylate-terminal spacer arm to which the *bis*-hydrazide compound is then coupled using EDC. Early methods described for the preparation of a hydrazide-support involved the reaction of adipic acid dihydrazide with a periodate-oxidized agarose matrix (Hoffman and O'Shannessy, 1988). However, the reactivity of this aldehyde-containing support is so great toward the *bis*-hydrazide spacer that a large portion of the gel ends up being tremendously crosslinked, even to the extent of forming particle aggregates and damaged beads. This occurs even when adipic dihydrazide is added to the support in large mole excess, indicating that the potential for hydrazone formation is so high that both ends of the *bis*-hydrazide compound inevitably end up reacting with aldehydes on the support.

A more controlled approach to making a hydrazide-activated support is to build it from a terminal carboxylate spacer arm derivative, which is coupled to the matrix initially and then activated to attach the *bis*-hydrazide (see section on spacer arms, this chapter). Activated carboxylates will react with a hydrazide group on a *bis*-hydrazide compound to form a secondary amide (hydrazino) bond with a short spacer arm, which then terminates in a free hydrazide group (Figure 15.84). The reaction rate of coupling the hydrazide to the carboxylate is much less than it is with an aldehyde-containing support, so the matrix does not become highly crosslinked and damaged during the process. The reaction can be made to occur through activation of the carboxylate spacer using a carbodiimide such as EDC or through the use of an NHS ester-activated support (see previous discussion on amine reactive activation methods, this chapter). NHS may also be added to an EDC reaction to generate an intermediate NHS ester and enhance the reaction rate with the *bis*-hydrazide molecules. The result of these reactions is the preparation of a hydrazide-activated support that is ready to covalently couple to aldehyde-containing ligands.

Hydrazide-activated supports are relatively stable in aqueous solution if a preservative is added to prevent growth. The coupling of carbonyl-containing ligands to the matrix can be done over a broad pH range, but

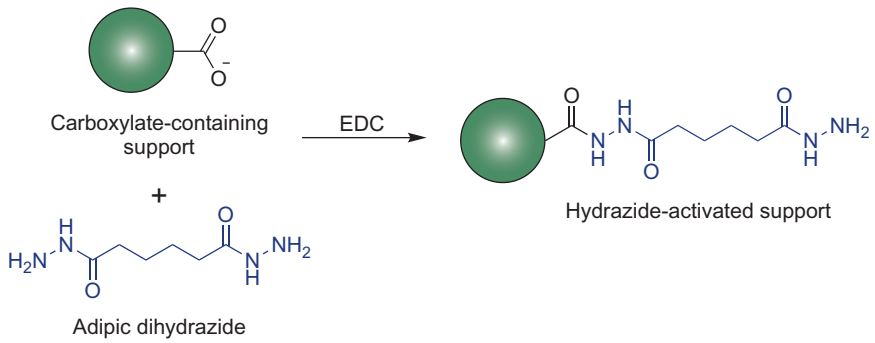

FIGURE 15.84 Preparation of a hydrazide support from a carboxylate spacer using EDC.

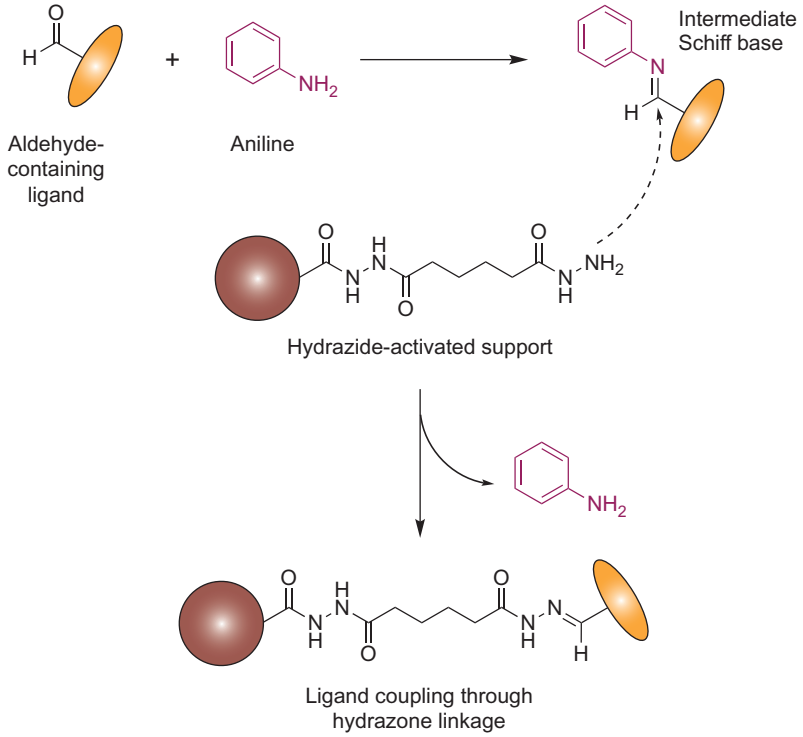

FIGURE 15.85 Immobilization of an aldehyde-containing ligand using an aniline catalyst.

is optimal under slightly acidic conditions (pH 5–6). It has also been found that the yield of hydrazone formation and the rate of the reaction can be increased dramatically by use of an aniline-catalyzed reaction process (Cordes and Jencks, 1962; Dirksen *et al.*, 2006a,b; Dirksen and Dawson, 2008; Byeon *et al.*, 2010). Aniline will react with an aldehyde group on the ligand to form an intermediate Schiff base between its aryl nitrogen and the carbon atom of the carbonyl group of the aldehyde. The aniline imine intermediate more rapidly gets protonated in solution than the initial oxygen of the aldehyde or ketone carbonyl, and it is this species that is the ideal form which can react with the hydrazide groups (Kohler, 2009). This aniline imine intermediate is then rapidly attacked by the hydrazides on the support, which results in displacement of aniline with associated hydrazone bond formation with the hydrazides (Figure 15.85). This two-step reaction process results in much faster hydrazone formation and ligand immobilization than reactions done without the aniline catalyst being present. Using aniline catalysis offers the potential of doing immobilization reactions under more neutral pH conditions while still maintaining high efficiency of hydrazone bond formation (Zeng *et al.*, 2009).

HYDRAZIDE ACTIVATION PROTOCOL

The following protocol describes the modification of a carboxylate-containing support with a *bis*-hydrazide compound to form a hydrazide-activated matrix. The prior creation of a carboxylate-containing support may be achieved by coupling a carboxylate-terminal spacer arm to a matrix using the methods described elsewhere in this chapter on spacer arm production. The *bis*-hydrazide compound used can be one of many; however, adipic dihydrazide probably is the most common. An alternative small bis-hydrazide reagent is carbohydrazide, which is just a single carbonyl group with two hydrazines. It is the most reactive dihydrazide available and can be used to minimize the amount of alkyl chains used in a spacer arm, especially to limit the potential for creating sites of hydrophobic binding and nonspecificity in the final matrix.

1. Wash 100 ml of a carboxylate-containing support material with water (at least 3 bed volumes) to remove storage buffers and preservatives. Wash the gel with an additional 2 bed volumes of 0.1-*M* MES, pH 4.75 (reaction buffer). The washing steps may be carried out using a sintered glass filter suspended in a suction filter flask and applying a gentle vacuum to facilitate drawing the wash solutions through the support. Drain the support to a moist cake.
2. Prepare 100 ml of a solution of 0.5-*M* adipic dihydrazide in the reaction buffer. Alternative *bis*-hydrazide compounds may be used at the same concentration with success. Readjust the pH if necessary.

3. Add the washed support to the dihydrazide solution with mixing. Continue to stir the support slurry by using an overhead paddle stirrer while adding 3 g of the carbodiimide EDC (fresh).
4. React for 3 h at room temperature with constant stirring.
5. Wash the support extensively with water, 1-*M* NaCl, and again with water to remove unreacted dihydrazide and any reaction byproducts. Store the hydrazide-containing support until use at 4°C as a 50% slurry in water containing a preservative.

LIGAND COUPLING TO HYDRAZIDE-ACTIVATED SUPPORTS

The following protocols describe the periodate oxidation of an antibody followed by its aniline-catalyzed immobilization onto a hydrazide-containing support. A subsequent immobilization protocol describes the immobilization of sugars, polysaccharides, or glycans through their reducing ends. Similar protocols can be used to immobilize other glycoconjugates or carbohydrates after periodate oxidation. In addition, small ligands containing aldehydes may be coupled to a hydrazide-containing support using the identical buffers and aniline addition process. Larger quantities of immobilized ligands may be prepared by proportionally increasing the amount of reagents used in these procedures.

(A) Periodate Oxidation of Antibody or Glycoprotein

1. Dissolve 1 to 10 mg of an IgG antibody that is glycosylated (or another glycoprotein) in 1 ml of coupling buffer (0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5). Be careful that the antibody does not contain an amine-containing buffer in solution, such as glycine or Tris, which may alter the pH of the coupling buffer or interfere with the subsequent coupling reaction. Dialyze or desalt the antibody using coupling buffer if necessary to remove interfering components before proceeding.
2. Weigh out 2.1 mg of sodium periodate into a small centrifuge tube and add the antibody solution to it with mixing using a vortex mixer. Continue to mix until the sodium periodate is completely dissolved and then wrap the tube in aluminum foil to protect it from light.
3. React for 30 min at room temperature with periodic mixing. Do not allow the oxidation to continue longer than this time period or oxidative damage may occur to the protein structure.
4. Stop the reaction by desalting the antibody solution using a size exclusion chromatography support having a molecular weight exclusion limit of no more than 10 kDa (i.e., a 10-ml column of Sephadex G-25 or the equivalent). Use coupling buffer to perform the chromatography and collect the protein peak, which will elute in the void volume before the salt peak. Spin columns may also be used for this operation, as they will result in less dilution of the protein solution during the separation and are quicker to use (e.g., Zeba Spin Desalting Columns from Thermo Fisher). Use the oxidized antibody or glycoprotein in the coupling reaction immediately to prevent the potential for protein crosslinking over time through Schiff base formation or Mannich reaction processes.

(B) Coupling an Oxidized Antibody to a Hydrazide Support

1. Wash 1 ml of a hydrazide-containing support with water to remove storage solutions and preservatives. Then wash with several ml of coupling buffer (0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5). The washing of a small quantity of a chromatography support may be done in a drip column or a spin column without a top frit. Drain the gel to a wet cake and place the bottom cap on the column to stop the flow. The coupling reaction may be done in a sealed column or the washed gel transferred to a small plastic centrifuge tube able to hold at least 2.5 ml of slurry.
2. Add the oxidized antibody or glycoprotein from part (A) to the washed gel cake and stir to resuspend the matrix.
3. In a fume hood, add 18 µl of aniline catalyst to the gel slurry with stirring. This results in approximately a 0.1-*M* aniline solution in the coupling reaction mixture.
4. Continue the reaction for at least 2 to 4 h with constant mixing. Proteins with higher glycosylation content will couple faster than proteins with lower amounts of carbohydrate. The mixing may be done by end-over-end rocking in a sealed container or column.
5. Blocking of excess hydrazide groups on the support may be done by the addition of glyceraldehyde to the reaction mixture at a final concentration of 0.1-*M* and continuing to mix for 30 min. In most cases of glycoprotein immobilization, blocking of the unreacted hydrazides is not necessary; however, if this step is performed, do not add any reducing agents to the mixture or glyceraldehyde-protein adducts also will be formed (Acharya and Manning, 1980).
6. Wash the support with several bed volumes of coupling buffer and collect the washes. The amount of protein coupled may be determined by the difference in the amount of protein present in the reaction medium before coupling and after coupling, taking into account volume differences. Note that aniline may interfere with some methods of protein

concentration determination (e.g., absorbance at 280 nm) and may have to be removed. Continue to wash the support extensively with water, 1-*M* NaCl, and water to remove the last traces of all reactants.

7. The hydrazone linkages on the support may be reduced to stabilize them, if necessary. Often with coupling glycoproteins or glycosylated antibodies, the reduction step is not needed, because multi-point attachment takes place to the matrix and creates a high avidity bond. However, if reduction is deemed necessary due to a slow leakage of ligand from the support, then in a fume hood add to the washed gel 1 ml of coupling buffer containing 100-m*M* sodium cyanoborohydride (6.2 mg) (dangerous compound!). Reduce the hydrazone bonds for 1 h with constant mixing. Finally, wash the support as in step (6) and store the affinity support as a 50% slurry in water or buffer containing a preservative at 4°C.

(c) Coupling the Reducing end of Carbohydrates to Hydrazide Supports

Many carbohydrates, including monosaccharides, disaccharides, oligosaccharides, and glycans, contain a reducing sugar at their anomeric end that is in a cyclic hemiacetal form containing a masked aldehyde group. The aldehyde is only available for reaction when it is in the open form, which is a minority of time in aqueous solution, so immobilization reactions with hydrazide-containing supports usually take much longer to go to completion than reactions with freely available aldehydes. The coupling of reducing sugars onto hydrazide supports can be achieved with or without the presence of a reducing agent and the result will be two different linkage types (Figure 15.86). If a reductant such as sodium cyanoborohydride is used in the reaction medium, then coupling will take place at the anomeric carbon atom through ring opening and the formation of a reduced hydrazone linkage. However, if the reaction is performed without a reducing agent being present, the result will be the creation of a glycosylhydrazide bond with an intact ring structure at the reducing sugar (Rothenberg *et al.*, 1993; Toomre and Varki, 1994; Bigge *et al.*, 1995; Leteux *et al.*, 1998; Srikrishna *et al.*, 2001). It may be important for some affinity chromatography applications to maintain the conformation of a cyclic sugar structure at the reducing end in order to ensure interaction with certain lectins.

The addition of an aniline catalyst to the coupling reaction with a reducing sugar has been shown to dramatically accelerate the formation of the hydrazone bond (Thygesen *et al.*, 2010). The aniline initially traps the open ring form of the sugar's aldehyde through

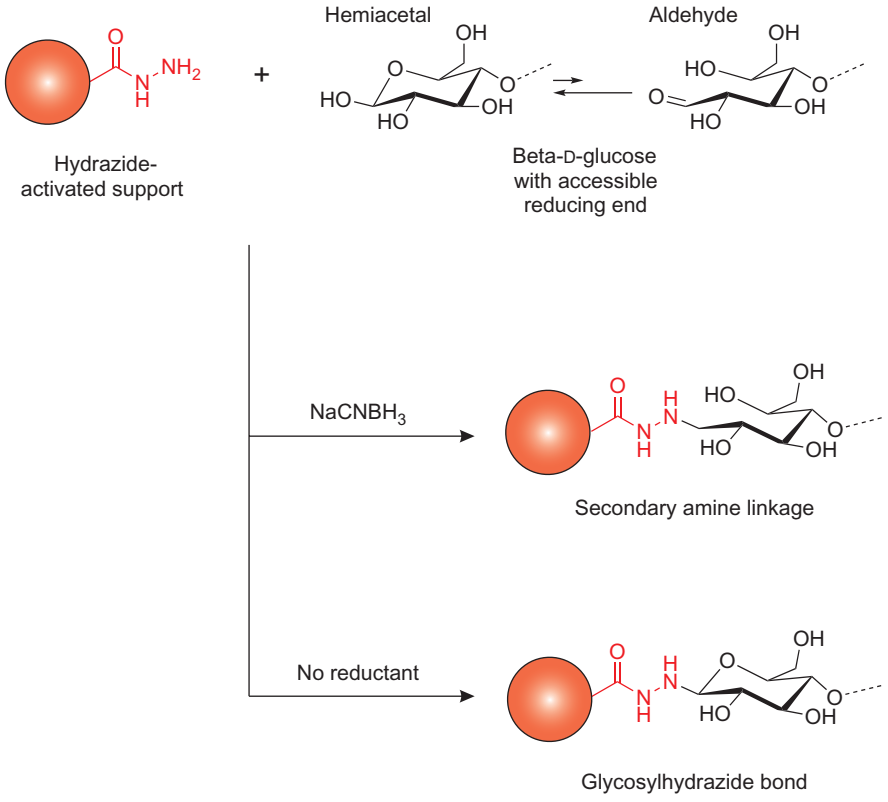

FIGURE 15.86 Coupling at the reducing end of a carbohydrate with and without a reducing agent.

the formation of an imine, which then gets attacked by the hydrazide to form the desired hydrazone with the matrix (Figure 15.87). The following protocol describes the catalyzed reaction with aniline being present in the coupling buffer.

1. Dissolve a carbohydrate, polysaccharide, or glycan (having a reducing end available) at a concentration of at least 5 to 100 µM in 1 ml of 0.1-*M* sodium acetate, 0.15 M NaCl, pH 5.5. Note: Higher concentrations may be used for more abundant carbohydrates as appropriate. The optimal concentration of the carbohydrate may have to be determined experimentally by making several small batches and varying the amount of ligand added to the reaction. Ultimately, the best performance of the immobilized carbohydrate in the intended affinity application should be used as the determining factor for the best concentration to use in the coupling reaction. An alternative coupling medium is a nonaqueous environment consisting of 30% glacial acetic acid in DMSO (v/v) or an acetic acid/pyridine mixture of 1 : 2 (v/v). Nonaqueous conditions may facilitate the dissolution of some carbohydrate molecules better than aqueous buffers.
2. Wash 1 ml of a hydrazide-containing support with water to remove storage solutions and preservatives. Then wash with several milliliters of coupling buffer (0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5). The washing of a small quantity of a chromatography support may be done in a drip column or a spin column without a top frit. Drain the gel to a wet cake and place the bottom cap on the column to stop the flow. Note: If an organic solvent medium is to be used for the immobilization reaction, sequentially wash the matrix into the acetic acid/solvent blend by first washing it into 100% solvent without the acid to completely remove water (e.g., DMSO) and then washing with the desired acetic acid/solvent mixture (e.g., 30% acetic acid/DMSO).
3. Add the carbohydrate solution to the washed gel cake and stir to resuspend the matrix. Transfer the slurry to a centrifuge tube that is large enough to hold a total volume of at least 4 ml.
4. In a fume hood, add 18 µl of aniline catalyst to the 2 ml gel slurry with stirring. This results in approximately a 0.1-*M* aniline solution in the coupling reaction mixture.
5. Seal the tube and continue the reaction for at least 4 h at room temperature and with constant mixing by end-over-end rocking.
6. The blocking of excess hydrazide groups on the support may be achieved by the addition of glyceraldehyde to the reaction mixture at a final concentration of 0.1-*M* and continuing to mix for 30 min.

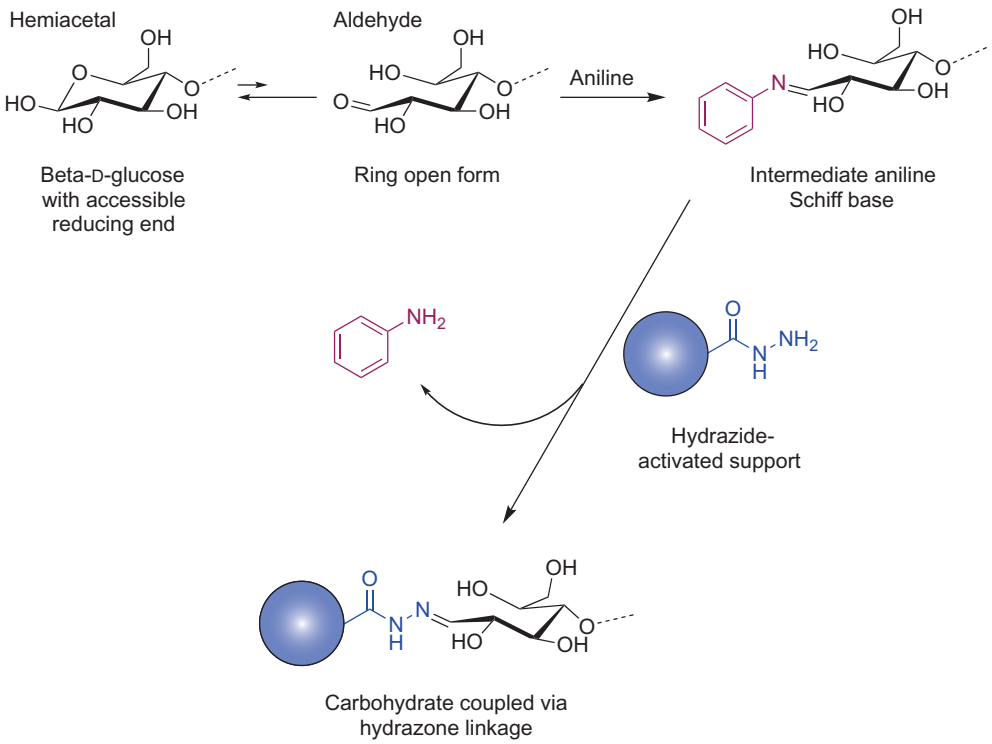

FIGURE 15.87 Immobilization through the reducing end of a carbohydrate using aniline.

7. The hydrazone linkages on the support may be reduced to stabilize them, if necessary. Often when coupling through a single hydrazone bond to a ligand, as in the reaction with the reducing end of a carbohydrate or glycan, the reduction step can be performed to prevent a slow leakage of ligand from the support. To the washed gel add 1 ml of coupling buffer containing 100-m*M* sodium cyanoborohydride (6.3 mg) (dangerous compound—use a fume hood!). Reduce the hydrazone bonds for 1 h with constant mixing.
8. In the fume hood, wash the support extensively with water, 1-*M* NaCl, and water to remove the last traces of all reactants and store the affinity support as a 50% slurry in water or buffer containing a preservative at 4°C.

Aminooxy Supports for Coupling Aldehydes or Ketones

The chemoselective ligation reaction of an aldehyde group with an aminooxy group ($–ONH_2$) to yield an oxime bond (aldoxime) has been described for use in many bioconjugation reactions, as well as in the coupling of ligands to insoluble supports including surfaces, for the organic synthesis of radiohalogenated compounds, and in the synthesis of drug candidates (Thumshirn *et al.*, 2003; Poethko *et al.*, 2004; Liu *et al.*, 2007; Colombo and Bianchi, 2010). This reaction with aminooxy groups also is quite efficient with ketones to form an oxime called a ketoxime. The simplest form of this reaction has been known for over a century and occurs with aldehydes or ketones as they react with the small compound hydroxylamine (Figure 15.88). The conversion of cyclohexanone to its oxime with hydroxylamine followed by subsequent treatment with sulfuric acid to yield caprolactam *via* a Beckmann rearrangement produces a raw material used in billions of kilogram quantities to create nylon-6 polymers by ring-opening polymerization.

Hydroxylamine derivatives that consist of an organic group linked to the oxygen also are very effective at forming oxime bonds with carbonyl groups. In this case, the hydroxylamine derivative typically is called an aminooxy functional group, which is also known as an aminoxy or alkoxyamine derivative. The aminooxy compound of this reaction contains a substituent off the oxygen group of hydroxylamine, which can consist of virtually any organic compound or even a chromatography support or modified surface containing a spacer arm that terminates in the $–ONH_2$ group. The immobilization of aldehyde- or ketone-containing affinity ligands onto support materials that have been activated to contain aminooxy groups can be done similar to the methods described previously for hydrazide containing supports. However, oxime formation usually occurs more rapidly than the reaction between a hydrazide group and an aldehyde or ketone and it typically provides more stable oxime bonds than hydrazones.

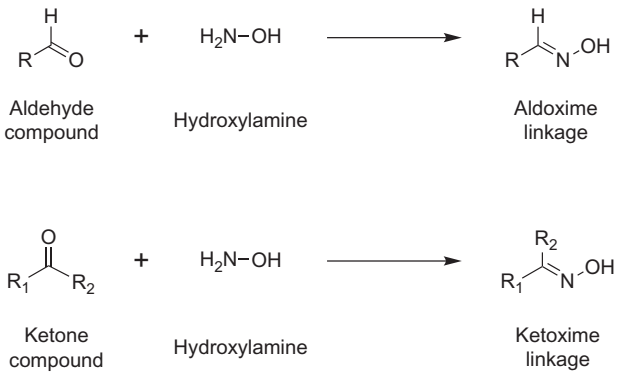

FIGURE 15.88 Basic reaction of an aldehyde or ketone with aminooxy group to give an oxime bond.

The formation of an aminooxy group on a chromatography support can be achieved through the creation of the appropriate spacer arm. There are many methods that can be used to build a spacer on a support (see section on spacer arms, this chapter). In most cases, the creation of the spacer must be performed using a protected aminooxy group, because the terminal amino group will react in amine coupling reactions, which are typically performed to build the spacer molecules. For instance, the first step in making a support with aminooxy functionalities might be to couple a diamine spacer to an amine-reactive support (see section on amine reactive immobilization methods, described previously in this chapter). This would provide an amine-containing intermediate that could then be used to link a protected aminooxy-containing molecule, such as phthalimidooxy $–dPEG_{12}–$NHS ester (Quanta Biodesign). This crosslinker contains a phthalimide-protected aminooxy group on one end and an amine-reactive NHS ester on the other end which can be used to modify the amine-containing support. The result of reacting with the NHS ester ends will be the formation of amide bonds with the amine groups on the support, which will create extremely hydrophilic PEG_{12} chains that extend off the matrix and terminate in the protected aminooxy functionalities. Subsequent removal of the phthalimide-protecting groups with hydrazine in aqueous solution yields the free aminooxy-activated support (Figure 15.89).

Another approach to forming aminooxy functionalities on a resin is to make use of an activated support containing tosyl groups (see previous section on tosyl activation, this chapter). This reactive group is usually used to immobilize amine-containing ligands, but it can also be used to react with hydroxyl groups in nonaqueous conditions. The reaction of a tosyl-activated support with the compound *N*-hydroxyphthalimide results in coupling through the available hydroxyl group on the reagent. This intermediate will result in a protected

aminooxy group immobilized on the support, which then can be deprotected by the addition of 0.5-*M* hydrazine in aqueous solution, thus producing the aminooxy-activated matrix (Figure 15.90).

Aminooxy groups have also been used on planar substrates to covalently array proteins to form nanopatterns on silicon wafers and other surface materials. In one example, the aminooxy functionalities were coated on the surface of wafers by Christman *et al.* (2008) using eight-arm PEG derivatives. The hydroxyl groups on the outer ends of the PEG arms were modified using a Mitsunobu-type reaction with *N*-hydroxyphthalimide and including triphenyl phosphine (PPh_3) with DIAD (diisopropyl azodicarboxylate) as the activators (Figure 15.91). Subsequent deprotection and removal of the phthalimide using hydrazine yielded the desired aminooxy groups.

The immobilization reaction using an aminooxy support with aldehyde- or ketone-containing ligands can be accelerated by the addition of an aniline catalyst. As in the formation of hydrazone linkages with aldehydes and hydrazide-activated supports, the formation of an oxime bond between an aldehyde or ketone and an aminoxy is dramatically increased in rate and yield by aniline (Cordes and Jencks, 1962; Dirksen *et al.*, 2006a,b; Dirksen and Dawson, 2008; Byeon *et al.*, 2010). The aromatic amine on aniline first reacts with the aldehyde or ketone group to form an intermediate imine, which then reacts with the aminooxy groups on the support to create the final oxime linkage (Figure 15.92). The intermediate aryl imine undergoes more rapid protonation in slightly acidic solution than does the oxygen of the aldehyde or ketone carbonyl, and it is this protonated species that can react with the aminooxy groups (Kohler, 2009).

The immobilization reaction on a surface that was activated with aminooxy groups to couple a peptide molecule was studied in detail to determine its kinetics (Lempens *et al.*, 2009). The peptide was prepared to contain an N-terminal aldehyde residue made *via* the pyridoxyl 5′-phosphate/sodium periodate method of Gilmore *et al.* (2006a,b) (also see Scheck and Francis, 2007; Scheck *et al.*, 2008). It was also found in this case that use of the aniline catalyst dramatically increased

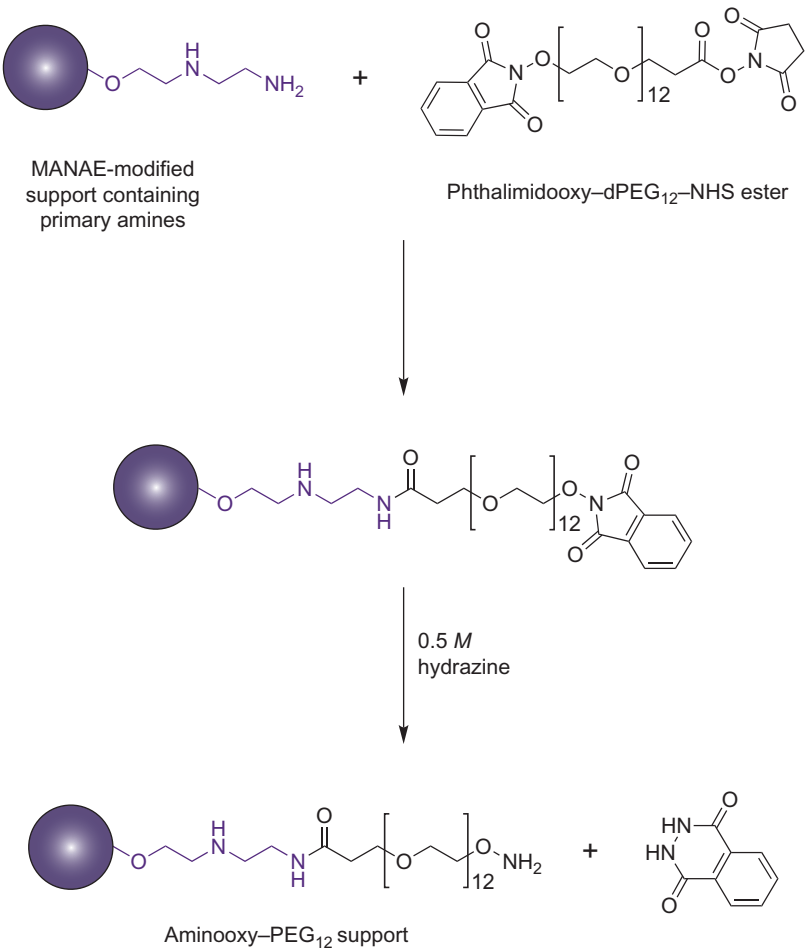

FIGURE 15.89 Preparation of an aminooxy support using PhthNO–dPEG$_{12}$–NHS ester.

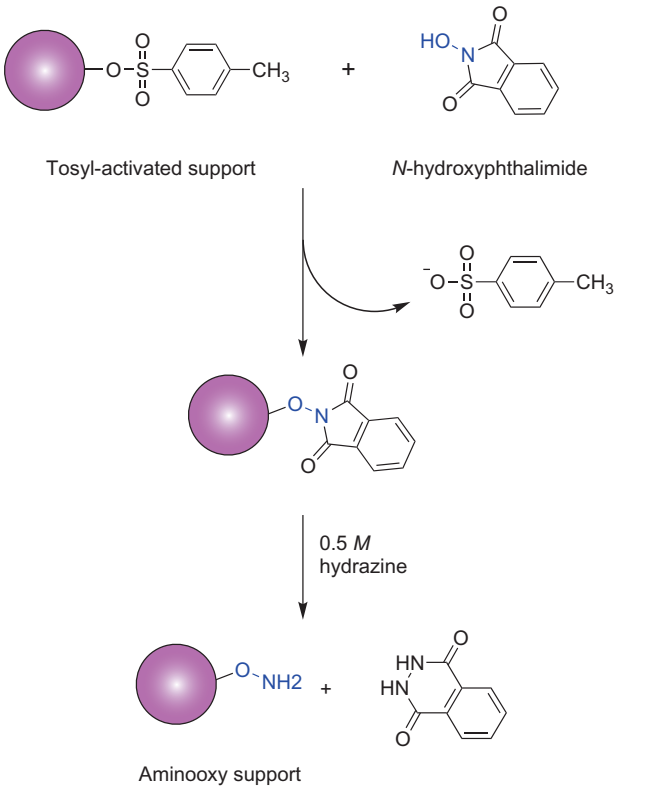

FIGURE 15.90 Formation of aminooxy groups on a support by reaction of *N*-hydroxyphthalimide with a tosyl-activated support.

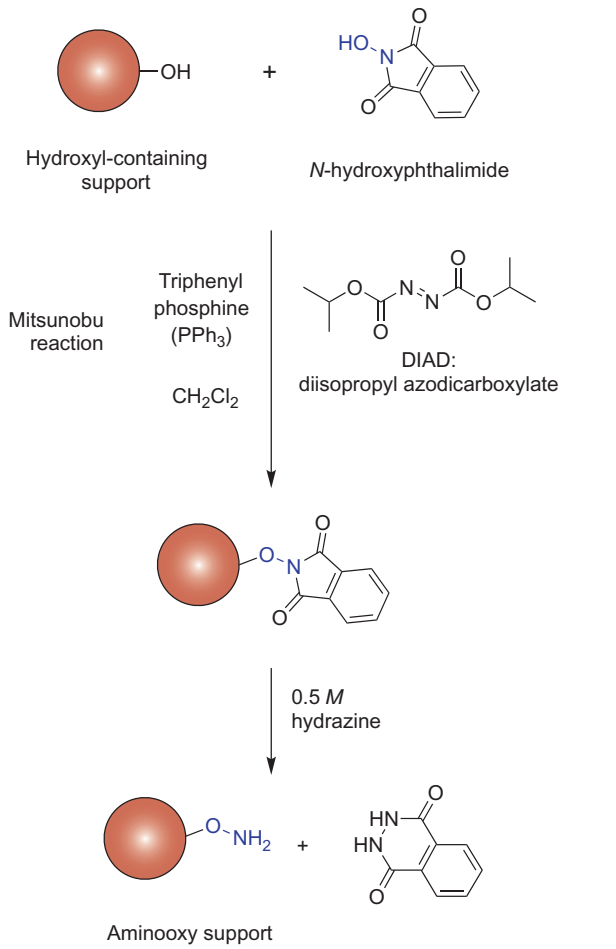

FIGURE 15.91 Aminooxy formation at the end of a PEG chain using the Mitsunobu reaction.

the reaction rate and coupling efficiency at all pH values investigated, with the greatest rate and yield obtained at pH 4.5. The rate at pH 6.0 was less than half that observed at the lower pH value; however, the difference between a catalyzed and an uncatalyzed reaction was significant at all the acidic pH environments studied. As the reaction pH is increased from 4.5 to more of a neutral pH environment, the rate and yield of coupling significantly slow down; however, for molecules sensitive to more acidic pH environments the reaction may be performed with good results at higher pH. To compensate for slower kinetics at higher pH, the time of the reaction should be increased to realize acceptable immobilization yields.

AMINOOXY ACTIVATION PROTOCOL

The following protocol describes the modification of an amine-reactive support with a diamine spacer and the subsequent reaction of the amino-support with an NHS–PEG_{12}–oxyphthalimide crosslinker followed by deprotection of the phthalimide to form the aminooxy derivative. Other amine-containing supports may also be used in this procedure, such as can be prepared using the spacer arms described elsewhere in this chapter. Use a fume hood and personal protective equipment for all operations.

1. In a fume hood, drain 10 ml of a CDI-activated agarose support of acetone storage solution (see section on CDI activation). Other amine-reactive supports may also be used to couple the diamine; however, follow the respective protocols for coupling ligands if another reaction is used. All of the washing steps may be carried out using a sintered glass filter suspended in a suction filter flask and applying a slight vacuum to facilitate drawing the wash solutions through the support. Pull a gentle vacuum on the suction filter flask and break up the resin into small pieces as the acetone drains through, but do not allow the support to dry. Next, add to the resin approximately 2 bed volumes of the solvent DMAC (note that DMSO may be used as an alternative solvent) and stir the gel to resuspend it in the new solvent. Continue to wash the support with DMAC for at least 5 bed volumes to remove most of the remaining acetone.
2. Prepare 10 ml of a solution consisting of 1.0-*M* ethylenediamine in DMAC (or DMSO). Notes: Alternative diamine compounds may be used at the

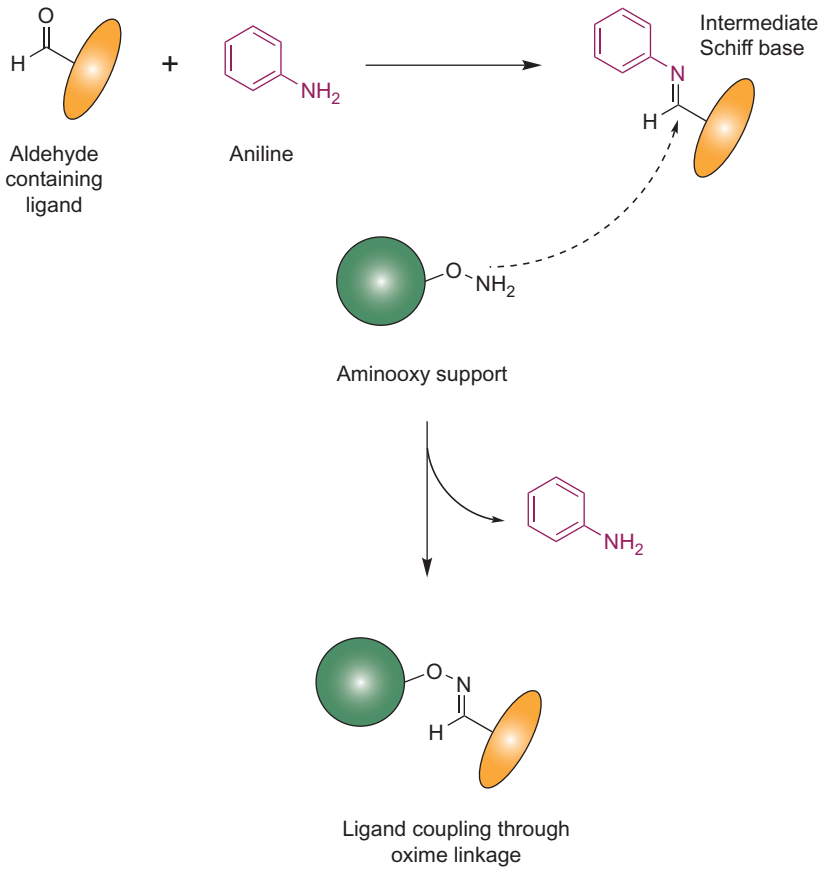

FIGURE 15.92 Immobilization of an aldehyde ligand on an aminooxy support using aniline catalysis.

same concentration with success; however, avoid the use of long aliphatic diamines as spacers, as this will create considerable hydrophobic character within the matrix and increase the potential for nonspecific interactions on the subsequent affinity support.

3. Add the washed support to the ethylenediamine solution with stirring. React for 1 h at room temperature with constant mixing. End-over-end rocking in a sealed container may be used to mix the support. Note: The addition of an organic base to the reaction to accept protons generated during the coupling of the spacer need not be done, because the free amine end of ethylenediamine will still be available.
4. Wash the amine-containing support extensively with DMAC to remove the last traces of diamine compound (use at least 20 bed volumes). Drain the washed support to a moist cake.
5. Prepare a solution of the heterobifunctional crosslinker PhthNO–dPEG$_{12}$–NHS ester (Quanta Biodesign) in 10 ml of DMAC dissolved at a concentration of at least 10 mg/ml (11.6 µmol/ml). Higher concentrations may be used to create higher densities of the final aminooxy groups on the matrix.
6. Add the washed support to the crosslinker solution and mix to resuspend the gel. To this suspension, add 0.65 g of dimethylaminopyridine (DMAP) as an organic base to catalyze the reaction and mix to dissolve (alternatively, the addition of 0.75 ml of anhydrous triethylamine (TEA) may be done or an equivalent mole amount of *N*,*N*-diisopropylethylamine (DIEA) may be added). React for 1 h at room temperature with constant mixing.
7. Extensively wash the modified support with DMAC to remove excess reactants and reaction byproducts (at least 20 bed volumes). Next, wash the support into water by sequentially washing with increasing concentrations of water in DMAC until 100% water is used. Continue washing with water until all traces of the solvent have been removed. Drain the gel to a wet cake.
8. In a fume hood, prepare 10 ml of an aqueous solution consisting of 0.5-*M* hydrazine (dangerous and toxic!) in 0.1-*M* MES, pH 6.0. If hydrazine dihydrochloride is used to prepare this solution, its dissolution in the buffer will not cause the pH to become highly alkaline. Avoid contact with hydrazine or its solutions by using the appropriate personal protective equipment, including being cautious to avoid contact with skin or eyes, and also avoiding the inhalation of dust. Prevent static charge buildup when dispensing and weighing the hydrazine compound by using the appropriate grounding precautions. Adjust the final pH of the solution back to 6.0, if necessary.

9. In the fume hood, add the washed gel containing the protected aminooxy groups with the hydrazine solution and mix by end-over-end rotation in a sealed container. React overnight to deprotect the aminooxy groups.
10. In the fume hood, drain the support of excess hydrazine deprotection reagent and wash the support extensively with water, 1-*M* NaCl, and water. Store the aminooxy-activated support until use as a 50% slurry in water or buffer containing a preservative at 4°C. (Note: Do not include any ketone- or aldehyde-containing compounds in the storage solution or the aminooxy groups will react and become inactive for coupling ligands.)

LIGAND COUPLING TO AMINOOXY-ACTIVATED SUPPORTS

The following protocols describe the periodate oxidation of sialic acid groups on glycoproteins followed by their aniline-catalyzed immobilization onto an aminooxy-containing support. A subsequent immobilization protocol describes the immobilization of sugars, polysaccharides, or glycans through their reducing ends. Similar protocols can be used to immobilize other glycoconjugates or carbohydrates after periodate oxidation or through their reducing ends, if available. In addition, small ligands containing aldehydes or ketones may also be coupled to an aminooxy-containing support using the identical buffers and an aniline catalysis process. Larger quantities of immobilized ligands may be prepared by proportionally increasing the reagent amounts used in these procedures.

(A) Periodate Oxidation of Sialic Acid Groups on Glycoproteins

1. Dissolve 1 to 10 mg of a glycoprotein containing sialic acid groups in 1 ml of coupling buffer (0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5). Be careful that the glycoprotein does not contain an amine-containing buffer in solution, such as glycine or Tris, which may alter the pH of the coupling buffer or interfere with the subsequent coupling reaction. For instance, dialyze or desalt a commercial antibody preparation containing Tris or glycine using coupling buffer to remove interfering components before proceeding. Chill the glycoprotein solution by placing it on ice.
2. Dissolve sodium periodate in water at a concentration of 10 mg/ml (46-m*M*). Continue to mix until the sodium periodate is completely dissolved and then wrap the tube in aluminum foil to protect it from light. Chill the periodate solution by placing it on ice.
3. Add 21.8 µl of the periodate solution to the 1 ml of glycoprotein solution and mix to dissolve (makes approximately 1-m*M* periodate final concentration in the glycoprotein solution). Maintain the solution on ice.
4. React for 30 min on ice with periodic mixing. Do not allow the oxidation to continue longer than this time or oxidation may occur at sites other than just sialic acid groups.
5. Stop the reaction by desalting the antibody solution using a size exclusion chromatography support having a molecular weight exclusion limit of no more than 10 kDa (i.e., at least 5 ml of Sephadex G-25 or the equivalent). Use cold coupling buffer to perform the chromatography and collect the protein peak, which will elute before the salt peak. Spin columns may also be used for this operation, as they will result in less dilution of the protein solution during the separation and are quicker to use (e.g., Zeba Spin Desalting Columns from Thermo Fisher). Use the oxidized glycoprotein in the coupling reaction immediately to prevent the potential for protein crosslinking over time through Schiff base formation or Mannich reaction processes.

(B) Coupling the Oxidized Glycoprotein to an Aminooxy Support

1. Wash 1 ml of an aminooxy-containing support with water to remove storage solutions and preservatives. Then wash with several milliliters of coupling buffer (0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5). The washing of a small quantity of a chromatography support may be done in a drip column or a spin column without a top frit. Drain the gel to a wet cake and place the bottom cap on the column to stop the flow. The coupling reaction may be done in a sealed column or the washed gel transferred to a small plastic centrifuge tube able to hold at least 2.5 ml of slurry. Note: The pH of the coupling buffer may be decreased to pH 4.5 to further enhance the reaction rate and yield of oxime bond formation.
2. Add the oxidized glycoprotein from part (A) to the washed gel cake and stir to resuspend.
3. In a fume hood, add 18 µl of aniline catalyst to the gel slurry with stirring. This results in approximately a 0.1-*M* aniline solution in the coupling reaction mixture.
4. Continue the reaction for at least 2 to 4 h with constant mixing. Proteins with higher glycosylation content will couple faster than proteins with lower amounts of carbohydrate. The mixing may be done by end-over-end rocking in a sealed container or column.
5. Blocking excess aminooxy groups on the support may be done by the addition of glyceraldehyde to the reaction mixture at a final concentration of 0.1-*M* and continuing to mix for 30 min. In most cases of glycoprotein immobilization, blocking the unreacted aminooxy groups is not necessary; however, if this step is performed, do not add any reducing agents to the mixture or glyceraldehyde–protein adducts will be formed (Acharya and Manning, 1980).

6. Wash the support with several bed volumes of coupling buffer and collect the washes. The amount of protein coupled to the resin may be determined by the difference in the amount of protein present in the reaction medium before coupling and that remaining after coupling, taking into account volume differences. Note that aniline may interfere with some methods of protein concentration determination (e.g., absorbance at 280 nm) and may have to be removed. Continue to wash the support extensively with water, 1-*M* NaCl, and water to remove the last traces of all reactants. Finally, wash the support as in step 6 and store the affinity support as a 50% slurry in water or buffer containing a preservative at 4°C.

(C) Coupling the Reducing end of Carbohydrates to Aminooxy Supports

Many carbohydrates contain a reducing sugar at their anomeric end that is in a cyclic hemiacetal form, which in reality is a masked aldehyde group. The aldehyde only is available for immobilization when it is in the open form, which is a minority of time in aqueous solution. For this reason, the immobilization reactions of reducing sugars and carbohydrates with aminooxy-containing supports usually take longer to go to completion than reactions with freely available aldehydes. The coupling of reducing sugars onto aminooxy supports is carried out very similarly to that described for hydrazide supports, described previously; however, a reducing step is optional to further stabilize the resultant bond. If the reaction is carried out without a reducing agent being present, the result will be the creation of an oxime bond yielding a mixture of an intact ring structure (glycosyl derivative) or acyclic oxime (open ring derivative) at the reducing sugar anomeric carbon. If a reductant is present during the reaction, only the acyclic derivative will result with the formation of a glycosyl-hydroxylamine linkage to the support (Peluso *et al.*, 2002) (Figure 15.93).

The addition of an aniline catalyst to the coupling reaction of an aminooxy group with a reducing sugar has been shown to dramatically accelerate the formation of the oxime bond (Thygesen *et al.*, 2010). The

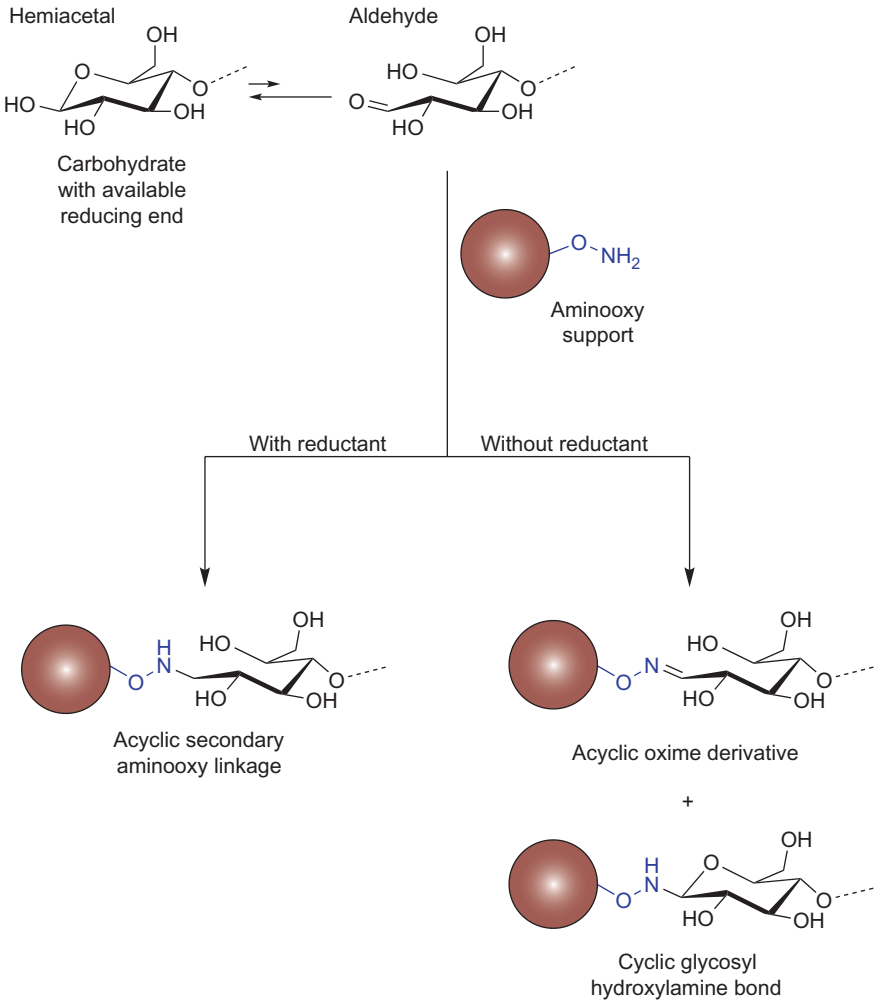

FIGURE 15.93 Immobilization of reducing carbohydrate onto an aminooxy support with and without the use of a reductant.

aniline initially traps the open ring aldehyde through the formation of an imine, which then gets attacked by the immobilized aminooxy group to form the desired oxime bond with the matrix (Figure 15.94). The following protocol describes the catalyzed reaction with aniline being present in the coupling buffer. Larger quantities of the immobilized ligand may be prepared by proportionally increasing the amount of reagents added at each step.

1. Dissolve a carbohydrate, polysaccharide, or glycan (having a reducing end available) at a concentration of at least 5 to 100 µ*M* in 1 ml of 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 4.5. Note: Higher concentrations may be used for more abundant carbohydrates as appropriate. The optimal concentration of the carbohydrate may have to be determined experimentally by making several small batches and varying the amount of ligand added to the reaction. Ultimately, the best performance of the immobilized carbohydrate in the intended affinity application should be the determining factor for the best coupling reaction conditions to use.

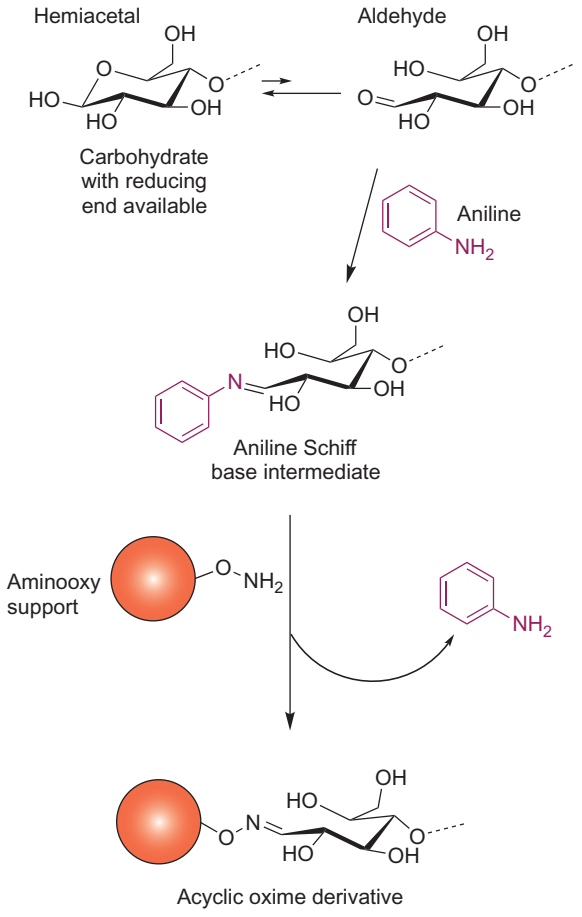

FIGURE 15.94 Immobilization through the reducing end of a carbohydrate using aniline.

2. Wash 1 ml of an aminooxy-containing support with water to remove storage solutions and preservatives. Then wash with several milliliters of coupling buffer (0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 4.5). The washing of a small quantity of a chromatography support may be done in a drip column or a spin column without a top frit. Drain the gel to a wet cake and place the bottom cap on the column to stop the flow.
3. Add the carbohydrate solution to the washed gel cake and stir to resuspend the matrix. Transfer the slurry to a centrifuge tube that is large enough to hold a total volume of at least 4 ml.
4. In a fume hood, add 18 µl of aniline catalyst to the 2-ml gel slurry with stirring. This results in approximately a 0.1-*M* aniline solution in the coupling reaction mixture.
5. Seal the tube and continue the reaction for at least 4 h at room temperature and with constant mixing by end-over-end rocking.
6. The blocking of excess aminooxy groups on the support may be done, if necessary, by the addition of glyceraldehyde to the reaction mixture at a final concentration of 0.1-*M* and continuing to mix for 30 min.
7. In the fume hood, wash the support extensively (at least 20 bed volumes) with water, 1-*M* NaCl, and water to remove the last traces of all reactants and store the affinity support as a 50% slurry in water or buffer containing a preservative at 4°C.

Amine-Containing Supports for Coupling Aldehydes, Ketones, or Carboxylates

Supports that have available primary amines on them can be used to immobilize carbonyl-containing ligands with good efficiency. The amines may be formed from the construction of a spacer arm on a base support or created as a result of the polymerization of functional silane compounds or vinyl monomers containing amines. The amine groups can react with aldehydes or ketones on affinity ligands using a reductive amination process to yield secondary amine linkages to the support. Free amine groups can also be used to immobilize carboxylate-containing ligands by amide bond formation using a carbodiimide-mediated reaction. The reaction of an immobilized amine with an aldehyde-containing ligand is just the opposite of the immobilization of an amine-containing ligand on an aldehyde support, which is described under the section Amine Reactive Immobilization Methods earlier in this chapter; however, the reaction principles are identical.

Amine-containing spacer arms can be added to a support by the reaction of a diamine compound with an amine-reactive matrix. Using this method, a variety

of spacer types may be used as desired to design particular properties into the resin, such as the use of short or long hydrophobic or hydrophilic cross-bridges, which may have an effect on subsequent affinity separations done on the support. Amines also can be added to particles using a functional silane reagent, such as aminopropyltrimethoxysilane, that can be used to coat the surface of particles and form the required primary amine groups. See the final section of this chapter for a discussion on the formation of spacer arms on supports and see also Chapter 13 for methods related to the use of functional silanes.

An amine-containing support can react with ligands containing aldehydes or ketones to form an initial Schiff base imine, which results from a dehydration reaction. This imine bond is highly reversible in aqueous environments and therefore must be stabilized by reduction to permanently link the ligand to the support (Figure 15.95). The reducing agent used in this process typically is sodium cyanoborohydride or other equivalent reagents that are capable of reducing the imine to a secondary amine, but will not reduce the initial aldehyde reactants. The use of an amine-containing support to immobilize aldehydes or ketones may not be the first or best choice, because hydrazide- or aminooxy-activated supports have better reaction characteristics and yield more stable linkages (see previous sections). However, if an amine-containing matrix is the desired starting point, the coupling of carbonyl ligands can be done with success using the cyanoborohydride reduction step to stabilize the linkage.

However, an amine-containing support is even more suitable for the immobilization of carboxylate-containing ligands. Carboxylates and amines can be made to react and form stable amide bonds. Although these two functional groups do not spontaneously react under normal conditions, the addition of an amide bond forming agent can be done to facilitate efficient coupling. The most common amide bond forming agents are carbodiimides, such as the water soluble EDC, as well as other such condensing agents that were originally developed to form bonds between amino acids in peptide synthesis applications. The water soluble reactants can be used in aqueous buffer to couple carboxylate-containing ligands that are soluble in water. EDC is a so-called "zero-length" crosslinker, since it mediates the formation of amide linkages without leaving behind a spacer molecule (Grabarek and Gergely, 1990). In addition, for carboxylate ligands that may be insoluble in aqueous conditions, amide bond forming agents that are soluble in organic solvents can be used. EDC reacts with the carboxylates on the ligand to form an intermediate reactive ester, which then goes on to react with the amines on the support surface to create amide bond linkages (Figure 15.96). See also Chapter 14 on the use of EDC for coupling of affinity ligands to microparticles and nanoparticles for additional information on the reactions involved with carbodiimide activation and immobilization.

In most cases, EDC-mediated amide bond formation is quite efficient and proceeds to completion within 2 to 4 h. Staros *et al.* (1986) developed a modification of this reaction that incorporates the addition of NHS (or sulfo-NHS) into the reaction medium to form an intermediate NHS ester on the activated carboxylate. This two-stage reaction results in the creation of an amide bond through the reaction of an intermediate NHS ester with the amine groups on the support. An NHS ester undergoes fewer side reactions and is more efficient at forming amide bonds than the intermediate EDC ester, so the desired product is formed at an accelerated rate.

LIGAND COUPLING TO AMINE-CONTAINING SUPPORTS

The following protocols make use of an amine-containing resin made through the modification of an amine-reactive support with a diamine spacer molecule (see the last section in this chapter on spacer arm construction).

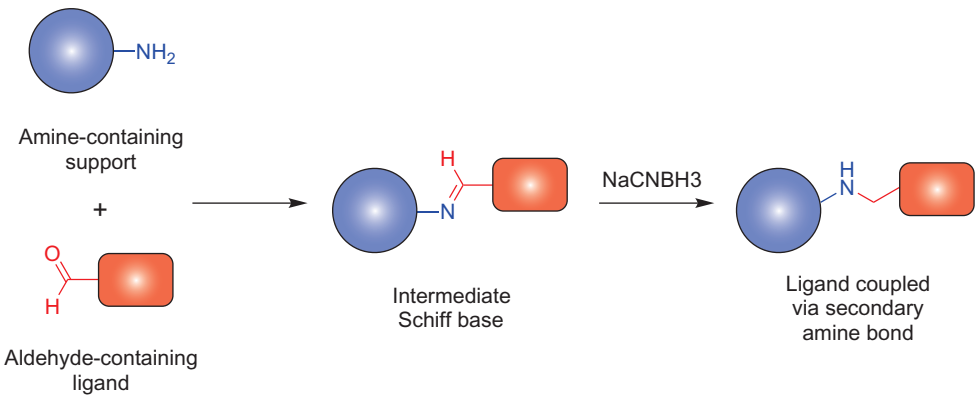

FIGURE 15.95 Immobilization of an aldehyde-containing ligand onto an amine-containing support.

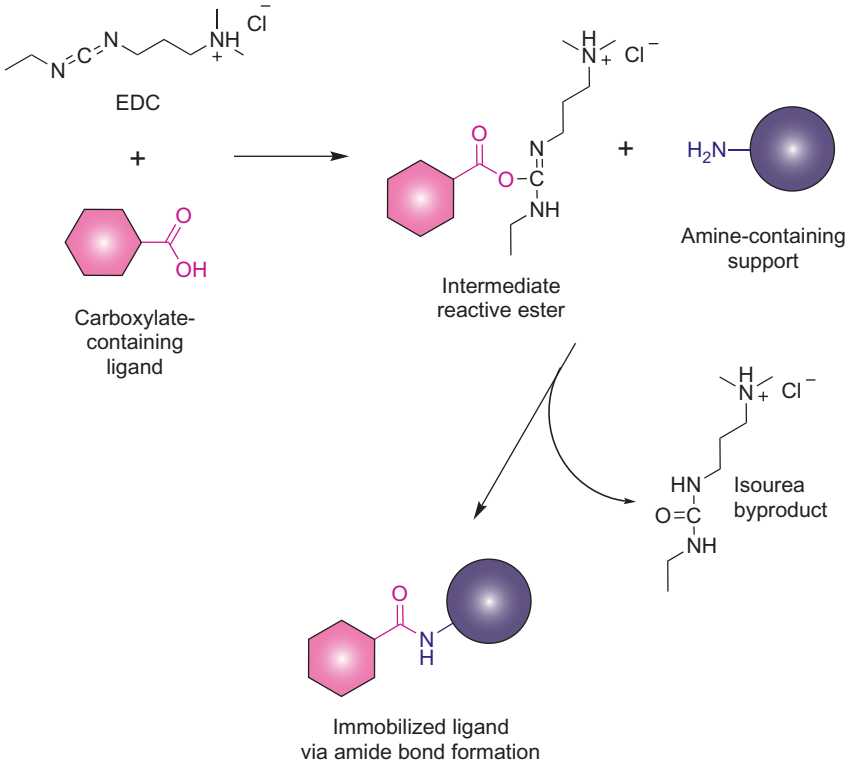

FIGURE 15.96 Immobilization of carboxylate ligands onto amine-containing supports using EDC.

Other amine-containing supports can also be used with success, such as polymeric supports prepared using amine-containing monomers during the polymerization process. Also see Chapter 14 for protocols related to the coupling of affinity molecules to micro- or nanoparticles.

Coupling Aldehydes or Ketones to Amine-Containing Supports

The following protocol makes use of sodium cyanoborohydride, which is a highly toxic compound that expels volatile cyanide into the atmosphere. For this reason, all operations using this compound as the solid or in solution should be done in a well-ventilated fume hood. Also use the appropriate personal protective equipment while doing this procedure, such as gloves, safety glasses, and a lab coat to prevent direct contact with the compound.

1. Wash 10 ml of the amine-containing support material into coupling buffer (0.1-*M* sodium phosphate, pH 7.2) and drain to a wet cake. Other buffer components may be added to the coupling buffer, such as the addition of 0.15-*M* NaCl or alternative buffer salts; however, avoid amine-containing compounds like Tris, glycine, or imidazole, which will compete in the reaction. In general, avoid buffer compounds containing primary or secondary amines as well as any other nucleophile that could react with an aldehyde on the ligand. In addition, certain detergents and other amphiphillic components have been shown to decrease the stability of the intermediate Schiff base and these additives should be used only after validating that they have no effect on the immobilization reaction (Viguera *et al.*, 1990). Reductive amination coupling in aqueous solution has been shown to effectively occur between pH 4 and 10, with an optimal range for cyanoborohydride reduction of pH 6 to 8.
2. Suspend the washed support material containing amine residues in an equal volume of 0.1-*M* sodium phosphate, pH 7.2, into which an aldehyde-containing ligand has been dissolved. Notes: For glycoprotein ligands, a typical concentration range may be 3 to 5 mg/ml gel, but much higher concentrations may be used if a high density of coupled protein on the gel is desirable. In some cases, reactions containing protein at up to 20 mg/ml gel can be done, but the need for this density on the final affinity support is unusual. For small aldehyde-containing affinity ligands, a concentration of 2 to 3 mg ligand/ml gel in the immobilization reaction may be sufficient to obtain good binding capacity on the resultant affinity gel. Alternatively, a concentration representing 5 to 10 times the

concentration of reactive amines on the matrix may be used to ensure a high density of the final coupled ligand. The ultimate concentration of ligand used in the reaction should be optimized by performing a series of coupling reactions at different initial ligand concentrations and determining the performance of the affinity supports in capturing and eluting the desired target molecule.

3. Stir the gel/ligand slurry in a fume hood using a paddle stirrer or using a rotator to maintain constant mixing.
4. Add to the gel slurry 63 mg of solid sodium cyanoborohydride ($NaCNBH_3$; MW = 62.84) [toxic!] or 0.2 ml of 5-*M* $NaCNBH_3$ in 1-*N* NaOH (Sigma) with stirring. If the alkaline solution of cyanoborohydride is used, check the pH and readjust to 7.2, if necessary. Continue the reaction for 4 h to overnight at room temperature. The amount of cyanoborohydride added—whether as the pure solid compound or as the solution—results in a 50-m*M* solution in the final reaction slurry, which is in a total volume of 200 ml. A shorter coupling time may be sufficient for many ligands, but the optimal conditions to give acceptable yields for a particular ligand should be determined by doing a series of coupling reactions at different time points. Reactions at 4°C may also be done for thermally sensitive proteins or ligands, but reaction times may have to be extended to get the same level of coupling as a room temperature reaction.
5. Transfer the gel slurry to a sintered glass filter funnel (in the fume hood) and wash with several bed volumes of water to remove most of the unreacted ligand and reaction byproducts.
6. Unreacted amine residues remaining on the support can be blocked by the addition of a small aldehyde-containing compound, such as glyceraldehyde. Avoid the blocking of excess amine groups if a protein ligand or a ligand containing more than one amine has been immobilized, as the glyceraldehyde also will modify amines on the ligand. Wash the support once with an equal volume of 0.1-*M* glyceraldehyde dissolved in coupling buffer at pH 7.2, and then transfer the wet gel cake to a clean flask or vessel used for mixing the reaction. Add with stirring 10 ml of the 0.1-*M* glyceraldehyde solution along with 63 mg (or 0.2 ml of the 5-*M* $NaCNBH_3$ solution) of sodium cyanoborohydride. Readjust the pH if necessary and continue the blocking reaction for 30 min at room temperature.
7. Wash the support extensively with water, 1-*M* NaCl, and again with water to remove all unreacted components from the gel. Additional wash solutions may be utilized to completely remove ligands that may have some nonspecific binding potential to remain noncovalently bound to the immobilized ligand, such as the use of acidic and alkaline washes as well as washes containing denaturants (such as guanidine). After washing, the affinity gel may be stored as a 50% aqueous slurry containing a preservative at 4°C.

Coupling Carboxylate-Containing Ligands to Amine-Containing Supports

The following protocol may be used to immobilize a carboxylate-containing ligand onto a support material containing amines. The process uses the water soluble carbodiimide EDC, which activates the carboxylate to an intermediate ester that then reacts with the amines on the support to form amide bonds. This method is not recommended for coupling ligands that contain both carboxylates and amines, such as proteins, because the ligand will become oligomerized in solution upon the addition of EDC.

1. Wash 10 ml of an amine-containing support with several volumes of water to remove storage solutions and then wash with coupling buffer (0.1-*M* MES, pH 4.7). Drain to a wet cake. Note: The EDC reaction occurs efficiently at slightly acidic pH values with an optimal rate in the range of pH 4.5 to 6.0. However, buffers at physiological pH may also be used with success (e.g., 0.1-*M* sodium phosphate, pH 7.0–7.5). The reaction at the higher pH will be somewhat slower, and the reaction time should be extended to obtain the same yield of coupling. For neutral pH reactions, the addition of 2 equivalents of NHS (or sulfo-NHS) over the amount of EDC added can be done to further accelerate the reaction kinetics.
2. Prepare 10 ml of the carboxylate-containing ligand to be coupled in coupling buffer. For many small ligands, the use of 3 to 5 mg ligand/ml is a sufficient concentration; however, some optimization of ligand concentration may have to be done to obtain the best performance of the affinity resin in the intended application. Note: For ligands that are not very soluble in aqueous solution the carboxylate molecule may be first dissolved in a water-miscible solvent such as ethanol, DMSO, DMF, or DMAC and then added to the coupling buffer to obtain the final mixture. The final percentage of solvent in the coupling buffer should not exceed about 20% for DMSO, DMF, or DMAC or the buffer salts may begin to precipitate out of solution. For an ethanol-containing final solution, ethanol may be added up to 50% in the coupling buffer and still maintain buffer solubility. For ligands that are particularly insoluble in aqueous environments, there may be a micro-precipitate in the final solution, but the reaction still should proceed without difficulty.
3. Mix the washed gel with the ligand solution with stirring and add 0.3 g of EDC and mix to dissolve.

4. React with constant mixing for 2 to 4 h at room temperature. The gel slurry may be placed in a sealed container and mixed by end-over-end rocking.
5. Unreacted amines on the support may be blocked by the addition of a small hydrophilic carboxylate compound, such as glyceric acid (or 2,3-dihydroxypropanoic acid) or just by using sodium acetate. If a blocking step is desired, add the chosen blocking agent to the coupling reaction to make a final concentration of 0.1-*M* and readjust the pH, if necessary. Add an additional 0.3 g of EDC and react for 1 h with mixing.
6. Wash the support extensively with water, 1-*M* NaCl, and again with water to remove all unreacted components from the gel. Additional wash solutions may be utilized to completely remove ligands that may have some nonspecific binding potential to remain noncovalently bound to the immobilized ligand, such as the use of acidic and alkaline washes as well as washes containing denaturants (such as guanidine). After washing, the affinity gel may be stored as a 50% aqueous slurry containing a preservative at 4°C.

2.5. Streptavidin-Mediated Immobilization Methods

One of the most useful affinity interactions for biological techniques involves the tight binding of biotin (vitamin H) to the protein avidin (from egg whites) or streptavidin (from the bacterium *Streptomyces avidinii*). Both of these proteins are tetrameric in structure and each subunit contains a binding pocket for biotin. The deep binding pocket that biotin sits in contains amino acid residues able to form eight hydrogen bonding interactions plus additional van der Waals interactions with the bicyclic structure of biotin, thus creating one of the strongest noncovalent interactions known (dissociation constant, (K_d): ~10^{-14}–10^{-15} M). For this reason, the binding of biotin to avidin or streptavidin is similar to a chemoselective ligation reaction forming a covalent bond—highly specific and nearly irreversible.

Streptavidin conjugates are widely used as universal detection reagents in immunoassays, cellular imaging, flow cytometry, and other targeting and assay applications. Conjugates of streptavidin with a fluorescent molecule or an enzyme can provide sensitive detection of biotinylated antibodies and other affinity targeting molecules (see Chapter 11). Immobilized streptavidin can also be used to capture biotinylated molecules out of complex solutions, providing a mechanism for isolating interacting proteins or other biological complexes *via* immunoprecipitation (IP) (Figure 15.97).

For instance, an immobilized streptavidin support can be used to retrieve a biotinylated antibody that has specificity toward and has interacted with a desired protein target within a biological sample. As the affinity support captures the antibody–antigen complex

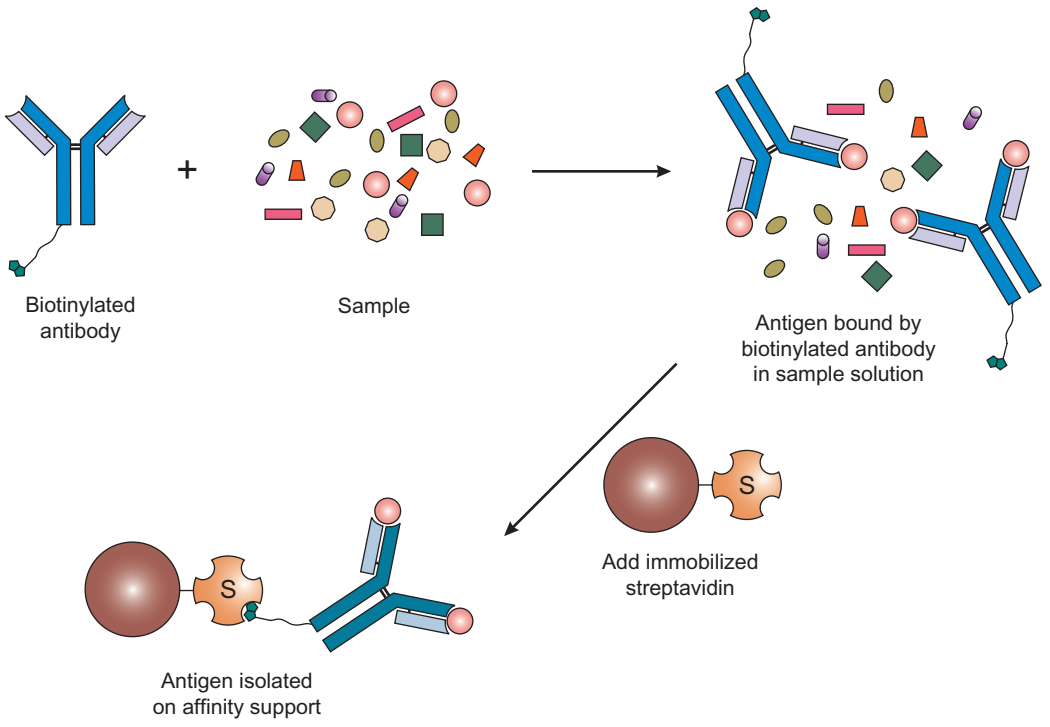

FIGURE 15.97 Use of immobilized streptavidin for IP and co-IP applications.

through the biotin modifications on the antibody, it may also pull out of solution any proteins or other biomolecules that have interacted with the antigen (a technique sometimes called a "pull-down" assay). Co-immunoprecipitation (co-IP) often is used to study interacting proteins if the protein complexes have sufficient affinity to remain intact during the affinity separation process (see Chapter 24). After washing off any non-interacting proteins in the sample, the co-IP isolated complexes then can be eluted from the affinity support using a variety of conditions, which can consist of an acid pH buffer (e.g., 0.1-*M* glycine, pH 2.8) to break the antigen–antibody interactions or much stronger elution agents such as 8-*M* guanidine hydrochloride, pH 1.5, or actually boiling the beads in SDS electrophoresis sample buffer, which will break the streptavidin–biotin interactions.

The preparation of an immobilized streptavidin affinity support can be achieved using amine-reactive resins, such as those described earlier in this chapter. For example, an aldehyde-containing matrix can be used to couple streptavidin by reductive amination and form a high-capacity affinity support for binding biotinylated proteins and other molecules. Coupling streptavidin to the support at a level of 5 to 10 mg/ml in the reaction medium will result in an excellent universal affinity gel for the noncovalent immobilization of biotinylated antibodies. Many such streptavidin affinity supports are available commercially (e.g., Thermo Fisher, Sigma).

Immobilization of Biotinylated Antibodies on Immobilized Streptavidin

The following protocol is a generalized method for the immobilization of biotinylated antibodies on a streptavidin-agarose affinity gel. Some optimization of the loading level on the support may have to be performed to obtain the best performance of the coupled antibody in its intended application. Biotinylation of the desired antibody, if not commercially available, can be done using methods described elsewhere in this book (Chapter 11 and Chapter 18).

1. Wash 1.0 ml of an immobilized streptavidin support with water to remove storage solutions and then with 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 (binding buffer). Washing may be carried out in a small column containing a bottom disk to prevent the gel from escaping. Wash with at least several column volumes. Drain to a wet cake and place the bottom cap on the column to prevent further flow.
2. Prepare a biotinylated antibody solution by dissolving it at a concentration of about 2 to 5 mg/ml in binding buffer. If the amount of antibody being immobilized is far less than this amount, then it is best to use a proportionally lower amount of immobilized streptavidin.
3. Mix the biotinylated antibody solution with the washed streptavidin-agarose and stir to resuspend the gel in the solution. Place a top cap on the column and mix by rotation for 10 to 15 min at room temperature. For a reaction with microliter quantities of immobilized streptavidin, transfer the biotinylated antibody slurry to a small centrifuge tube, seal it, and mix by rotation for the recommended time.
4. Wash the immobilized antibody support extensively with binding buffer to remove any not-bound protein (at least 10 column volumes). After washing, the affinity gel may be stored as a 50% aqueous slurry containing a preservative at 4°C.

2.6. Protein A-, Protein G-, or Protein A/G-Mediated Antibody Immobilization Methods

The immunoglobulin binding proteins protein A, protein G, and protein A/G have been used extensively in immobilized form on chromatography supports for the purification of antibodies. Protein A is a 56-kDa cell wall constituent of the bacterium *Staphylococcus aureus* that contains five identical binding domains, each able to interact with the heavy chains of immunoglobulins in the region of the Fc fragment and in some cases within the region of the Fab fragments (Figure 15.98) (Graille *et al.*, 2000; Idusogie *et al.*, 2000). The recombinant form of protein A is typically truncated to about 45 kDa and is a robust, single polypeptide protein that can be immobilized onto chromatography supports through its lysine amine groups.

Protein G is another immunoglobulin binding protein that originates in group C and G *Streptococcal* bacteria. The native protein is expressed as a 56-kDa or 58-kDa polypeptide that contains multiple binding sites for immunoglobulins as well as a binding site for albumin. The recombinant form of the protein is a truncated version that has the albumin binding site removed, but retains the IgG binding capabilities of the native molecule. Protein G binds to antibodies through the heavy chains in the region of the Fc fragment, but at a different site than that of protein A. The differences in antibody binding between protein A and protein G translate into differential binding specificities and affinities and thus offer options in binding and purifying antibodies, depending on the type of antibody desired.

A chimeric fusion protein consisting of the combination of protein A and protein G, called protein A/G, merges the advantages of both protein specificities into one molecule. Protein A/G often is the immobilized immunoglobulin binding protein of choice for the purification of a wide range of antibody types from various species.

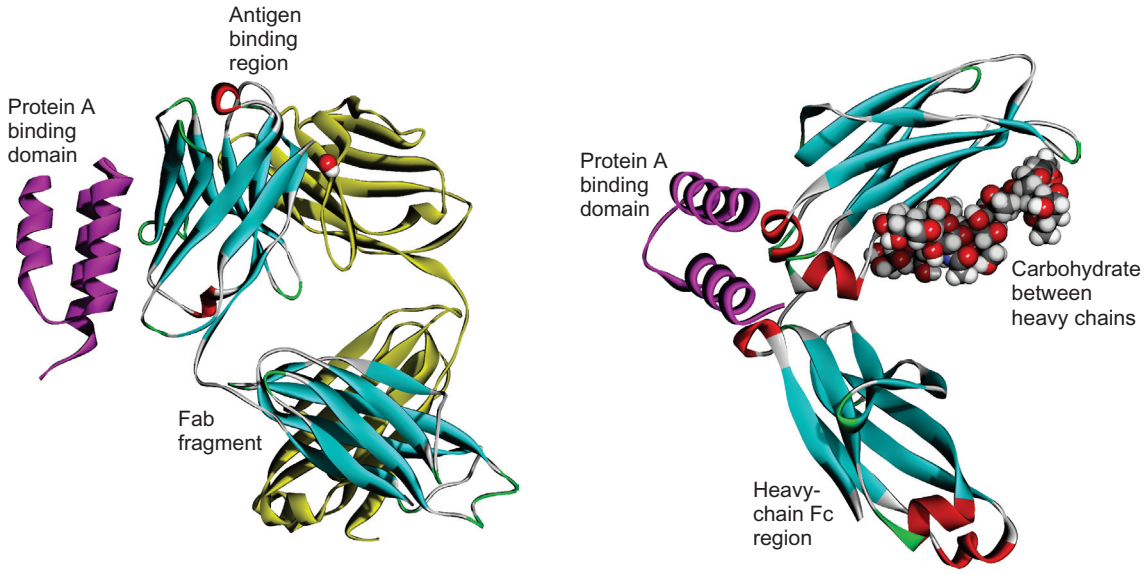

FIGURE 15.98 Three-dimensional molecular model of protein A binding to the Fc and Fab regions in antibodies (Graille *et al.*, 2000; Idusogie *et al.*, 2000; PDB IDs 1DEE and 1L6X.

However, the use of immobilized immunoglobulin binding proteins has been extended beyond just the affinity purification of antibodies. These supports can also be used to bind an antibody for subsequent targeting and immunoaffinity isolation of an antigen for which the antibody is designed to bind. Since most IgG type antibodies bind to protein A, G, or A/G in the region of their Fc fragments on the heavy chains, the antigen binding areas at the ends of the Fab fragments remain open to interact with antigens. This oriented binding of the antibody molecules places them in the ideal position to most effectively use both antigen binding sites and thus maximize the capacity of an immunoaffinity support. Other methods of antibody immobilization may result in almost random orientations of the antibody attached to the support, thus blocking some antigen binding sites by the antibody being positioned with the Fab ends facing the matrix instead of pointing out from it.

Schneider *et al.* (1983) described the use of immobilized protein A for the secondary immobilization of IgG type antibodies. Since the initial interaction of the antibody with protein A is potentially reversible just by changing the buffer conditions, this technique also uses a crosslinking agent to covalently trap the antibody on the support after binding to the protein A molecules. After applying the desired antibody to the protein A support and washing off excess not-bound material, the homobifunctional reagent DMP (dimethyl pimelimidate; see Chapter 5, Section 2.2) is incubated with the bound antibody–protein A complex. The imidoester ends of this crosslinker effectively locks the antibody onto the support by reacting with lysine amines on both the protein A and the antibody and forming covalent amidine bonds (Figure 15.99). This method has become quite popular but unfortunately it has one significant shortcoming: the amidine bonds formed from the reaction of the imidoesters with lysine amines are unstable and continually break down and leach antibody. This results in the presence of antibody in any isolated antigen preparations, which negatively affects the purity of most IP or co-IP experiments done.

Pierce (now Thermo Fisher) developed a modification of the Schneider method that solved the problem of continually leaching antibody. Instead of using DMP with its imidoester reactive groups to lock in place the antibody–protein A interaction, the homobifunctional crosslinker DSS (disuccinimidyl suberate; see Chapter 5, Section 1.2) is used. The NHS ester ends of DSS are much more able to effectively crosslink and stabilize the protein A–antibody interactions, and since the resultant linkages involve the formation of amide bonds the stability of the immobilized antibody is excellent. Essentially no leaching of antibody molecules is observed using this technique for IP or co-IP experiments. The crosslinker also stabilizes the antibody itself from breaking off the support and releasing light or heavy chains during the elution process from an experiment. In addition, this same crosslinking procedure can be used with immobilized protein A, protein G, or protein A/G supports to create immunoaffinity resins that are useful for the capture of any targeted protein or other antigen molecules from a complex biological solutions.

The downside of using an immunoglobulin-binding protein to immobilize an antibody with a crosslinker is that there may be nonspecific binding potentially

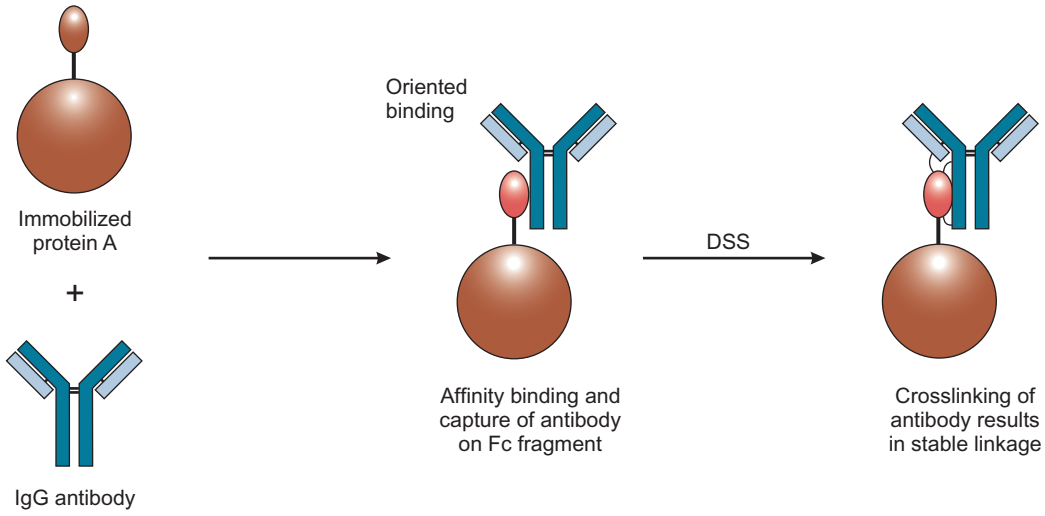

FIGURE 15.99 An immobilized protein A support can be first loaded with antibody through noncovalent affinity interactions with the Fc region of an IgG and then crosslinked with a homobifunctional reagent to stabilize the complex.

created by the presence of the other components besides the antibody. Protein A, for instance, may have a tendency to interact with unwanted proteins in a sample, or the presence of crosslinker modifications may cause some additional nonspecificity especially if the cross-bridge is somewhat hydrophobic. In particular, samples containing immunoglobulins should not be used with these supports, because the protein A on the matrix still has capacity to bind considerable IgG even with an antibody crosslinked onto its surface. Although the Schneider method and its various derivations are popular techniques to prepare an immunoaffinity support, if nonspecific binding is observed it may be advantageous to explore a method that allows direct coupling of the antibody to an amine-reactive, thiol-reactive, or carbonyl-reactive support as described previously in this chapter. Direct coupling would avoid any potential for nonspecific binding due to the protein A or the crosslinker used to stabilize the linkage.

Antibodies immobilized using a crosslinking process onto immunoglobulin binding supports have been used for many studies involving IP and co-IP procedures. Rubenstein *et al.* (2011) used an immobilized primary antibody on protein A/G–agarose to investigate the regulation of endogenous ENaC functional expression by CFTR (cystic fibrosis transmembrane conductance regulator) in airway epithelial cells. Qian *et al.* (2011) coupled a primary antibody to immobilized protein G on agarose to study the regulation of the alternative splicing of tau exon 10 by SC35 and Dyrk1A.

Immobilization of Antibodies on Protein A/G Supports

The following protocol is a generalized method for the binding and crosslinking of an IgG type antibody (polyclonal or monoclonal) onto an immobilized protein A/G support. Avoid the use of Fab fragments, as these will not interact as effectively with the protein A/G on the matrix surface, even though many Fab fragments do have a protein A binding site. Protein A/G is used instead of protein A due to its property of being a fusion protein and containing the combined properties of both protein A and protein G, thus providing excellent binding potential toward the widest variety of antibody species and subclasses. This procedure is adjusted to be appropriate for the immobilization of 100 to 200 µg of IgG antibody onto 100 µl of immobilized protein A/G; however, the amount of resin prepared may be scaled up or down by proportionally changing the quantity of each reagent used. The protein A/G support material may be obtained commercially (e.g., Thermo Fisher) or it can be prepared by reacting 5 to 10 mg protein A/G per ml of an amine-reactive support. See the section in this chapter on amine-reactive immobilization methods for additional information.

1. Wash 100 µl of immobilized protein A/G with several volumes of water and then equilibrate the gel with coupling buffer (0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2). The washing steps may be done in an appropriately sized drip column or spin column. If a spin column is used, avoid centrifuging at higher than about 100 to 300× *g* to prevent gel damage or clumping. Drain to a wet gel cake and place the bottom cap onto the column.
2. Prepare 100 µg of the antibody to be coupled at a concentration of 1 µg/µl in 100 µl of coupling buffer. If the antibody is already in solution in another buffer, dialyze or buffer exchange it into coupling buffer using size exclusion chromatography.

3. Mix the antibody solution with the immobilized protein A/G support with stirring to resuspend the gel. Place the top cap on the column or alternatively, transfer the slurry to a small tube and seal the tube with a cap. Mix the reaction medium with end-over-end rocking for 30 to 60 min to ensure complete binding of the antibody to the immobilized protein A/G.
4. Wash the support with 3 to 5 bed volumes of coupling buffer to remove any not-bound antibody and drain the gel to a wet cake.
5. Weigh 2 mg of the crosslinker DSS into a microfuge tube and dissolve it in 217 µl of dry DMSO or DMF to prepare a 25-m*M* solution. Make a 1 : 9 dilution with solvent by taking 20 µl of the DSS solution and diluting it with 180 µl of additional solvent to result in a 2.5-m*M* solution.
6. Add 300 µl of coupling buffer to the washed gel cake and mix to resuspend the gel. With mixing, add 100 µl of the diluted DSS solution to the gel slurry. The total slurry volume will be 500 µl, including the hydrated matrix. This mixture makes a final DSS concentration of 500 µ*M* in the reaction, which will be sufficient to crosslink and stabilize the antibody onto the protein A/G attached to the resin.
7. React with constant mixing for 30 to 60 min at room temperature.
8. After the reaction is complete, wash the immunoaffinity resin with an elution buffer designed to remove antibodies from protein A/G affinity supports. A suggested buffer is 0.1-*M* glycine, pH 2.8. The acidic pH will break any remaining noncovalent protein A/G–antibody interactions and thus elute off non-crosslinked species. Wash with at least 5 column volumes of elution buffer to fully remove non-crosslinked antibody.
9. Wash the immunoaffinity support with water, 1-*M* NaCl, and water to completely remove the remaining buffers and reactants. The affinity gel may be stored as a 50% aqueous slurry containing a preservative at 4°C.

2.7. Reactive Hydrogen-Mediated Immobilization Methods

The methods commonly used to immobilize proteins or other biomolecules as well as couple organic compounds to chromatography supports usually relate to the covalent attachment of the ligand through a functional group, which most often includes amines, thiols, carboxylates, aldehydes, ketones, and occasionally hydrazides or aminooxy groups. However, sometimes a ligand does not contain any of these standard functional groups to facilitate easy immobilization using the activation methods thus far described in this chapter. In such cases, either the ligand must be derivatized to provide a functional group appropriate for coupling or another option must be used to facilitate immobilization.

One potential route to coupling ligands that do not have this common set of functionalities is to use a reactive hydrogen-mediated method, which targets certain replaceable hydrogen atoms within the compound's structure. These methods may work for compounds containing reactive aromatic hydrogens that may be present within the ligand structure, as is often the case with certain drugs, steroidal compounds, dyes, or other aromatic organic compounds.

The following sections describe two reaction strategies that might be used to immobilize ligands having none of the standard functional groups, as described in the previous sections of this chapter.

Diazonium Activation

Diazonium reactions have been used for many years in organic synthesis as well as for protein modification, crosslinking, and immobilization procedures (Higgins and Fraser, 1952; Phillips *et al.*, 1965; Inman and Dintzis, 1969; Cuatrecasas, 1970). Some of the earliest dyes contained diazo groups within their structure, which were formed from the reaction of a diazonium intermediate with a reactive hydrogen on another aromatic compound. The preparation of reactive chromatography supports containing diazonium groups can be done using an intermediary *p*-aminobenzylalkyl group, which in turn is created from the prior immobilization of a *p*-nitrophenyl derivative. A sequence of reactions is needed to form the required intermediate aminophenyl groups and then activate them to the diazonium derivatives. For immobilization reactions on chromatography supports, the diazonium groups need to be made immediately before use due to their high reactivity and instability.

Two routes to the formation of a reactive diazonium group on a support are shown in Figure 15.100. In one option, an amine-terminal spacer arm on a support is reacted with *p*-nitrobenzoyl chloride (Sigma-Aldrich) under nonaqueous conditions to create a nitrophenyl intermediate. In the second reaction option, the modification reagent *N*-succinimidyl-*p*-nitrophenylacetate (SNPA; Bachem) is coupled to the amine-terminal spacer arms on the support to form an amide bond linkage, which terminates in the nitrophenyl groups. In both options, the nitro groups are then reduced to aromatic amines through treatment with sodium dithionite in aqueous solution to form the necessary aminophenyl derivatives. This intermediate is stable for long-term storage until the support is needed to immobilize an affinity ligand. Just before the coupling reaction, the support is activated using an ice-cold solution of

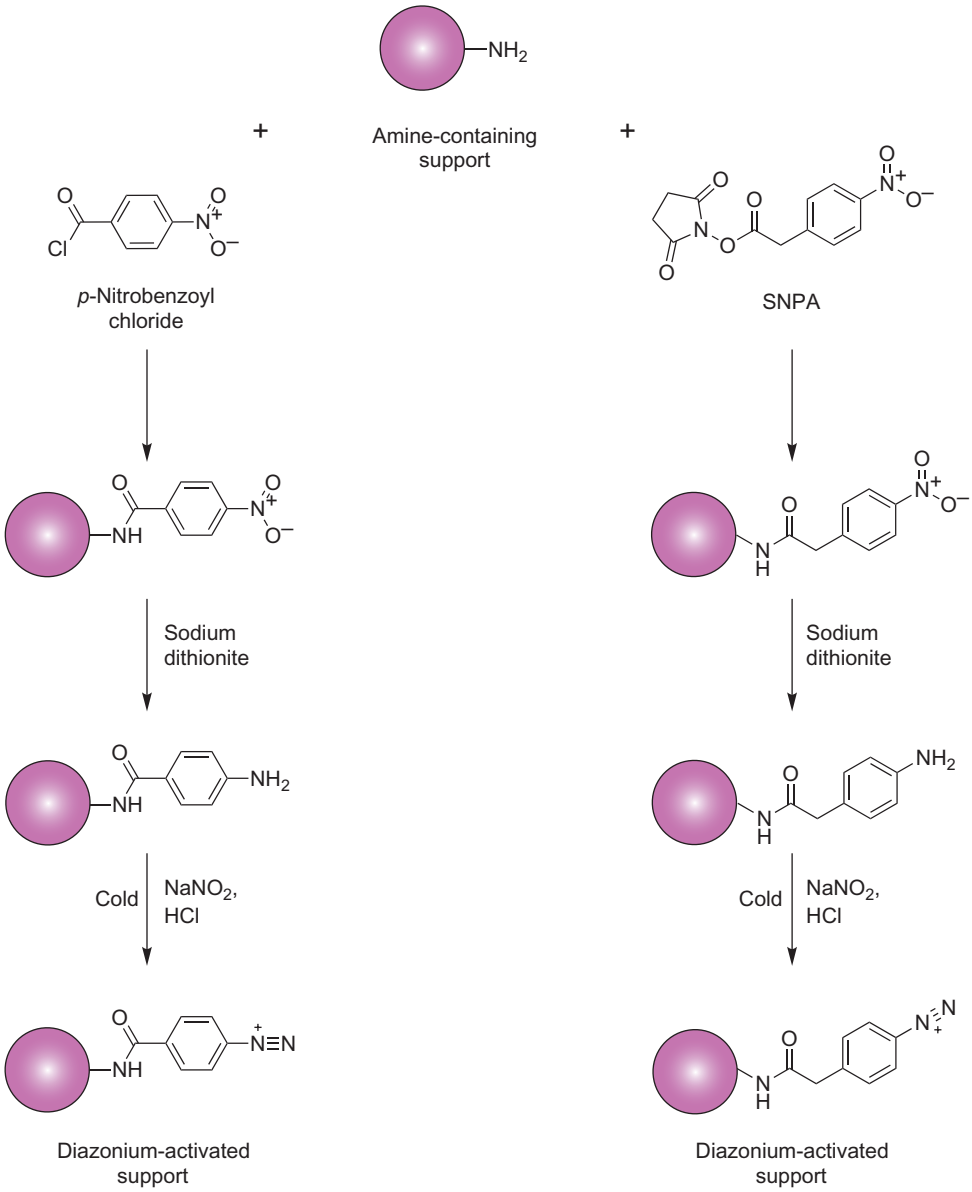

FIGURE 15.100 Modification of an amine-containing support with *p*-nitrobenzoyl chloride or SNPA with subsequent reduction with sodium dithionite to form aryl amines. These intermediates can then be treated with sodium nitrite in cold, acidic conditions to create reactive diazonium groups.

sodium nitrite in HCl to create the reactive diazoniums from the aminophenyl groups. The reaction is done in the cold to prevent the diazonium group from immediately reacting with water to form phenol and nitrogen gas.

Diazonium groups are relatively unstable and should be used immediately to couple a ligand. The rate of diazo bond formation is extremely rapid with ligands, but even if no ligand is added to the support, diazo bond formation can be observed to occur within the matrix due to intramolecular crosslinks. This is due to the reaction of a diazonium group with the aminophenyl precursor molecules and will result in extensive crosslinking and inactivation of the activated support within about an hour after activation. For this reason, ligand should be added quickly to limit the potential for the crosslinking side reactions.

Histidine and other imidazole-containing compounds can be coupled to a diazonium-activated support at pH 8, while tyrosine and phenolic compounds are best immobilized in the range of pH 8 to 10. Figure 15.101 shows the reactions associated with ligand immobilization to create the final diazo linkage with the support. Ligands coupled using this method often result in a highly colored resin due to the presence of the diazo bonds. During the reaction, the support

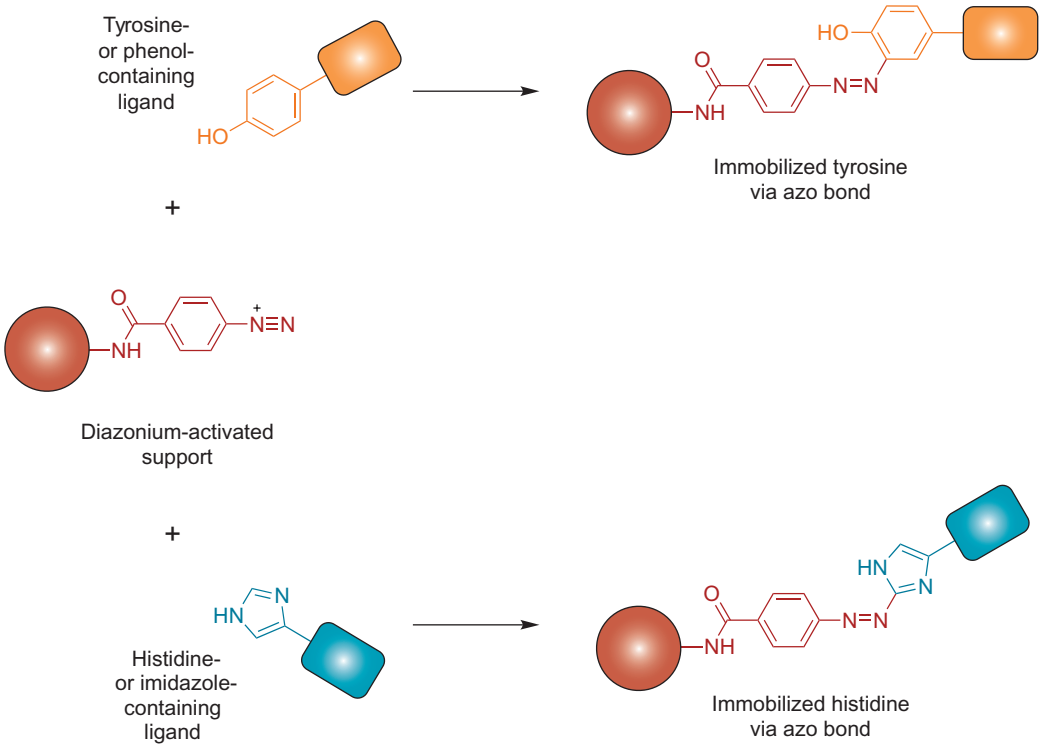

FIGURE 15.101 Immobilization of histidine (imidazole) or tyrosine (phenolic) ligands onto diazonium supports.

can turn dark-brown or even black as the ligand molecules are coupled. This color is normal and should not be viewed as unusual or a problem for subsequent use of the support for affinity separations. The diazo bonds also can be cleaved resulting in bond breakage and release of the immobilized ligand from the support. Treatment with 0.1-*M* sodium dithionite in 0.2-*M* sodium borate, pH 9.0, results in complete bond cleavage as evidenced by the disappearance of the diazo bond color within the support.

PREPARATION OF DIAZONIUM-ACTIVATED SUPPORTS

The following methods assume that an amine-containing support has previously been prepared according to the procedures outlined in the last section of this chapter. All operations should be done in a fume hood while wearing the appropriate personal protective equipment to prevent contact with chemical compounds and solvents.

(A) Preparation of Aminophenyl Groups on the Support

1. Wash 10 ml of an amine-containing resin with water to remove any storage solutions and then wash the support into DMF (dry) using sequentially increasing concentrations of DMF in water (e.g., 30%, 60%) until 100% DMF is used. Washing can be performed using a sintered glass filter funnel suspended in a vacuum filter flask in the fume hood. Continue to wash with at least 10 to 20 bed volumes of DMF until all remaining water is removed. Drain the support to a moist cake.
2. Prepare a solution of SNPA (Bachem) in DMF by dissolving 0.3 g of the modification reagent in 10 ml solvent. Mix thoroughly to dissolve.
3. With stirring, add the gel cake to the SNPA solution and mix the support to create a uniform suspension.
4. React with constant mixing for 1 h at room temperature. The mixing may be carried out in a sealed centrifuge tube by rotating it on an end-over-end mixer.
5. Wash the support extensively with DMF to remove excess reactants and reaction byproducts (at least 10 column volumes). Next, sequentially wash the support back into water by using decreasing concentration of DMF in water until pure water is used. Continue to wash with water (at least 10 column volumes) and then wash the support with several volumes of 0.1-*M* sodium borate, pH 9.0. Drain to a moist cake.
6. Prepare a solution of sodium dithionite in 0.1-*M* sodium borate, pH 9.0, by dissolving 1.2 g in 10 ml of buffer. Mix thoroughly to dissolve.
7. Add the moist gel cake to the dithionite solution with mixing. The dithionite will reduce the nitrophenyl

groups on the support to aminophenyl groups, the precursors used to form diazonium groups. React for 1 h at room temperature.
8. Wash the support thoroughly with 0.1-*M* sodium borate, pH 9.0, and then with water to remove all remaining reactants. The gel may be stored at this point before activation and coupling of ligand if desired. Storage should be done at 4°C as an aqueous slurry in the presence of a preservative.

(B) Activation to Form Diazonium Groups and Coupling of Ligands

Note that the following activation steps should be performed using ice-cold reagents and the reactions performed at 4°C. Do not allow the activated support to sit around for any length of time before coupling ligand, as the diazonium groups will quickly degrade and the support will lose coupling capacity. For this reason, the ligand solution (step 6) should be prepared prior to beginning the activation procedure.

1. Wash 10 ml of the aminophenyl-support prepared in (A) with ice-cold water and then with several bed volumes of cold 0.3-*N* HCl. Finally, suspend the gel in 10 ml of cold 0.3-*N* HCl using a 50-ml centrifuge tube or small vessel that can be sealed. Maintain the solution on ice.
2. Prepare 2.5 ml of a solution consisting of sodium nitrite ($NaNO_2$) in cold water by dissolving it at a concentration of 50 mg/ml.
3. Add the sodium nitrite solution to the gel slurry with stirring.
4. React with mixing for 15 min at 4°C on ice.
5. Quickly wash the activated gel with several bed volumes of cold 0.3-*N* HCl, cold water, and then with cold coupling buffer (0.1-*M* sodium phosphate, pH 8.0, for coupling histidine/imidazole-containing ligands or 0.1-*M* sodium borate, pH 9–10, for coupling tyrosine/phenolic compounds). Drain the gel to a moist cake.
6. Prepare a ligand solution in the chosen coupling buffer (cold) at a concentration of 3 to 10 mg/ml for proteins or 3 to 5 mg/ml for small peptides or organic molecules. Some optimization of the ligand concentration should be carried out to obtain the best performance in the intended application. For ligands which are not very soluble in aqueous solution, the borate coupling buffer may be made with up to 50% ethanol (v/v) to aid in solubility. The ligand may first be dissolved in ethanol and then diluted in coupling buffer to promote solubility in the reaction medium.
7. Immediately add the ligand solution to the washed, activated support with stirring to resuspend the gel. React overnight at 4°C in a sealed container with constant mixing (e.g., end-over-end rocking).
8. Wash the affinity support with coupling buffer (containing ethanol if that was used to aid in solubility during the reaction) and then with water (again containing ethanol, if used), and finally with water alone. The affinity support can be stored until use at 4°C as a 50% aqueous slurry in the presence of a preservative.

Mannich Condensation

The methods available to immobilize molecules are highly diverse and well characterized for ligands that contain a common functional group, which can easily be targeted and covalently linked to a support. Ligands that have at least one amine, carboxylate, aldehyde, ketone, thiol, or hydroxyl group can be coupled to a reactive solid support using one or more of the appropriate reactions discussed previously in this chapter. However, for molecules that possess no such functionalities the route toward successful immobilization may not be as clear. In some cases, ligands such as drugs, steroidal compounds, inhibitors, dyes, or other organic molecules simply do not have a convenient functional group for linking to a support. In other cases, functional groups that are present may have low reactivity or be sterically hindered to allow efficient coupling to an activated matrix.

Frequently, however, such difficult-to-immobilize molecules may contain reactive hydrogens (i.e., replaceable) within their structures to facilitate coupling in a Mannich condensation procedure. The classic Mannich reaction involves the condensation of formaldehyde (or another aldehyde compound) with ammonia (as its salt), and a third compound containing an active hydrogen. The product of this reaction, usually performed under acidic conditions, involves the replacement of the active hydrogen with the methylene group from formaldehyde, and then attached to this is an amine, which originates from the ammonia. Instead of using ammonia, the reaction can also be performed using an amino group (primary or secondary) to achieve the linkage of the amine-containing compound with the active hydrogen-containing molecule through the methylene (CH_2) bridge. An example of this reaction using acetophenone, formaldehyde, and an organic amine salt proceeds as follows (the active hydrogens shown in bold text):

$$C_6H_5COC\mathbf{H}_3 + CH_2O + RNH_2 \cdot HCl \rightarrow C_6H_5COCH_2{-}CH_2{-}NH{-}R \cdot HCl$$

Hermanson *et al.* (1992) first described the use of the Mannich reaction to immobilize ligands that did not have any common functional groups, but had sufficiently active hydrogens to participate in this reaction. Chapter 19, Section 6, also describes the use of this reaction for the bioconjugation of active hydrogen-containing haptens to carrier proteins to produce immunogens suitable for immunization. The same reactions can be used to immobilize ligands onto amine-containing supports using formaldehyde as the third reactant.

The use of the Mannich reaction to couple active hydrogen-containing ligands assumes the prior preparation of a support that contains spacer arms that terminate in the primary amino groups required to participate in the process (see the final section in this chapter for spacer arm preparation). The coupling reaction is driven in aqueous buffer by mildly acidic conditions and moderate heat, which most ligands of this type can tolerate without degradation. In addition, since one component of the reaction is already coupled to the support, no potential is present for uncontrolled polymerization of the ligand in solution, as is often the case with molecules containing more than one reactive hydrogen undergoing Mannich condensation. Figure 15.102 illustrates the immobilization of a steroidal molecule onto an amine-containing support using this reaction process. The exact point of coupling to the ligand will be the most reactive or most replaceable hydrogen; however, there may be more than one orientation of ligand attachment if more than one active hydrogen site is present.

A modification of a Mannich coupling reaction for biomolecules was made by Joshi *et al.* (2004). This reaction uses aniline as the amine component similar to the methods used to enhance oxime or hydrazone formation (see previous sections, this chapter). However, instead of being a catalyst as it is in the reactions of aldehydes with hydrazides or aldehydes with aminooxy compounds, in the Mannich reaction aniline actually becomes incorporated into the final product. It first reacts with the formaldehyde (or another aldehyde) component to create an intermediate imine, which then goes on to specifically react with phenolic molecules in solution at positions *ortho* or *para* to the –OH group (Figure 15.103). The result is much more efficient end product formation even at room temperature than the standard Mannich reaction procedure, which is a benefit for coupling sensitive biomolecules.

This bioconjugation method of aniline-promoted Mannich condensation may also be extended to the immobilization of phenolic molecules by using immobilized aniline as the reactive group on the support. An

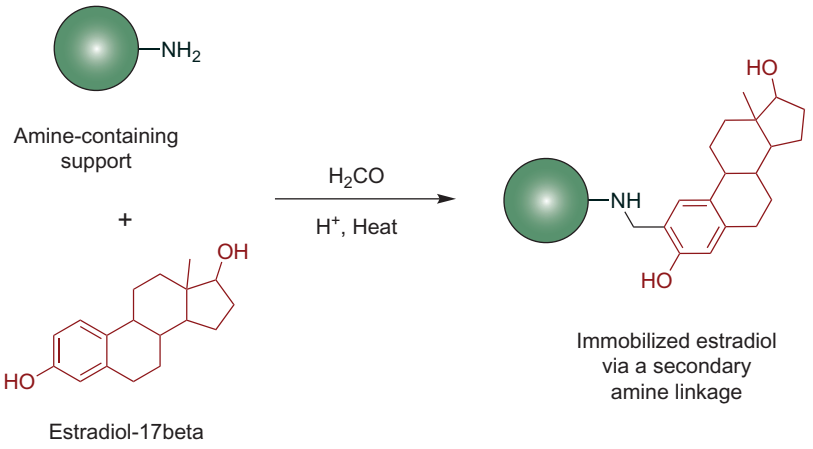

FIGURE 15.102 Immobilization of estradiol-17beta onto an amine-containing support using the Mannich reaction.

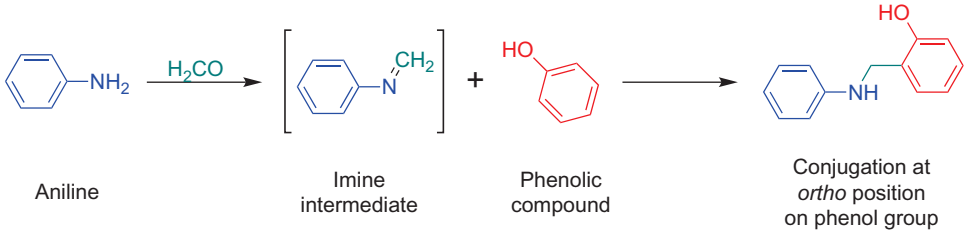

FIGURE 15.103 Mannich condensation reaction using aniline.

aniline-modified support was prepared in the previous section as a precursor to a diazonium-activated support. That same aniline intermediate may also be used in the Mannich reaction to couple with active hydrogens on phenolic compounds for the preparation of affinity chromatography supports in a mild reaction process. Indeed, even proteins or peptides containing a tyrosine residue may be coupled specifically through the phenolic side chain using this reaction without affecting any other functional group on the molecule. The only requirement for proteins to efficiently participate in this reaction is that the tyrosine groups must be surface accessible. The reaction proceeds at room temperature and is optimal at a pH range of 5.5 to 6.5, which is mild for most biomolecules. Figure 15.104 illustrates the immobilization of a tyrosine-containing peptide on a support containing aniline groups using the Mannich reaction.

Therefore, using the Mannich reaction two potential reaction paths are possible: (1) coupling of active-hydrogen containing molecules onto aliphatic amine-containing supports when a ligand contains no other available common functional groups to facilitate coupling; and (2) immobilization of tyrosine-containing proteins or peptides onto aniline-containing supports specifically through tyrosine's phenolic side chain while avoiding the reaction of other functional groups. These choices make the Mannich reaction a powerful alternative for the immobilization of certain affinity ligands.

Because of the versatility of the Mannich condensation method of immobilization it is being used more frequently for reactive hydrogen-containing ligands. Pyell and Stork (1992) used the method to prepare immobilized 8-hydroxyquinoline on an aminopropyl silane-modified silica support for use as a chelating agent. In addition, the phenol derivatives 4-(2-pyridylazo) resorcinol, 8-hydroxyquinoline, and 1-(2-pyridylazo)-2-naphthol were immobilized onto an amino-silica particle using the Mannich reaction (Tertykh *et al.*, 2000), while Pu *et al.* (1998) used a similar reaction process to couple 2-mercaptobenzothiazole to aminopropyltriethoxysilane-modified silica gel. In addition, Zhang *et al.* (2009) used the Mannich reaction to immobilize phenolphthalein onto an amine-modified polyacrylonitrile fiber for use as a halochromic fiber, which would change color with rapid response time depending on the pH of the environment. Members of this same group also used the Mannich reaction to produce a heavy-metal-detection fiber by coupling 4-(2-pyridylazo)-1,3-benzenediol onto ethylenediamine-modified polyacrylonitrile fibers (Li *et al.*, 2010).

COUPLING LIGANDS *VIA* MANNICH CONDENSATION

The following protocols describe the use of either an aliphatic amine-containing matrix to immobilize active-hydrogen-containing ligands or an aniline-containing support to couple tyrosine-containing (or phenolic) ligands. Both reactions involve the use of formaldehyde and should be carried out in a fume hood using the appropriate personal protective equipment to prevent contact with reactants or solvents.

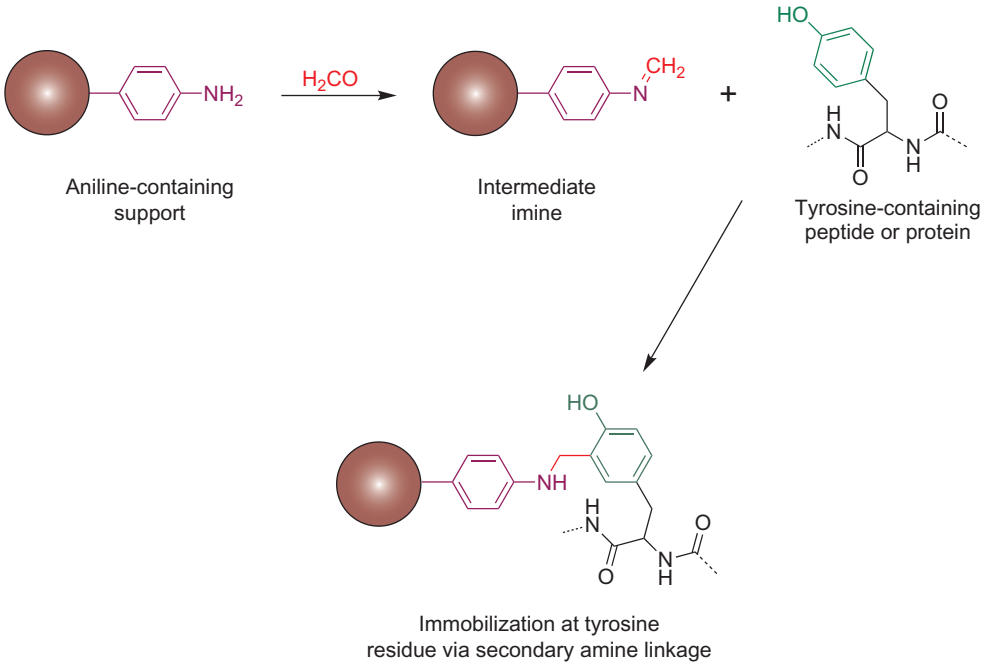

FIGURE 15.104 Immobilization of a tyrosine-containing peptide on a support containing aniline groups using the Mannich reaction.

(A) Mannich Reaction with Active Hydrogen-Containing Ligands

This protocol assumes the prior preparation of an aliphatic amine-containing support as described in the last section of this chapter on the modification of supports with spacer arms.

1. Wash 10 ml of a primary amine-containing support with water to remove any storage solution and then with 0.1-*M* MES, pH 4.7 (coupling buffer). Examples of primary amine-containing spacer arm gels that work well in this process include MANAE–agarose and DADPA–agarose. Wash with at least 3 to 5 bed volumes of the solutions. The washing steps may be carried out in a small sintered glass filter funnel suspended in a suction filter flask. After washing, drain the support to a moist cake.
2. Dissolve the ligand containing an active hydrogen site in 10 ml of coupling buffer. If the ligand is relatively insoluble in aqueous buffer, it may first be dissolved in ethanol and then an aliquot added to the final buffer solution, making the total volume up to 10 ml; however, the final concentration of ethanol in the MES buffer should not exceed 50% to avoid buffer salt precipitation.
3. Mix the ligand solution with the washed amine-support and stir to resuspend the gel. Place the slurry in a sealable container and in a fume hood add to it 1.0 ml of 37% formaldehyde solution with mixing. Seal the container.
4. React at 37 to 57°C with constant mixing for a minimum of 24 h. For compounds with a slower reaction rate in the Mannich reaction, a longer reaction time or a higher temperature may be required for effective coupling yields. Some degree of optimization may have to be done to determine the best reaction conditions for a given molecule.
5. Wash the support extensively with coupling buffer and then with water (both containing ethanol, if used) to remove excess unreacted ligand. If the ligand is especially soluble in ethanol, a wash with 100% ethanol may be done after the water/ethanol wash to completely remove the last traces of free ligand. Finally, wash sequentially back into water and then with pure water. The affinity support may be stored as a 50% aqueous slurry at 4°C containing a preservative.

(B) Mannich Reaction with Tyrosine-Containing Ligands

This protocol assumes the prior preparation of an aniline-containing support as described in the previous section on diazonium activation. Note that an alternative approach to creating an immobilized aniline intermediate is to immobilize 2-(4-aminophenyl)ethylamine directly onto an amine-reactive support through the aliphatic amino end. See the previous sections in this chapter on the preparation and use of amine-reactive supports for information on how to prepare this type of aniline-containing resin.

1. Wash 10 ml of an aniline-containing support with water to remove any storage solution and then with 0.1-*M* MES, pH 6.0 (coupling buffer). The washing steps may be done in a small sintered glass filter funnel suspended in a suction filter flask. After washing, drain the support to a moist cake.
2. Dissolve the ligand containing a tyrosine residue (i.e., protein, peptide, or a phenolic compound containing a free *ortho* or *para* position relative to its –OH group) in 10 ml of coupling buffer. If the ligand is relatively insoluble in aqueous buffer, it may first be dissolved in ethanol and then an aliquot added to the final buffer solution, making the total volume up to 10 ml; however, the final concentration of ethanol in the MES buffer should not exceed 50% to avoid buffer salt precipitation.
3. Mix the ligand solution with the washed aniline-support and stir to resuspend the gel. Place the slurry in a sealable container and in a fume hood add formaldehyde to make a final concentration of 25-m*M*. Mix well and seal the container.
4. React at room temperature (i.e., 20–25°C) with constant mixing for a minimum of 24 h.
5. Wash the support extensively with coupling buffer and then with water (both containing ethanol, if used during the coupling reaction) to remove excess unreacted ligand. If the ligand is especially soluble in ethanol, a wash with 100% ethanol may be done after the water/ethanol wash to completely remove the last traces of free ligand. Finally, wash sequentially back into water and then with pure water. The affinity support may be stored as a 50% aqueous slurry at 4°C containing a preservative.

2.8. Creating Spacer Arms on Chromatography Supports

The most common route of preparing an affinity chromatography support involves the direct activation of a solid-phase material followed by the coupling of the affinity ligand. Most of the methods described in the previous sections of this chapter use this path to ligand immobilization. Occasionally, however, it is useful to create an intermediate derivative on the support that includes the formation of a spacer arm, which might terminate in a functional group useful for subsequent reactions. Spacers are typically low-molecular-weight molecules that are most often linear and consist of

alkyl or hetero-alkyl components that extend out from the matrix from about 2 to 20 atoms in length. Spacer arms can serve multiple purposes on chromatography supports. They can simply be a bridge between an initial functional group or reactive group on a support and the creation of another needed functionality at the other end of the spacer. They also can provide a long tether that extends the affinity ligand out from the matrix surface, thus providing greater steric accommodation for target molecules that may interact or dock with it. This is an especially important feature if the binding site for a ligand is a deep pocket within the target protein, such as is the case for avidin or streptavidin in binding to immobilized biotin. Even with much larger ligands, however, spacers can be used to extend the molecule away from the matrix surface for better accessibility to bind targets. Extremely long spacers such as PEG-based compounds can provide much greater freedom of motion for immobilized proteins, thus allowing greater potential for interactions to occur within the support. This may be especially important if an immobilized protein has more than one binding site for a target molecule, as is the case for many immunoglobulin-binding proteins (i.e., protein A, protein G, and protein A/G) or in the case of avidin or streptavidin used to capture biotinylated proteins.

Spacers can also create additional properties on a support, such as the introduction of increased hydrophilicity that can reduce nonspecific binding to the final affinity resin. An early report recognized the benefit of using hydrophilic linker arms in the design of affinity chromatography supports (O'Carra *et al.*, 1974). Spacers can also consist of branched constructs that create multi-point immobilization sites for an affinity ligand, which can stabilize some proteins or enzymes (e.g., glycidol modified supports, see previous corresponding section, this chapter). If desired, the cross-bridge of a spacer arm can also be chosen to be cleavable to permit chemical release of an affinity ligand after it has bound a target. Sometimes, in the design of an affinity support, it takes one or two spacer arm modifications to create the desired effects and functionalities on the matrix prior to the immobilization of the affinity ligand. In other cases, a spacer is formed during matrix activation or coupling of a ligand, such as in activation methods using a *bis*-epoxide compound or in the immobilization of an amine-containing ligand to an azlactone-activated support (see previous sections, this chapter).

The options available for adding spacer groups onto chromatography supports are numerous and mixing and matching these options can multiply the design choices dramatically. In the most fundamental spacer arm design, there are functional groups on both ends of a molecule that are separated by an aliphatic or heteroaliphatic chain. Less frequently, there might be aromatic groups present in the bridging portion of the spacer, but this is less common due to the hydrophobicity such groups can add to the final support. Spacers can even be constructed from the use of homobifunctional or heterobifunctional crosslinking agents through the reaction of one end of the crosslinker to a functional group on the surface of the support, which leaves the other reactive group free to couple with a ligand or another spacer molecule. The epoxy activation of a support using the *bis*-epoxide compound 1,4-butanediol diglycidyl ether yields a hydrophilic 12-atom spacer, which terminates in a reactive epoxide group before a ligand is coupled.

It is also important to consider the overall chromatography effects in having a spacer arm in the design of an affinity resin. Some of the potential consequences of an inappropriate linker arm include the introduction of hydrophobic or ion-exchange interactions that can result in binding to nonrelevant molecules in a sample, resulting in lower purity for the desired isolated target molecule. For instance, long aliphatic chains can create considerable hydrophobicity on an otherwise fairly hydrophilic base support. Although spacer arms of long length may seem desirable, increasing the length of an aliphatic spacer may only serve to increase the hydrophobic interaction potential of the final affinity resin. A better alternative would be to choose a hydrophilic spacer instead of a hydrophobic one, which may provide the extended length needed while still maintaining or even improving the hydrophilicity, and therefore low nonspecific binding character, of a support. Similarly, some spacers may create charges on a support from ionized or protonated groups, thus generating the potential for nonspecific binding with oppositely charged molecules in a sample. Secondary amine-containing spacers are particularly notorious for creating positive charge on a matrix, which may lead to undesirable interactions. Spacers containing carboxylates or sulfonates may also generate nonspecific binding characteristics from creating negative charges on the support.

Figure 15.105 shows examples of common spacer molecules used in the preparation of immobilized affinity ligands, which is by no means exhaustive. Many of these molecules contain aliphatic or hydrophobic cross-bridges, which should be used with caution to avoid nonspecific binding issues in the final support. Even the spacers containing only a six-carbon aliphatic bridge can result in considerable hydrophobic interaction potential, even though they are used quite frequently with success in designing affinity supports. For hydrophilicity in the final support, it is important to choose a spacer composition containing polar groups within an alkyl chain, which can reduce or eliminate hydrophobic character. The best choices for water solubility and low nonspecific binding include

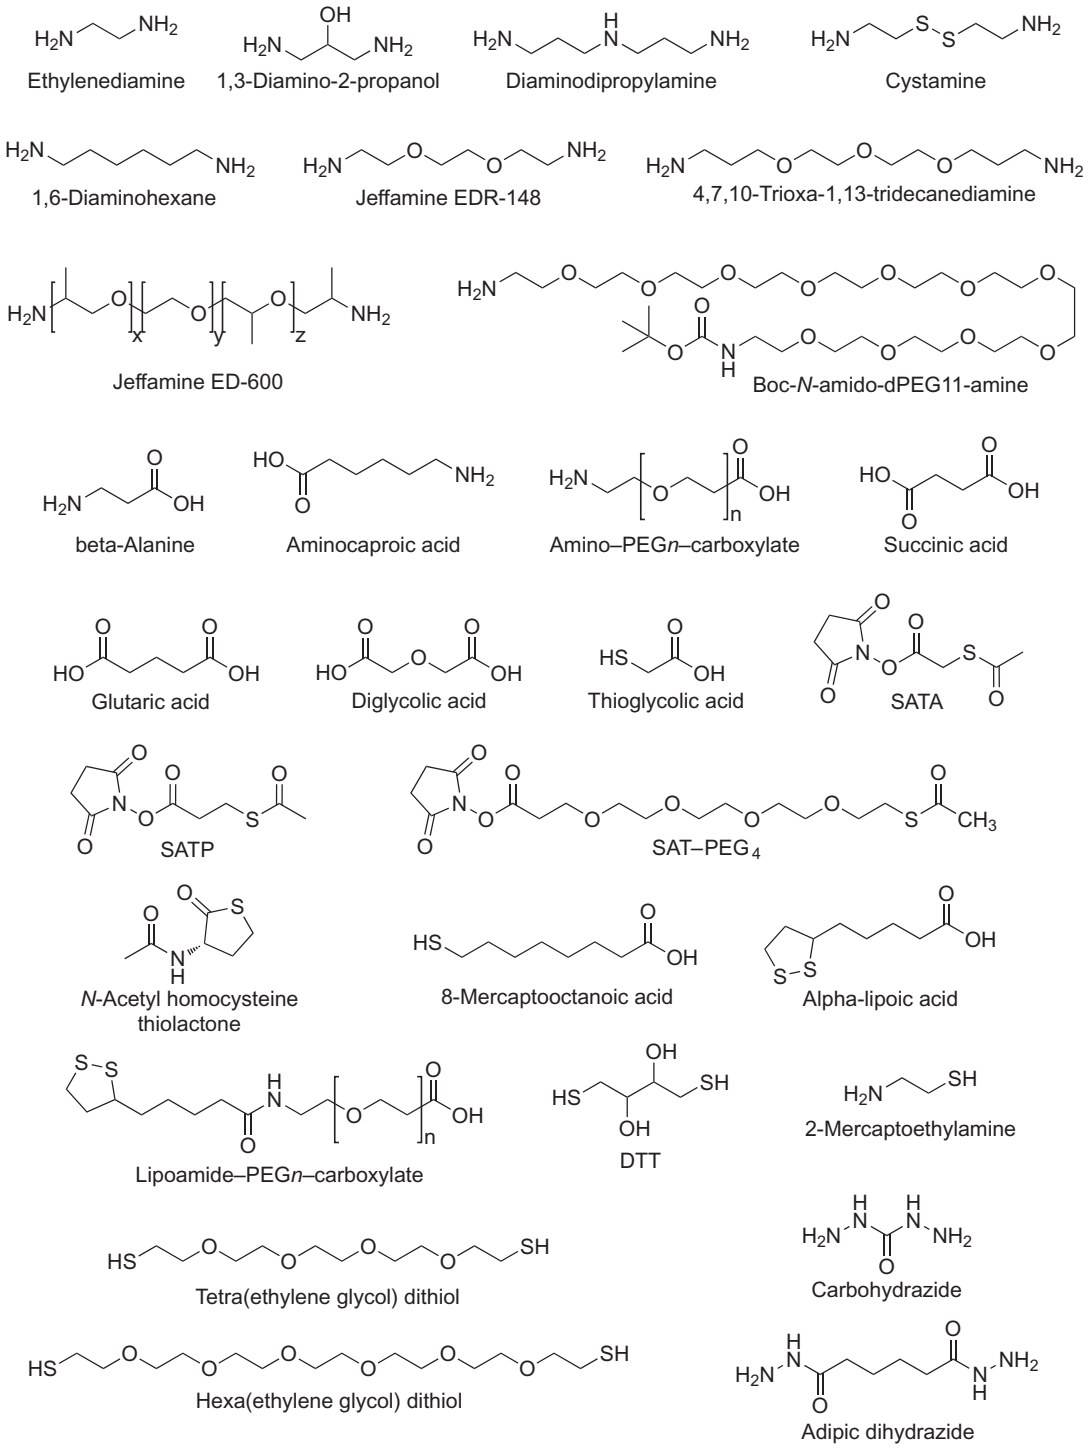

FIGURE 15.105 Small molecules used as spacers in affinity chromatography.

polar components such as secondary amines, carbonyl groups, amide bonds, ether groups, and hydroxyls. If possible, avoid charged groups, such as protonated secondary (or tertiary) amines or carboxylates, which may introduce ion-exchange effects. Perhaps a superior choice in this regard is to use a PEG-based spacer, which avoids both the issue of hydrophobicity and also does not generate within the cross-bridge any charged sites with ion-exchange potential. There are now many discrete PEG-based spacers and crosslinkers available for the design of virtually any immobilized ligand (see Chapter 18). A list of spacers and modification reagents

that have been used to create linker molecules on solid phases and categorized by the type of spacer follows.

Diamine Spacers
- Ethylenediamine
- 1,3-Diamino-2-propanol
- DADPA
- Cystamine
- 1,6-Diaminohexane
- Jeffamine EDR-148
- Jeffamine ED-600
- 4,7,10-Trioxa-1,13-tridecanediamine
- Boc-*N*-amido-dPEG$_{11}$-amine
- Boc-*N*-amido-dPEG$_3$-amine

Amino–Carboxylate Spacers
- Beta-alanine
- Aminocaproic acid
- Amino–PEG$_n$–carboxylate compounds

***bis*-Carboxylate Spacers**
- Succinic acid (or succinic anhydride)
- Glutaric acid (or glutaric anhydride)
- Diglycolic acid (or diglycolic anhydride)

Thiol–Carboxylate Spacers
- Thioglycolic acid
- SATA
- SATP
- *N*-Acetyl homocysteine thiolactone
- 8-Mercaptooctanoic acid
- Alpha-lipoic acid
- Lipoamide–PEG$_n$–carboxylate compounds
- Thiol–PEG$_n$–carboxylate compounds
- NHS–PEG$_n$–acetylated thiol compounds (SATA-like)

***bis*-Thiol Spacers**
- DTT
- Tetra(ethylene glycol) dithiol
- Hexa(ethylene glycol) dithiol
- Poly(ethylene glycol) dithiol

Amino–Thiol Spacers
- 2-mercaptoethylamine

***bis*-Hydrazide Spacers**
- Adipic dihydrazide
- Carbohydrazide

Of course, some hydrophobic spacer molecules may be purposely chosen to result in a resin having hydrophobic character designed into the gel for certain separations. Various forms and lengths of hydrophobic linkers can be coupled to a support to create a resin useful for hydrophobic interaction chromatography. In this case, the longer the hydrophobic spacer arm, the greater will be the hydrophobic interaction potential. A 4-carbon chain, for instance, will have much weaker hydrophobic interaction potential with proteins than an 8-carbon chain. The extreme hydrophobicity of an 18-carbon aliphatic chain is often designed into HPLC chromatography resins, which is the length typically used for reverse phase separations.

The following sections describe some of the most popular spacer molecules used to make affinity resins and the reactions that can be used to prepare the derivatized supports. The choice of spacer for a particular immobilization reaction should be done based upon the functional groups required at both ends of the spacer and the length and physical properties of its cross-bridge. To design an optimal affinity resin containing a spacer molecule, it is often best to evaluate a number of spacer arm types to determine which one performs best for a given application. For instance, if there is a need for a diamine spacer in the construction of an immobilized ligand, then it is best if several different diamines are compared to see how changes in spacer structure and length affect the final affinity separation.

Diamine Spacers

Spacer molecules containing an amine at both ends often are used to create a primary amine on a support for further modification or for the coupling of carboxylate-containing ligands. They are also used as an intermediary in the creation of some activated supports, such as in the preparation of an iodoacetyl-support useful for coupling thiol-containing ligands (see earlier section, this chapter). To couple a diamine spacer to a support, an amine-reactive resin should first be created according to the methods described previously. The diamine is then reacted in large excess with the amine-reactive support to result in one end of the spacer coupling to the support and the other end remaining free. To reduce the potential for crosslinking that results in both ends of the spacer being linked to the support, the reaction needs to be performed at a minimum concentration of 0.5-*M* diamine. Alternatively, if the diamine spacer molecule is available with one end protected (one amine blocked), then a much lower concentration can be used for coupling; however, the final product then needs to be deblocked to reveal the terminal amine for further modification. Typical protecting groups for amines include carbobenzyloxy (Cbz), *tert*-butyloxycarbonyl (BOC), and 9-fluorenylmethyloxycarbonyl (FMOC), which allow one end of the diamine to be immobilized without the potential for crosslinking. Removal of the protecting groups is by catalytic hydrogenolysis (Cbz), strong acid such as trifluoroacetic acid (TFA) (BOC), or an organic base such as piperidine (FMOC). Use care to ensure that the deprotection step does not cause adverse effects on the base support. In this regard, deprotection of Cbz groups may not be compatible with porous chromatography supports, as the typical reagent used for this procedure is a particulate Pd/C suspension and hydrogen. The Pd/C particles

may get entrapped within the matrix and not be easily removed. A better protecting group would be FMOC, because the addition of a 20% piperidine solution in DMF for the deprotection step would be tolerable for most support materials.

Diamine compounds that are in the free base form (not as salts) are extremely caustic in aqueous solution and upon dissolving will typically give a pH > 11. The dissolving process in water and the subsequent neutralization reaction with acid can be hazardous, as both are exothermic processes. If the dihydrochloride salt of a diamine is commercially available, then the neutralization step is not needed and the diamine typically is supplied as a solid and is much more convenient to work with. To neutralize diamines safely, always use a fume hood and proper personal protective equipment to avoid contact with solutions and inhalation of fumes. To limit the exothermic heat effect, a diamine compound may be first added to an excess of crushed, deionized ice (equal to a little less than the final desired solution volume) and then 6-*N* HCl added slowly with stirring. As the diamine is neutralized, the ice will melt and prevent the solution from becoming extremely hot. Once the diamine solution is neutralized, the appropriate buffer salt may be added and the pH adjusted to the proper value for the coupling reaction being done.

DIAMINODIPROPYLAMINE

One of the more common diamine spacer molecules used in affinity chromatography is diaminodipropylamine (DADPA), also known as 3,3′-iminobispropylamine (Figure 15.106). It is a nine-atom spacer with a central secondary amine and a primary amine at each of the ends. The central secondary amine aids in overall hydrophilicity, but may also be a potential site of positive charge due to protonation at physiological pH. In addition, the secondary amine might participate in some reactions that are targeted at the terminal primary amine, thus complicating the structural nature of the final immobilized ligand. DADPA is liquid at room temperature (d = 0.938 g/ml; mp = −14°C) and volatile with a strong amine odor; therefore, all solutions should be handled in a fume hood. The reagent is soluble in aqueous solution for buffered reactions and it is also soluble in many organic solvents suitable for work with chromatography supports (i.e., DMSO, DMAC, DMF, acetone, dioxane, and ethanol).

Amine-reactive supports may be modified with DADPA to produce spacer arms terminating in a primary amine. When using amine-reactive supports that are labile in aqueous environments (e.g., due to hydrolysis), then the DADPA coupling reaction can be done in organic solvent to eliminate the competing

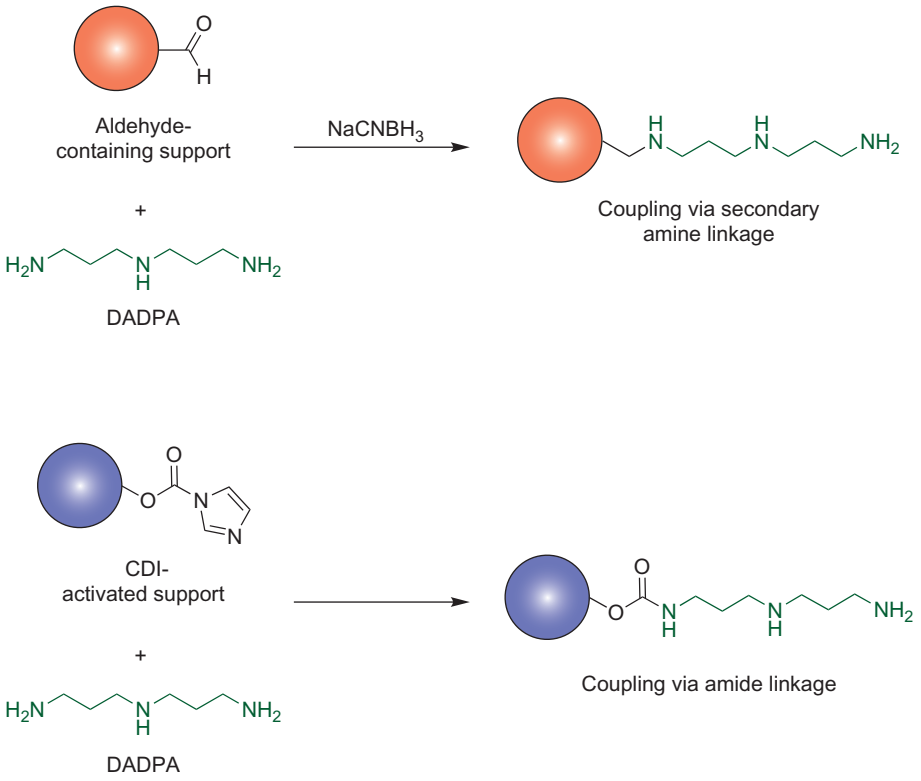

FIGURE 15.106 Coupling the diamine spacer DADPA to periodate-oxidized agarose and CDI-activated agarose.

hydrolysis reaction and maximize yields. DADPA reactions should be done with a large excess of diamine (at least 0.5-*M*) to limit the potential for crosslinking within the matrix and maximize the probability of only one end of each molecule reacting with the support.

Immobilized DADPA has been used to couple carboxylate-containing antigens using the carbodiimide EDC, which resulted in an affinity support for the purification of specific antibodies from immune serum (Tsai *et al.*, 1998). It has also been used as a precursor in the preparation of a maleimide-activated support by reacting the heterobifunctional crosslinker SMCC (Chapter 6, Section 1.3) with the amine on the support to yield a thiol-reactive derivative for the coupling of the rat GIP receptor epitope using a cysteine-terminal peptide. This affinity support was subsequently used to purify antibodies against the intact receptor protein (Lewis *et al.*, 2000). Shenouda *et al.* (2002) similarly used immobilized DADPA to couple a hapten peptide sequence (human urotensin-II) to the support using the EDC amide bond forming method, and the affinity support then was used to purify anti-urotensin-II antibodies from rabbit antiserum. In addition, Kost *et al.* (2011) used DADPA–agarose to couple the CNS-modulating compound clavulanic acid *via* its carboxylate using EDC and subsequently was able to isolate two proteins that specifically interacted with this ligand from neuronal cells.

PREPARATION OF A DADPA-MODIFIED SUPPORT

The following protocols represent two methods of coupling DADPA to amine-reactive supports. Analogous methods may be used with other short diamine spacers, such as ethylene diamine or 1,3-diamino-2-propanol. In the first method, a periodate-oxidized agarose support is used in a reductive amination procedure in aqueous solution (see previous section on immobilization by reductive amination, this chapter). In the second protocol, DADPA is coupled to a CDI-activated support in a nonaqueous solution to eliminate the hydrolysis reaction, which would occur with the reactive support in aqueous solution. Both of these methods yield supports containing spacer arms that terminate in free primary amines for further reactions. The CDI coupling procedure will give a higher density of amines on the support, but both work quite well for subsequent immobilization reactions. All operations should be carried out in a fume hood.

(A) Coupling DADPA to Periodate-Oxidized Agarose

1. Wash 100 ml of periodate-oxidized agarose (or another aldehyde-containing support) with water to remove storage solutions and then into coupling buffer (0.1-*M* sodium phosphate, pH 7.2). Washing steps may be performed with a sintered glass filter funnel suspended in a vacuum filter flask. Wash with at least several bed volumes for each wash step. Drain to a moist cake.
2. In the fume hood, add 20 g (21.3 ml) of DADPA to about 100 ml of crushed, deionized ice (use personal protective equipment to prevent contact with the highly caustic diamine and the acid used for neutralization). Slowly add 8 to 10 ml of concentrated HCl to the DADPA/ice slurry with manual stirring. Add the acid slowly using a pipette. As the acid is added, the solution will warm and the ice will melt. After the acid has been added, stir the solution using a magnetic stir bar and continue to neutralize the solution to about pH 7 with acid. Add to this solution a quantity of sodium phosphate buffer salt to make the final concentration 0.1-*M* phosphate when the total volume is diluted to 100 ml. Stir and readjust the pH to 7.2 using acid or base. The final solution is 1.52-*M* DADPA, 0.1-*M* sodium phosphate, pH 7.2. Allow the solution to come to room temperature before continuing.
3. Add the washed periodate-oxidized agarose to the DADPA solution and mix to resuspend the gel.
4. In the fume hood weigh out and add 0.63 g of sodium cyanoborohydride (toxic!) to the gel slurry and mix for 2 to 4 h. Mixing may be done using an overhead paddle stirrer (not a stir bar) or in a sealed plastic container by end-over-end rocking. Avoid the use of sealed glass containers, because there is some gas evolution during the reductive amination process.
5. Extensively wash the DADPA–agarose support with water, 1-*M* NaCl, and water to completely remove unreacted diamine and reaction byproducts. The support may be stored as a 50% slurry containing a preservative at 4°C until use.

(B) Coupling DADPA to CDI-Activated Supports

1. In a fume hood, dissolve 20 g of DADPA (21.3 ml) in 100 ml of dry acetone with stirring (makes a 1.52-*M* DADPA solution).
2. Drain 100 ml of a CDI-activated support prepared in acetone of excess solvent using filtration on a sintered glass filter.
3. Add the drained support as an acetone-wet cake to the DADPA solution with mixing to resuspend the gel.
4. Stir the reaction slurry for 2 to 3 h using an overhead paddle stirrer or in a sealed container by end-over-end rocking.
5. Wash the modified support with 1 l of acetone to completely remove excess diamine. Next, sequentially wash the support into water by using increasing concentrations of water in acetone (e.g., 30%, 60%, and 100%). Continue to wash with water to completely remove the last traces of acetone, and

then with 1-*M* NaCl, and again with water. The support may be stored as a 50% slurry containing a preservative at 4°C until use.

1,6-DIAMINOHEXANE

The aliphatic diamine spacer 1,6-diaminohexane (DAH; also called hexamethylenediamine) has been used in a variety of applications in organic synthesis, including the formation of spacer arms on chromatography supports. DAH consists of a linear six-carbon linker arm with a primary amine on each end, and it is a solid at room temperature (mp 42–45°C) with hygroscopic properties. The crystals of DAH should be white or off-white in color, but occasionally may have a yellow tint to them. These are typically all right to use without further purification; however, avoid highly colored material as they are likely to be oxidized or contaminated. Nearly one billion kilograms of DAH are produced annually as a key ingredient for several polymers. The use of DAH as a spacer arm for the preparation of affinity supports dates to the earliest research on matrix preparation (O'Carra and Barry, 1972).

Since DAH does not contain any other polar constituents in its cross-bridge, it is considerably more hydrophobic than DADPA, discussed previously. For this reason, spacer arms built from DAH on chromatography supports will create more hydrophobic character on the matrix surface, even after an affinity ligand is attached. This can have detrimental effects on the specific binding potential of an affinity support, because hydrophobic molecules in samples may bind through hydrophobic interactions and result in lower selectivity for capturing the desired target molecule. In some cases, however, DAH has been found to be optimal in creating affinity supports with certain ligands immobilized, such as the dye Cibacron Blue 3GA (Suen and Tsai, 2000). In addition, for some applications of immobilized metal affinity chromatography (IMAC) it was found that medium-length hydrophobic spacers created a support with the best binding characteristics toward penicillin G acylase (Liu *et al.*, 2005). Recent novel applications of immobilized ligands in the field of supported photosensitizers (SPS) indicate that even longer aliphatic spacer arms showed better efficiency than those with shorter chains (Pineiro *et al.*, 2010).

DAH has also been used as a type of affinity ligand in the isolation of human IgG from serum and plasma, which involved a one-step purification process using HEPES buffer at pH 6.8 (de Souza *et al.*, 2010). Bayramoglu *et al.* (2006) used DAH as a spacer on polymer beads containing epoxy groups to subsequently couple L-histidine as an affinity ligand for the purification of immunoglobulins.

DAH dissolved in aqueous solution is extremely caustic and should be handled with care. Upon dissolution, the pH should be adjusted to the recommended point for coupling the spacer to an amine-reactive support and maintained with the appropriate buffer. Neutralization should be carried out using HCl and cooled on ice, similar to the procedure outlined in the previous section on DADPA. Alternatively, the dihydrochloride form of DAH can be used, which does not affect the pH of an aqueous solution, nor does it require titration with acid for neutralization.

PREPARATION OF A DAH-MODIFIED SUPPORT The following protocol describes the coupling of DAH to a tresyl- or tosyl-activated support, prepared according to the procedures described previously in this chapter (Figure 15.107). Other amine-reactive supports may also be used, such as the activated supports and general procedures outlined in the section on the spacer DADPA.

1. In a fume hood, dissolve 15.28 g of DAH dihydrochloride in 100 ml of coupling buffer (0.2-*M* sodium phosphate, pH 7.5) and mix to dissolve. Adjust the pH back to 7.5 if necessary. Note: Alternatively, dissolve 10 g of DAH (as the free base) in a minimum quantity (~70 ml) of coupling buffer. Cool the solution in an ice bath. Slowly titrate the pH back down to 7.5 using concentrated HCl (caution: highly so use personal protective equipment!), while maintaining the solution cool to control the heat of the exothermic process. After the proper pH is reached, adjust the total solution volume to 100 ml by the addition of coupling buffer.
2. Drain 100 ml of a tresyl- or tosyl-activated support of acetone using a sintered glass filter suspended in a suction filter flask in a fume hood. Pull a gentle vacuum on the support and break up the matrix into small pieces using a spatula. Do not allow the support to dry. Remove the vacuum and add an equivalent bed volume of water and mix to resuspend the support. Continue to quickly wash the support with 3 bed volumes of water and 2 volumes of coupling buffer. Drain to a moist cake.
3. Mix the washed support with the DAH solution and mix to resuspend the gel.
4. If a tresyl-activated support was used to couple DAH, react with constant mixing for 2 to 4 h at room temperature. If a tosyl-activated support was used, the reaction should be continued overnight at room temperature to realize maximal coupling yields. Mixing may be performed using an overhead paddle stirrer or in a sealed container by end-over-end rocking.
5. Wash the support with coupling buffer, 1-*M* NaCl, and again with water to remove excess uncoupled DAH. The support may be stored as a 50% slurry containing a preservative at 4°C until use.

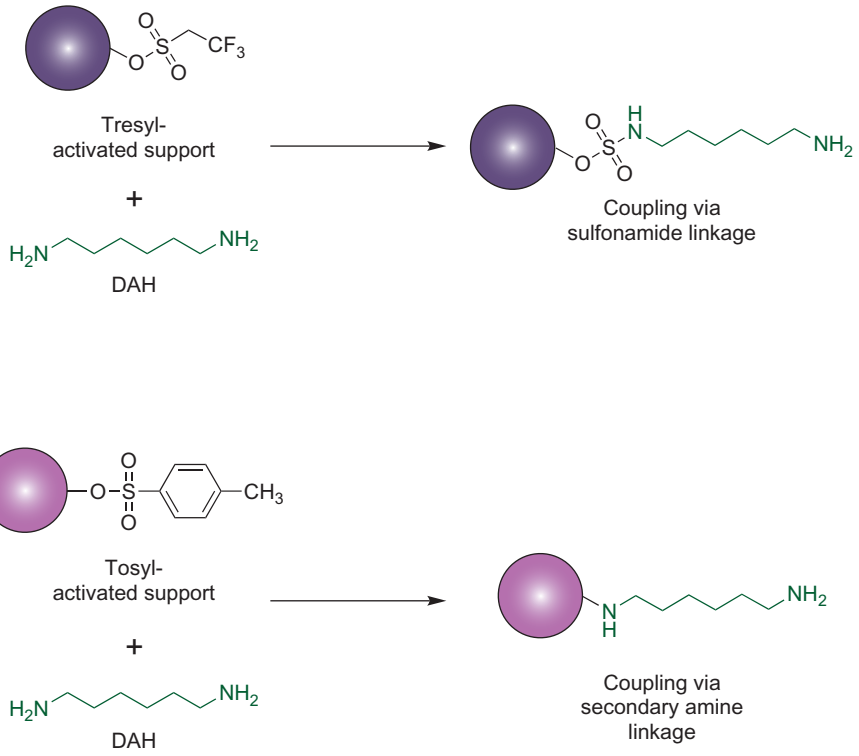

FIGURE 15.107 Coupling the diamine spacer DAH to tresyl- and tosyl-activated supports.

DIAMINE–PEG COMPOUNDS

Diamine spacers that contain a central PEG chain with amines on both ends are among the most hydrophilic bridges that can be created on a chromatography support. There are compounds available in this design that have a broad range of spacer arm lengths, from short PEG chains to those with high-molecular-weight long polymer chains. The discrete, short PEG compounds are useful for building amine functionality on a support while maintaining a hydrophilic and low nonspecific binding character on the base matrix. Longer PEG spacers might be chosen to further mask a more hydrophobic base support by developing a polyether coating that terminates in an amine. For the development of affinity supports for use with biomolecules, the choice of a diamine–PEG spacer may be an excellent starting point for high purity target molecule purification, as the spacer itself will not create hydrophobic or ionic interaction sites on the final support.

Diamine compounds containing a linear PEG bridge can be obtained from a number of sources. The shortest diamine–PEG spacers can be obtained from Aldrich [2,2′-(ethylenedioxy)*bis*(ethylamine)] or Huntsman (Jeffamine EDR-148) in the form of a PEG_2 length and having ethylamine groups on each end. This compound is available in bulk quantities from Huntsman (from 5-gallon pails to tank-car loads), and Aldrich offers it in 100-ml and 500-ml package sizes, which are more appropriate for small-scale affinity support production. This compound can easily be coupled to an amine-reactive support to yield a 10-atom spacer, which terminates in an amine. Another, slightly longer diamine–PEG compound is available from Aldrich that contains a PEG_3 bridge with propylamine groups on each end (4,7,10-Trioxa-1,13-tridecanediamine). This compound is still extremely hydrophilic and provides a 15-atom spacer once it is coupled with an amine-reactive support (Figure 15.108). Both the PEG_2 and PEG_3 diamine spacers need to be reacted in high molar excess to avoid the potential for both ends of the molecules reacting with the activated support and crosslinking within the matrix.

Longer PEG-based diamine spacers can be obtained from Huntsman with the additional incorporation of a propylene oxide-capped polyethylene glycol internal construct. For instance, the Jeffamine ED series (e.g., ED-600) (Figure 15.109) contains a core PEG_9 repeat with several propylene oxide groups at each end, which are terminally capped with a primary amine. The reagents are extremely hydrophilic and provide longer PEG-based spacers at relatively inexpensive price points. These are good choices if a longer spacer arm is needed to move an affinity ligand away from the base matrix to provide better accessibility for the docking of biomolecules.

Discrete diamine PEG–compounds are also available from Quanta Biodesign. Two of these spacers have

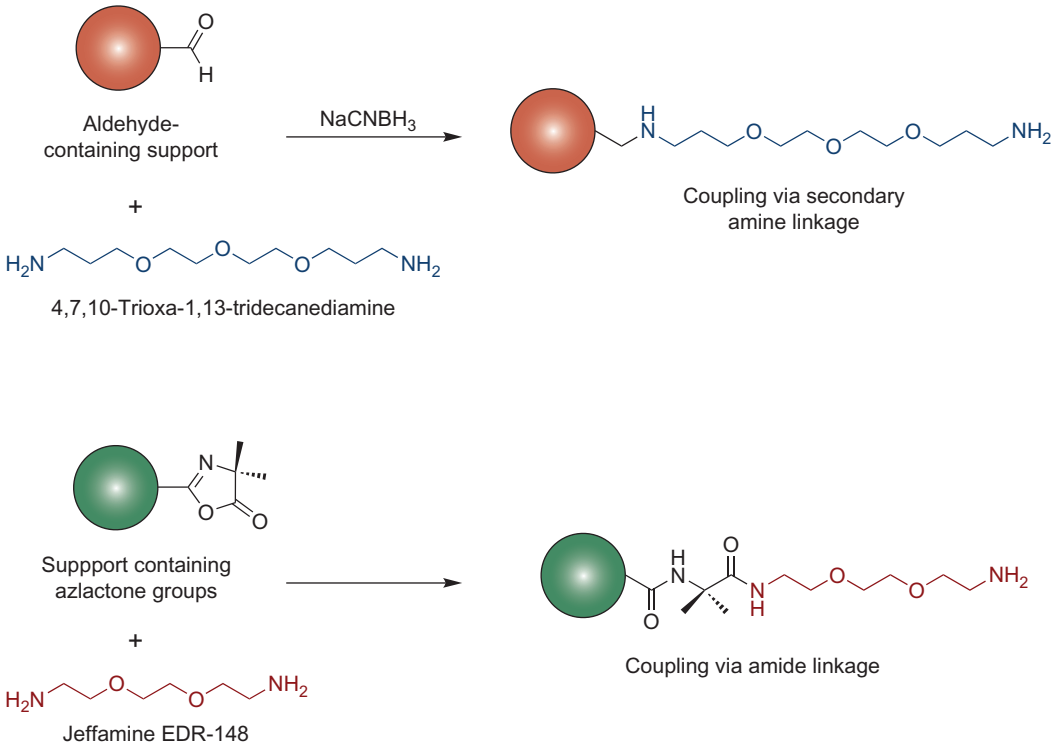

FIGURE 15.108 Coupling of Jeffamine EDR-148 or the diamine–PEG_3 compound to amine-reactive supports to yield terminal amine groups.

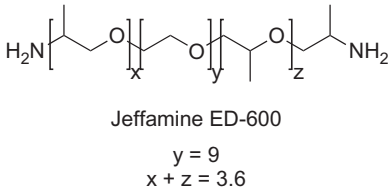

FIGURE 15.109 Jeffamine ED-600 structure.

one of their two amine groups protected to facilitate coupling to a support without the need to use a large molar excess to avoid crosslinking. Since only one amine will initially couple to the amine-reactive support the final density of amines on the matrix can be finely controlled to an optimal level for immobilizing whatever affinity ligand is desired. This avoids having a high density of amines on the support that could contribute to an ion-exchange character, especially if the excess amines are not blocked after coupling a ligand. The particularly long protected diamine–PEG reagent t-boc-*N*-amido–$dPEG_{11}$–amine contains a 37-atom cross-bridge that is extremely hydrophilic with a free amine on one end and a BOC-protected amine on the other end. The use of a protected diamine–PEG spacer does require a deprotection step after coupling to a support to free the protected amine for further modifications. The type of protecting agent used with these reagents is a *tert*-butyloxycarbonyl (BOC) group, which typically requires strongly acidic conditions (TFA; 30–90%) in a water-immiscible solvent (dichloromethane) for deprotection. Some supports may not be able to tolerate these conditions without some degradation and washing in and out of a water immiscible solvent is problematic. Some modifications to this standard scheme may work for aqueous phase deprotection. Heating to 60 to 100°C in a neutral pH water solution was found to be efficient in one study and may be viable for use with crosslinked chromatography supports (Wang *et al.*, 2009). In addition, a modified acidic deprotection method was investigated by Han *et al.* (2001) that demonstrated fast deprotection using 4-*N* HCl in anhydrous dioxane. This method uses acidic cleavage of the protecting group, but it does so in a water-miscible solvent, which makes operations using chromatography supports more amenable to washing in and out of an aqueous environment. Two examples of discrete diamine–PEG compounds are shown in Figure 15.110, both of which use the BOC protecting group. The coupling and deprotection reaction for the shorter compound is illustrated in Figure 15.111.

COUPLING A DIAMINE–PEG-BASED SPACER The following protocols describe the use of diamine–PEG-based spacers to modify amine-reactive supports for additional reactions or for the coupling of

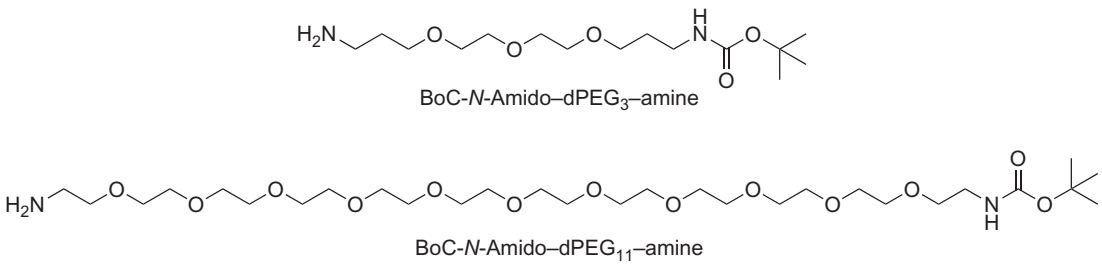

FIGURE 15.110 Diamine–PEG$_n$ compounds with one end blocked by a BOC group.

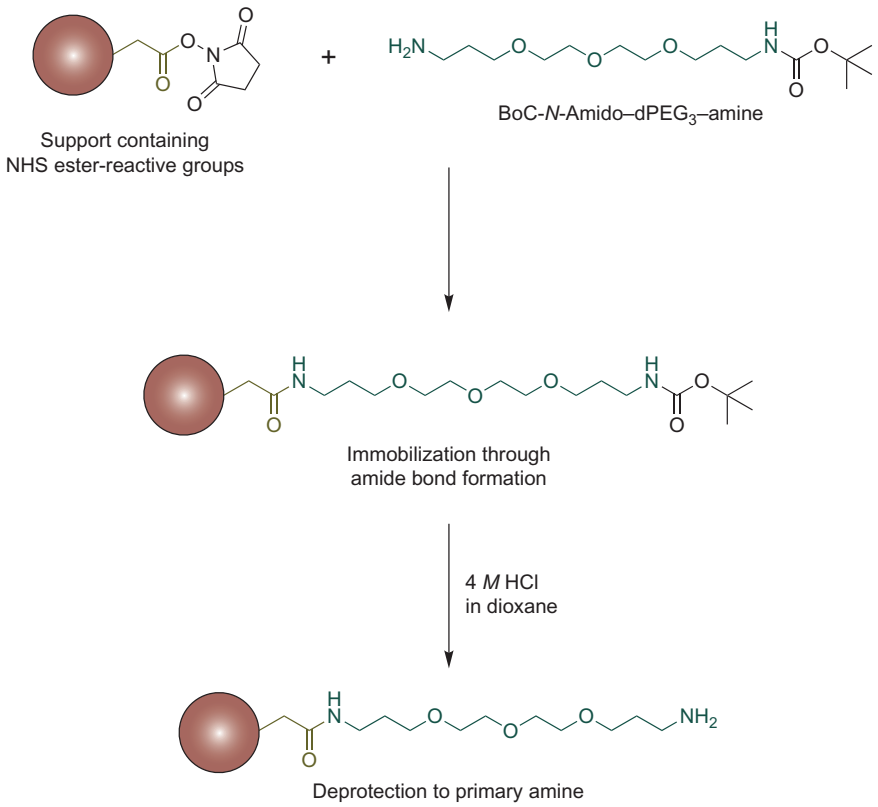

FIGURE 15.111 Coupling of a BOC-protected diamine–PEG compound to an amine-reactive support with subsequent deprotection with 4-*M* HCl in dioxane or heating to 60 to 100°C.

a carboxylate-containing ligand. The first procedure makes use of 4,7,10-Trioxa-1,13-tridecanediamine as the free amine (not protected and not as the dihydrochloride salt) in the modification of an aldehyde-containing support using reductive amination (see discussion on reductive amination, this chapter). The second protocol makes use of a discrete diamine–PEG compound that has one end protected with a BOC group.

(A) Coupling of 4,7,10-Trioxa-1,13-tridecanediamine to Periodate-Oxidized Agarose

1. Wash 100 ml of periodate-oxidized agarose (or another aldehyde-containing support) with water to remove storage solutions and then into coupling buffer (0.1-*M* sodium phosphate, pH 7.2). Washing steps may be performed with a sintered glass filter funnel suspended in a vacuum filter flask. Wash with at least several bed volumes for each wash step. Drain to a moist cake.
2. In the fume hood, add 33.5 g (33.4 ml) of 4,7,10-trioxa-1,13-tridecanediamine (Aldrich) to about 100 ml of crushed, deionized ice (use personal protective equipment to prevent contact with the highly caustic diamine and the acid used for neutralization). Slowly add 8 to 10 ml of concentrated HCl to the diamine/ice slurry with manual stirring. Add the acid slowly using a pipette. As the acid is added, the solution will warm and the ice will melt. After the acid has

been added, stir the solution using a magnetic stir bar and continue to neutralize the solution to about pH 7 with acid. Add to this solution a quantity of sodium phosphate buffer salt to make the final concentration 0.1-*M* phosphate when the total volume is diluted to 100 ml. Stir and readjust the pH to 7.2 using acid or base. The final solution is 1.52-*M* diamine, 0.1-*M* sodium phosphate, pH 7.2. Allow the solution to come to room temperature before continuing.

3. Add the washed periodate-oxidized agarose to the diamine solution and mix to resuspend the gel.
4. Add 0.63 g of sodium cyanoborohydride (toxic!) to the gel slurry and mix for 2 to 4 h. Mixing may be carried out using an overhead paddle stirrer (not a stir bar) or in a sealed plastic container by end-over-end rocking. Avoid the use of sealed glass containers, because there is some gas evolution during the reductive amination process.
5. Extensively wash the diamine-agarose support with water, 1-*M* NaCl, and water to completely remove unreacted diamine and reaction byproducts. The support may be stored as a 50% slurry containing a preservative at 4°C until use.

(B) Coupling of a BOC–Amido–PEG–Amine Spacer to CDI-Activated Supports

The following protocol may be used to couple a *bis*-amino–PEG_n compound that has one amino end blocked with a BOC protecting group. The support material used in this procedure must be able to withstand the deprotection conditions for removing the BOC group using formic acid in solvent. Small samples of a given support should be tested for stability in a formic acid/DMAC solution before proceeding to use this procedure. Many crosslinked or polymeric supports should be able to tolerate the deprotection step without difficulty.

1. In a fume hood, drain 10 ml of A CDI-activated support of excess acetone using a sintered glass filter funnel suspended in a suction filter flask (see Carbonyl Diimidazole (CDI) Activation in Section 2.1, this chapter). While pulling a gentle vacuum to remove the remaining excess acetone, break the support up into small pieces so that it resembles fluffy snow. Do not allow the support to dry. Remove the vacuum and resuspend the matrix in dry DMAC with mixing. Wash with DMAC to remove the last traces of acetone (at least 10 bed volumes). Drain to a moist cake.
2. Dissolve the blocked diamine compound BOC-*N*–amido–$dPEG_{11}$–amine (Quanta Biodesign) in 10 ml of DMAC at a concentration of 12.8 mg/ml, which will equal a level of 20 µmol/ml gel in the reaction medium. Control of the final density of amines on the support can be accomplished by adjusting the reaction concentration of the spacer. The optimal concentration of spacer to be used in the coupling reaction should be determined experimentally on small quantities of activated support to identify the best final affinity support performance in its intended application. Add an organic base to the ligand solution, such as DMAP, DIEA, or TEA, to make a final concentration of 2-m*M*.
3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for 1 to 2 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. Longer reaction times may be used if appropriate.
4. Excess CDI reactive groups on the support may be blocked by the addition of ethanolamine to the reaction slurry at a final concentration of 0.1-*M*. Continue to mix for 1 h at room temperature.
5. Transfer the gel slurry to a sintered glass filter in the fume hood that is suspended in a suction filter flask and wash extensively (at least 10 bed volumes) with solvent to remove the remaining ligand and reaction byproducts. Finally, drain the support of excess solvent by pulling a gentle vacuum on the filter flask while breaking up the support into small, finely divided pieces using a spatula, but be careful not to allow the matrix to dry out. Once the support is broken into small pieces, remove the vacuum and resuspend the gel in neat formic acid with mixing (caution: highly corrosive; use a fume hood and personal protective equipment to avoid contact or inhalation of vapors). Stir for 1 h at room temperature.
6. Wash the support with 2 bed volumes of formic acid and then wash extensively with DMAC to completely remove all traces of remaining acid. Once the acid has been thoroughly removed, the support should be washed into water by sequential washes using increasing concentrations of water in DMAC until 100% water is attained. Continue to wash the support with water until all traces of solvent have been removed. Additional washes with 1-*M* NaCl as well as low and high pH conditions may be done as appropriate. Finally, wash with water and store the amine-containing support as a 50% slurry in water containing a preservative at 4°C until used.

AMINO–CARBOXYLATE SPACERS

Spacer arms containing an amine group on one end and a carboxylic acid group on the other end are popular choices for building many affinity supports. This type of spacer is typically used to modify a support to contain a terminal carboxylate for further coupling to amine-containing molecules. The spacer's cross-bridge

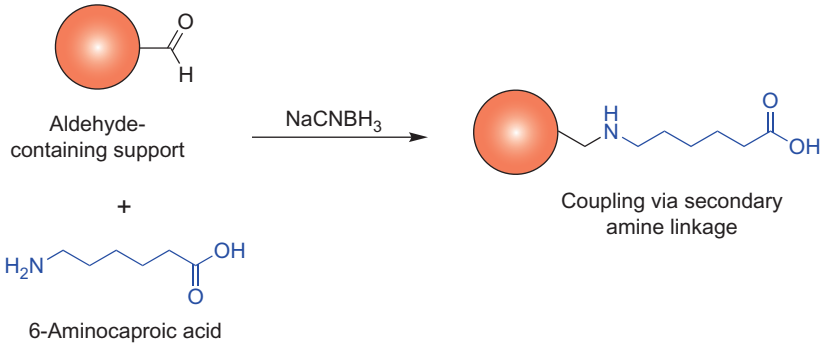

FIGURE 15.112 Coupling of 6-aminocaproic acid to an aldehyde-containing support via reductive amination.

can be designed to possess additional properties that may be beneficial to the final affinity support being created. For instance, short or long spacers can be chosen to modify the support, depending on the total length desired to tether a ligand away from the matrix surface. In addition, the spacer cross-bridge can be designed to be relatively hydrophobic (aliphatic) or hydrophilic (typically hetero-aliphatic construction).

The shortest amino–carboxylate spacer is β-alanine, which contains two central methylene groups with an amine on one end and a carboxylic acid group on the other end (3-aminopropanoic acid). This short spacer is used often in the design of modification and cross-linking agents, and it also can be used as a spacer on chromatography supports to provide a terminal carboxylate for subsequent coupling reactions. β-Alanine is extremely water soluble and will not contribute any hydrophobicity to a support, which may occur with a longer aliphatic cross-bridge; however, the molecule also is quite short, which means it cannot be used to extend a ligand out from the matrix to facilitate greater binding accessibility for a target molecule. It is mainly used just to form a carboxylate on the support for further modification reactions or for facilitating ligand immobilization.

One of the most common, medium length, aliphatic amino–carboxylate spacers is 6-aminocaproic acid, which contains a six-atom methylene cross-bridge between the two functional groups. This compound has been widely used to modify amine-reactive supports to contain carboxylates for further immobilization of an amine-containing ligand. Usually, the use of a spacer is done to move the ligand away from the matrix to allow efficient docking of target molecules to bind with the ligand. For instance, Bansal *et al.* (2006) coupled *p*-aminobenzamidine by its amine to a monolithic cryogel containing aminocaproic acid spacers and used the resultant affinity support to isolate urokinase from cell culture broth of human kidney cells. The hydrophobic nature of the cross-bridge in 6-aminocaproic acid can provide some enhancement of binding toward certain target molecules, depending on the circumstances of the interaction. The spacer has found use in other areas of bioconjugation as well, including its incorporation into the very popular biotinylation reagent, NHS–LC-biotin (see Chapter 11, Section 6.2). The 6-aminocaproic acid spacer has also been used to modify a matrix to create an NHS ester, amine-reactive support by forming the active ester on the terminal carboxylate after the spacer has been attached (Wilchek and Miron, 1987).

The spacer 6-aminocaproic acid is an inexpensive compound that has very good water solubility (50 mg/ml). It can be dissolved in aqueous buffers without significantly effecting the pH of the solution (unlike the diamine compounds described previously). The compound is an analog to the amino acid lysine and has antifibrinolytic properties *in vivo* by inhibiting plasminogen. The coupling of 6-aminocaproic acid to an aldehyde-containing support using reductive amination is illustrated in Figure 15.112. Other amine-reactive supports can be used in a similar process to create a carboxylate-terminal spacer.

COUPLING 6-AMINOCAPROIC ACID TO AN AMINE-REACTIVE SUPPORT The following protocol describes the modification of an aldehyde-containing support, such as periodate-oxidized agarose (see earlier section, this chapter) with 6-aminocaproic acid to provide a carboxylate derivative for subsequent immobilization of amine-containing ligands. The subsequent immobilization of an affinity ligand to form an amide bond may be performed using the methods previously described in this chapter, such as a carbodiimide-mediated coupling reaction (using EDC) or through NHS ester formation.

1. Wash 100 ml of periodate-oxidized agarose (or another aldehyde-containing support) with water to remove storage solutions and then into coupling buffer (0.1-*M* sodium phosphate, pH 7.2). Washing steps may be performed with a sintered glass filter

funnel suspended in a vacuum filter flask. Wash with at least several bed volumes for each wash step. Drain to a moist cake.

2. In the fume hood, add 10 g of 6-aminocaproic acid (Acros, Aldrich) to 100 ml of coupling buffer. Stir the solution to dissolve and readjust the pH to 7.2 using acid or base, if necessary. The final solution is 0.76-*M* aminocaproic acid, 0.1-*M* sodium phosphate, pH 7.2. Lower concentrations of 6-aminocaproic acid may be used for this reaction to create a lower density of carboxylates on the surface of the support. Some experimentation may have to be carried out to determine the optimal level of carboxylates for the intended affinity chromatography application.
3. Add the washed periodate-oxidized agarose to the aminocaproic acid solution and mix to resuspend the gel.
4. In a fume hood, add 0.63 g of sodium cyanoborohydride (toxic!) to the gel slurry and mix for 2–4 h. Mixing may be performed using an overhead paddle stirrer (not a stir bar) or in a sealed plastic container by end-over-end rocking. Avoid the use of sealed glass containers, because there is some gas evolution during the reductive amination process.
5. Extensively wash the aminocaproic acid-agarose support with water, 1-*M* NaCl, and water to completely remove unreacted reagent and reaction byproducts. The support may be stored as a 50% slurry containing a preservative at 4°C until use.

AMINO–PEG$_n$–CARBOXYLATE SPACERS

A version of an amine-carboxylate spacer that has a PEG-based cross-bridge is available that makes the linker extremely hydrophilic (Thermo Fisher, Quanta Biodesign). These spacers are particularly advantageous for creating support derivatives that have very low nonspecific binding character, unlike aliphatic spacers that may increase the nonspecificity of a support. PEG-based spacers can also increase the freedom of motion of tethered affinity ligands, thus making them more likely to be able to interact with a target molecule. A series of amino–PEG$_n$–carboxylate compounds are available depending on the spacer need, ranging from PEG$_4$ to PEG$_{36}$ in cross-bridge length (Quanta). The shortest is an amino–PEG$_4$–carboxylate that has a 16 atom spacer about 18 Å in length. A longer length amino–PEG$_8$–carboxylate compound has a 33.6-Å spacer and the amino–PEG$_{12}$–carboxylate reagent contains a 46.8-Å tether. The longest compound in this series has an internal PEG$_{36}$ chain with a linear cross-bridge of 132.7 Å, making it perhaps the longest discrete spacer available for modification of chromatography supports. The largest spacer arm is actually longer than the average diameter of a typical IgG antibody molecule (~110 Å), which ensures that any affinity ligand tethered at the end of it will be accessible to virtually any docking protein or biomolecule that may bind to it (Figure 15.113).

Amino–PEG$_n$–carboxylate spacers can be reacted with an amine-reactive support to give a covalent linkage forming an amide or secondary amine bond with the surface. The terminal carboxylate then can be used to build another reactive group for subsequent coupling of an affinity ligand, such as in the creation of an NHS ester or a hydrazide group (see previous sections, this chapter). The carboxylate may also be used to directly immobilize an amine-containing molecule through the use of a carbodiimide-mediated reaction sequence, which ultimately will form an amide bond with the ligand (see previous section, this chapter, on EDC coupling). A possible reaction sequence using these spacers is illustrated in Figure 15.114. The use of these long PEG spacer molecules will create an extremely hydrophilic layer on any solid-phase surface, which will lower nonspecific binding character and maximize the purity of any target molecule captured.

Any of the amine-reactive immobilization methods described previously in this chapter can be used to couple an amino–PEG$_n$–carboxylate spacer to a support. In the following protocol examples, first a DSC-activated hydroxylic support is used in nonaqueous solvent to couple the amino–PEG$_n$–carboxylate spacer to form an amide bond and in the second example a periodate-oxidized agarose support containing aldehyde groups is used to couple the spacer using reductive amination to form a secondary amine bond. Other reactive supports may be used by following the recommended coupling protocols found in previous sections.

COUPLING AMINO–PEG$_n$–CARBOXYLATE SPACERS

(A) Coupling Amino–PEG$_8$–Carboxylate to a DSC-Activated Hydroxyl-Support

1. In a fume hood, drain 10 ml of A DSC-activated support of excess acetone using a sintered glass filter funnel suspended in a suction filter flask. While pulling a gentle vacuum to remove the remaining excess acetone, break the support up into small pieces so that it resembles fluffy snow. Do not allow the support to dry. Remove the vacuum and resuspend the matrix in dry DMAC with mixing. Wash with DMAC to remove the last traces of acetone (at least 10 bed volumes). Drain to a moist cake.
2. Dissolve the amino-PEG$_8$-carboxylate spacer compound (Quanta BioDesign or Thermo Fisher) in 10 ml of DMAC at a concentration of 8.83 mg/ml, which translates into a level of 20 µmol/ml gel in the reaction medium. Control of the final density of amines on the support can be accomplished by adjusting the reaction concentration of the

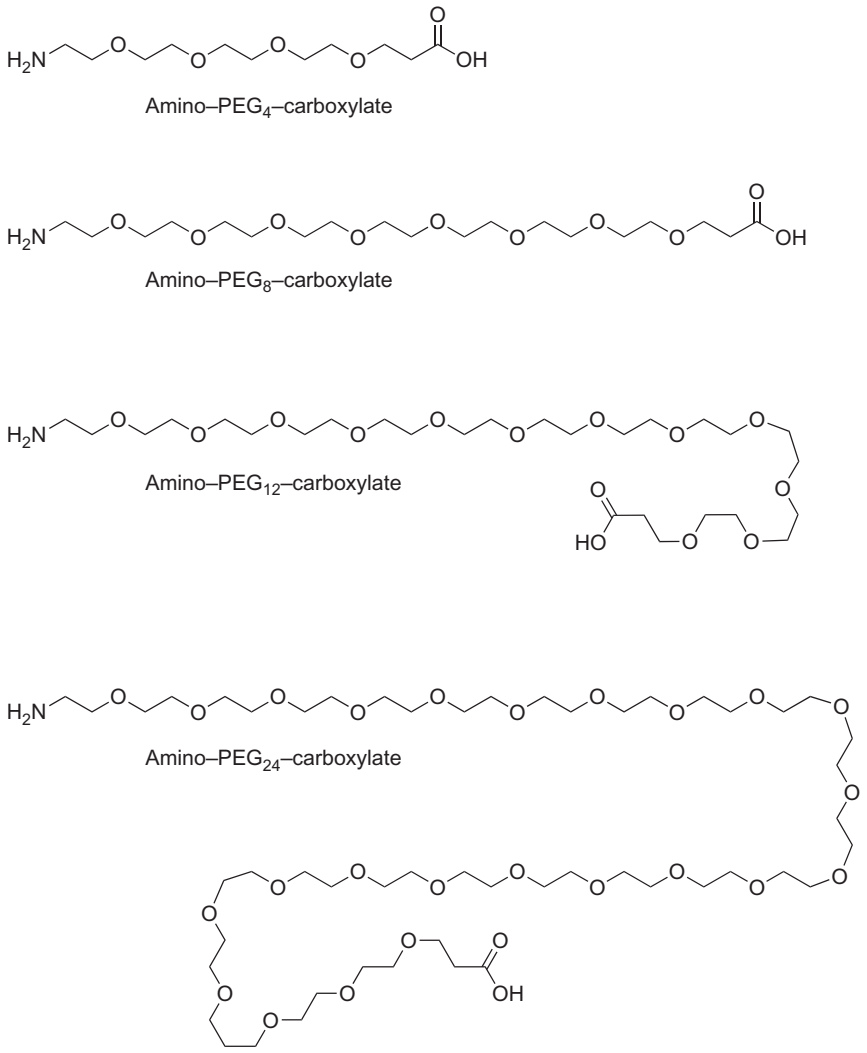

FIGURE 15.113 Examples of amino–PEG$_n$–carboxylate spacers.

spacer. The optimal concentration of spacer to be used in the coupling reaction should be determined experimentally on small quantities of activated support to identify the best final affinity support performance in its intended application. Add an organic base to the ligand solution, such as DMAP, DIEA, or TEA, to make a final concentration of 2-m*M*.

3. Add the activated wet gel cake to the ligand solution with stirring to fully resuspend the gel. Mix the reaction slurry for 1 h using an overhead paddle stirrer or by end-over-end rocking in a sealed container. Longer reaction times may be done if appropriate.
4. Excess NHS carbonate reactive groups on the support may be blocked by the addition of ethanolamine to the reaction slurry at a final concentration of 0.1-*M*. Continue to mix for 1 h at room temperature.
5. In the fume hood, transfer the gel slurry to a sintered glass filter that is suspended in a suction filter flask and wash extensively (at least 10 bed volumes) with solvent to remove the remaining ligand and reaction byproducts. Finally, drain the support of excess solvent by pulling a gentle vacuum on the filter flask while breaking up the support into small, finely divided pieces using a spatula, but be careful not to allow the matrix to dry out. Once the support is divided into small pieces, remove the vacuum and resuspend the gel in water with mixing. Continue to wash the support with water until all traces of solvent have been removed. Additional washes with 1-*M* NaCl as well as low and high pH conditions may be done as appropriate. Finally, wash with water and store the carboxylate-containing support as a 50% slurry in water containing a preservative at 4°C until used.

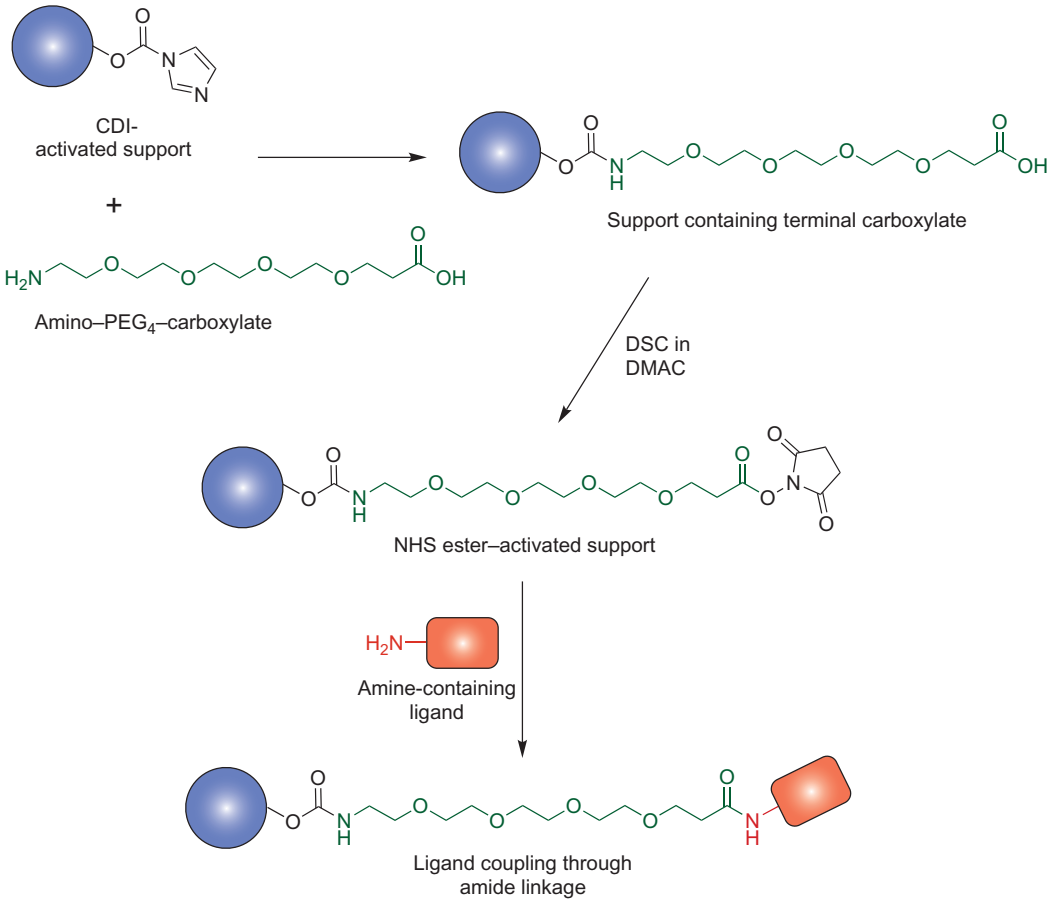

FIGURE 15.114 Coupling of an amino–PEG$_n$–carboxylate to an amine-reactive support followed by NHS ester formation and the immobilization of an amine-containing ligand.

(B) Coupling Amino–PEG$_8$–Carboxylate to a Periodate-Oxidized Agarose Support

1. Wash 10 ml of periodate-oxidized agarose (or another aldehyde-containing support, such as a glycidol/periodate-treated polymeric support) with water to remove storage solutions and then into coupling buffer (0.1-*M* sodium phosphate, pH 7.2). The washing steps may be done with a sintered glass filter funnel suspended in a vacuum filter flask. Wash with at least several bed volumes for each wash step. Drain to a moist cake.
2. In the fume hood, add 176 mg of amino–PEG$_8$–carboxylate spacer compound (Quanta BioDesign or Thermo Fisher) to 10 ml of coupling buffer. Stir the solution to dissolve and readjust the pH to 7.2 using acid or base, if necessary. The final solution is at a concentration of 40 µmol/ml of the spacer in 0.1-*M* sodium phosphate, pH 7.2. Higher or lower concentrations of amino–PEG$_8$–carboxylate may be used for this reaction to create custom densities of carboxylates on the surface of the support. Some experimentation may have to be done to determine the optimal level of carboxylates for the intended affinity chromatography application.
3. Add the washed periodate-oxidized agarose to the amino–PEG$_8$–carboxylate solution and mix to resuspend the gel.
4. Add 63 mg of sodium cyanoborohydride (toxic!) to the gel slurry and mix for 2 to 4 h. Mixing may be performed using an overhead paddle stirrer (not a stir bar) or in a sealed plastic container by end-over-end rocking. Avoid the use of sealed glass containers, because there is some gas evolution during the reductive amination process.
5. Extensively wash the carboxylate-agarose support with water, 1-*M* NaCl, and water to completely remove unreacted reagent and reaction byproducts. The support may be stored as a 50% slurry containing a preservative at 4°C until use.

BIS-CARBOXYLATE SPACERS

bis-Carboxylate spacer compounds are useful in extending an amine-containing support and converting the amine to a terminal carboxylate for further coupling

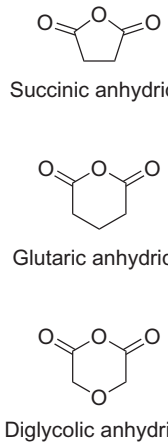

FIGURE 15.115 The structures of common anhydride compounds used to create terminal carboxylate groups on amine-containing supports.

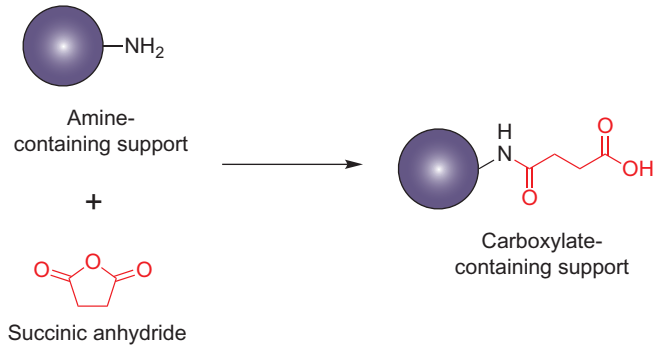

FIGURE 15.116 Reaction of succinic anhydride with an amine-containing support.

or immobilization reactions. Most often, a *bis*-carboxylate spacer is added to a support through reaction of its corresponding cyclic anhydride with the amino groups on a matrix to create amide bond linkages. Ring opening of the anhydride forms the short spacer group as the other carboxylate is freed at the uncoupled end. Several anhydride compounds are commonly used to form these spacers on supports (Figure 15.115). Succinic anhydride is the shortest of these spacers, containing a 4-carbon ring structure, which when reacted with an amine-containing support provides a 2-atom methylene bridge between the two terminal carboxylates. Glutaric anhydride is a 5-carbon compound that when opened results in a 3-atom methylene bridge between the two terminal carboxylates. Diglycolic anhydride is the most hydrophilic in this series, which after ring opening contains a 5-atom spacer between the two terminal carboxylate groups and also has a central ether group, which adds water solubility to the compound. All three anhydride compounds may be used in similar reaction schemes to modify an amine-containing support to contain terminal carboxylates. The reaction of succinic anhydride with an amine-containing support is illustrated in Figure 15.116.

The following protocol describes the modification of an amine-containing support with succinic anhydride to form a carboxylate-containing support for further ligand immobilization reactions. The other anhydride compounds may be used similarly.

Coupling Succinic Anhydride to Amine-Containing Supports

1. Wash 100 ml of an amine-containing support with water to remove storage solutions and then wash with several bed volumes of reaction buffer (1.0-*M* sodium bicarbonate, pH 8.0). Finally, suspend the support in an equal volume of reaction buffer. Other reaction buffers and pH conditions may be used over the range of about pH 6 to pH 9 with success. Some protocols just use water, but maintain the pH at the desired value with periodic titration with base (NaOH at 50%).
2. Stir the gel slurry using an overhead paddle stirrer and slowly add 10 g of succinic anhydride. Initially, the anhydride will not be fully soluble in the reaction mixture, but it will go into solution as it reacts and hydrolyzes in the buffered solution.
3. React with constant stirring for 1 h at room temperature.
4. Wash the succinylated support with reaction buffer, water, 1-*M* NaCl, and again with water to completely remove unreacted succinic anhydride or succinic acid. The carboxylic acid-containing support may be stored as a 50% slurry containing a preservative at 4°C until use.

Other anhydride compounds may be used in a similar reaction protocol with success; however, adjust the mole quantity of anhydride addition to be equivalent to the succinic anhydride protocol.

THIOL–CARBOXYLATE SPACERS

Spacer arms containing a thiol group on one end and a carboxylate group on the other end have been used extensively for some applications involving immobilized affinity ligands. Most of these applications have involved the use of a solid phase that contains a metallic surface, either planar or particulate in nature. In this case, the thiol end of the spacer is usually coupled to the metal by way of a dative bond, wherein the unshared pair of electrons on the sulfur atom are shared with the metal. The application of these spacers to modify metallic microparticles or nanoparticles is described in Chapter 14. Although chromatography supports typically do not use metallic solid phases, in certain instances it may be advantageous to use a thiol–carboxylate spacer to

modify an amine-containing matrix with the carboxylate end, and thus create a thiol group on a support for subsequent immobilization of thiol-containing ligands. Terminal thiols created in this manner on a support can be activated to couple ligands through disulfide bonds, which then can be reversed to subsequently release interacting molecules (see previous section on thiol-reactive immobilization methods, this chapter). Of course, it also is possible to use a thiol–carboxylate spacer to modify a thiol-reactive support to create a terminal carboxylate, but this probably is less frequently done than coupling the spacer in the reverse way.

A number of thiol–carboxylate spacer arms are available to modify a support, including molecules that contain aliphatic cross-bridges as well as the more hydrophilic PEG-based linkers. The shortest thiol–carboxylate spacer is thioglycolic acid, which is 2-mercaptoacetic acid (note that this compound is not thioacetic acid, which is the acetylated thiol in a thioester form). An analog to thioglycolic acid is SATA (Chapter 2, Section 4.1), which has a protected thiol at one end and an NHS ester at the other end of the acetate bridge. SATA, or the similar compound SATP which is one carbon atom longer, can provide rapid modification of an amine-containing support to convert it to a protected thiol-containing support. The NHS ester end will react with the amines on the support to result in an amide bond, and the protected thiol end is stable in this form until needed for immobilization of ligands. The thiol can be deprotected with hydroxylamine under alkaline conditions to reveal the thiol. These short compounds can be useful if an amine-containing support already has a long spacer arm present and all that is desired is to convert a terminal amine into a thiol group.

There also are longer thiol–carboxylate spacers available to form tethers of greater length on supports for the coupling of affinity ligands. Both hydrophobic, aliphatic spacer molecules can be used as well as hydrophilic, PEG-based spacers. A PEG-containing spacer will provide greater hydrophilicity within the support and have a tendency to decrease the nonspecific binding potential of biomolecules. There is a wide selection of different spacer lengths available for these compounds with PEG groups ranging from PEG_4 to PEG_{20} in size (Quanta BioDesign, Thermo Fisher). However, the use of a thiol-carboxylate spacer without having the thiol group protected can be problematic. The reactions that have to occur to couple the carboxylate end to an amine-containing support are unfortunately interfered with by the thiol end. If an active ester is formed on the carboxylate to couple with the amines on the support without protecting the thiol, then the ester can potentially react with the thiol groups to form thioester bonds, causing polymerization of the reagent in solution. In addition, if the carbodiimide EDC is used to attach the carboxylate to the amino groups, then EDC can also react with the thiol end to form an irreversible complex. Fortunately, thiol-protected versions of these reagents are available that allow these reactions to occur without interference. These compounds are SATA-like in structure, having an NHS ester on one end and a protected (acetylated) thiol on the other end, but with the added feature of containing an internal PEG cross-bridge to provide increased hydrophilicity over that of the aliphatic reagent. Figure 15.117 illustrates the major thiol-carboxylate reagents available for use as spacers in chromatography supports and Figure 15.118 shows the reactions involved with coupling one of these reagents to an amine-containing support.

Coupling NHS–PEG_4–Thioacetyl to an Amine-Containing Support

The following protocol describes the use of a NHS–PEG_4–thioacetyl compound in the modification of an amine-containing support to provide an alteration that terminates in a protected thiol group. The reagents $SAT(PEG)_4$ from Thermo and $dPEG_4$-SATA from Quanta BioDesign are identical structurally and can be used in this method with success. This method describes the reaction of the NHS ester end with the amine groups on the support in a nonaqueous environment to eliminate the hydrolysis of the ester during coupling. All operations with solvent should be performed in a fume hood using the appropriate personal protective equipment. The reaction may also be carried out in an aqueous buffer (e.g., 0.1-*M* sodium phosphate, pH 7.2), but the amount of reagent added may have to be increased to account for some yield loss due to hydrolysis. The optimal density of protected thiols on the support should be investigated experimentally by assessing the performance of the ultimate affinity support in the intended application. Adjusting the concentration of the reagent in the reaction will control the density of the protected thiols after the reaction is complete, and so will adjusting the initial concentration or density of amines on the support.

1. Wash 10 ml of an amine-containing support with water to remove storage solution and preservatives. Then wash the support into DMAC by washing with sequentially increasing concentrations of solvent-in-water until 100% DMAC is used. Continue to wash with DMAC for at least 10 to 20 bed volumes to completely remove the last traces of water. Drain the support to a wet cake, but do not allow it to dry.
2. Dissolve 421 mg of the NHS–PEG_4–thioacetyl compound in 10 ml of DMAC. This will result in 100 µmoles of reagent per milliliter of amine-containing gel within the reaction mixture.
3. Add the washed gel to the reagent solution with mixing to resuspend the matrix. An organic base

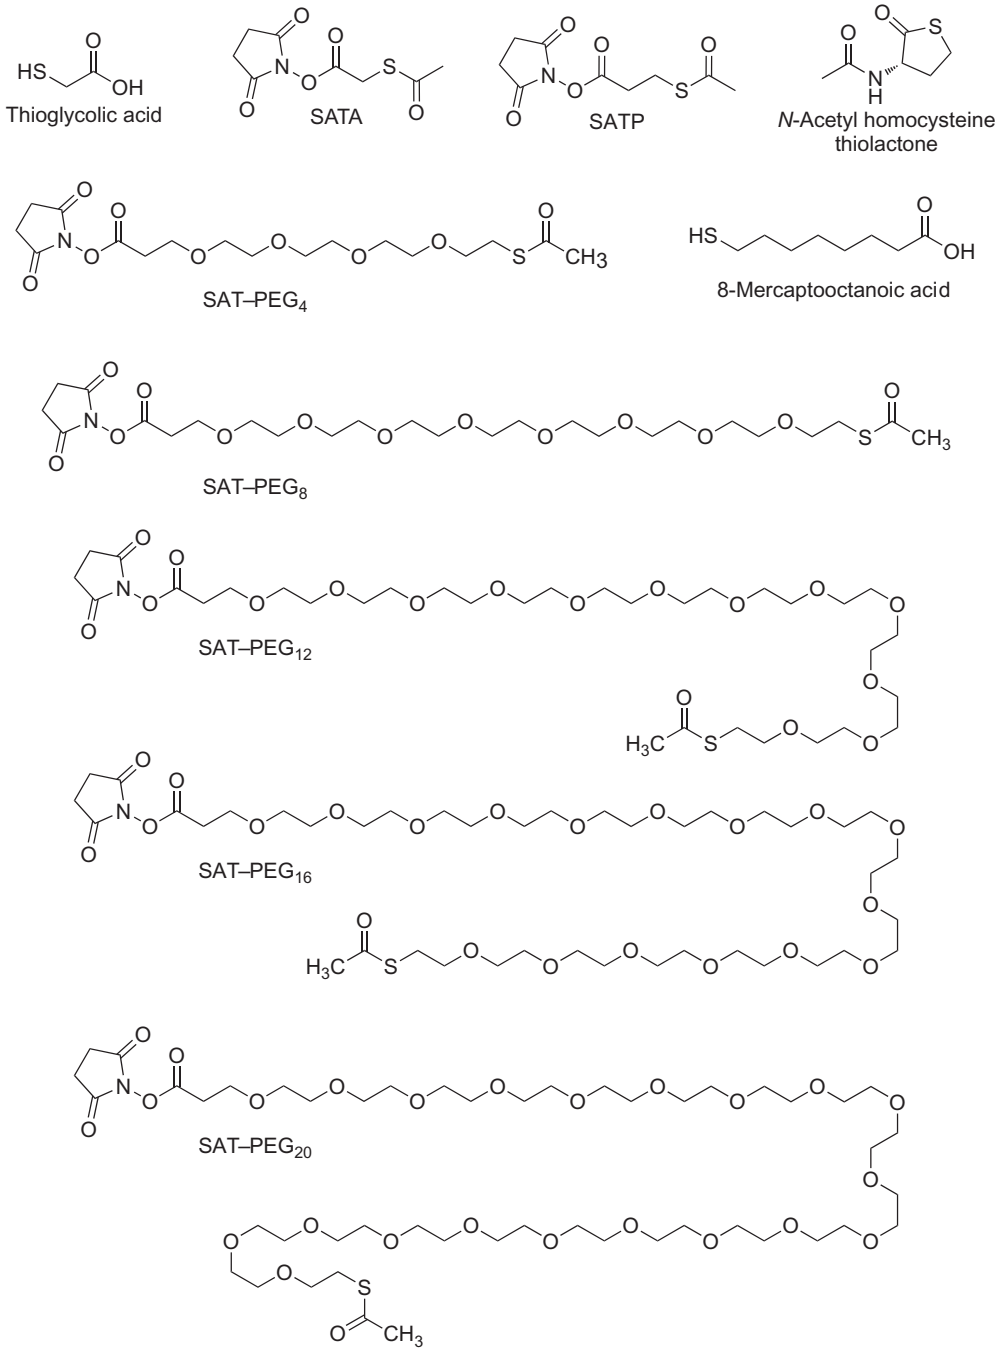

FIGURE 15.117 Thiol–carboxylate reagents for spacer arm applications.

may be added to the mixture to accelerate the reaction, such as DMAP, DIEA, or TEA, to make a final concentration of 2-m*M*. React for 1 h at room temperature with constant mixing. The mixing may be accomplished by use of a paddle and overhead stir motor or by end-over-end rocking in a sealed container.

4. Wash the support with DMAC to remove excess reagent (at least 10 column volumes) and then wash sequentially back into water by using increasing concentrations of water-in-solvent until 100% water is used. Continue to wash with water for 10 to 20 bed volumes to completely remove the solvent. The protected thiol-containing support may be stored at 4°C as a 50% slurry containing a preservative until use. As needed, the gel can be treated to deprotect the thiol groups prior to immobilizing a ligand or doing further reactions.

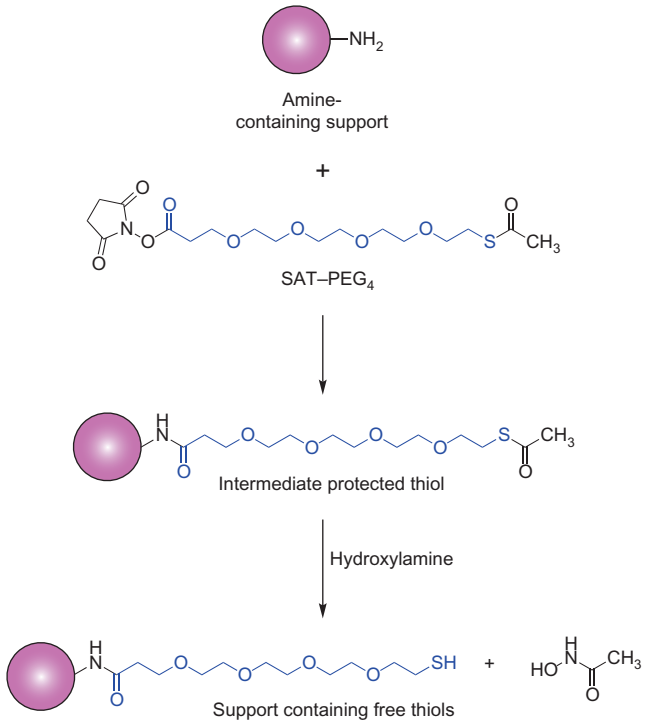

FIGURE 15.118 Coupling of a NHS–PEG$_n$–thioacetyl reagent to an amine-containing support with subsequent deprotection of the thiol using hydroxylamine.

Deprotection of the Thioacetyl-Containing Support

1. Prepare 20 ml (or 2 times the amount of protected thiol-containing resin to deprotect) of an aqueous solution containing 0.5-*M* hydroxylamine in 0.1-*M* sodium phosphate, pH 7.2, containing 25-m*M* EDTA.
2. Wash 10 ml of the protected thiol resin with several bed volumes of water to remove storage solution and then slowly wash with 10 ml of the hydroxylamine solution. Drain to a wet cake.
3. Add the washed support to the remaining 10 ml of hydroxylamine solution and mix to resuspend the gel. React for 2 h at room temperature with constant mixing to remove the acetyl protecting groups.
4. Wash the deprotected support extensively with water to completely remove the hydroxylamine solution and reaction byproducts. The thiol-containing matrix should be used immediately to immobilize a ligand or in another reaction to couple with the free –SH group. Avoid storage of the support in this form, because thiol oxidation likely will take place rapidly and degrade the amount of thiols available. EDTA (25-m*M*) may be added to the wash solutions or reaction buffers to prevent metal-catalyzed oxidation.

CHAPTER

16

Buckyballs, Fullerenes, and Carbon Nanotubes

1. BUCKYBALLS AND FULLERENES

1.1. Properties of Fullerenes

Carbon is an incredible element that is able to form structures having highly diverse properties depending on its bonding patterns and 3-dimensional organization. Natural allotropes of carbon include diamond, graphite, amorphous carbon, and several other known forms (Figure 16.1). Depending on the bond structure and atomic orientation that carbon takes on within the structure of an allotrope, the resultant characteristics can range from the hardest-known abrasive mineral, diamond, to the extremely soft graphite, which is used as a lubricant.

In 1985, the story of carbon allotropes took a dramatic turn with the discovery of C_{60}, which resulted in a new type of carbon structure, called fullerenes (Kroto *et al.*, 1985). This discovery earned the 1996 Nobel Prize in chemistry for Harold Kroto, Robert Curl, and Richard Smalley. Buckminsterfullerene (named after Buckminster Fuller for his geodesic dome architectural design) is a spherical cage of carbon having 60 atoms forming a truncated icosahedron of average diameter 0.72 nm, which contains 12 pentagons and 20 hexagons of bonded carbon (Figure 16.2). The shape is exactly the same as a modern soccer ball, with the pentagon and hexagon configurations clearly outlined on its surface.

There now are known to be a whole family of caged carbon structures having various numbers of carbon atoms, including C_{30}, C_{50}, C_{70}, C_{72}, C_{76}, C_{84}, and the huge C_{540}. The name "fullerene" has replaced the unwieldy, "Buckminsterfullerene" used to describe this general spheroid structure of carbon, although they still are referred to as "Buckyballs."

Of all the fullerene forms, the nearly spherical properties of C_{60} have attracted the greatest attention, especially in the field of bioconjugation (Montellano *et al.*, 2011). In addition to its physical properties, C_{60} fullerenes have unique photo-optical and electrochemical properties, which make them useful as carriers for biomedical research applications. For instance, upon exposure to light C_{60} will generate singlet oxygen, which can be used *in vivo* to cleave biological molecules, particularly DNA and RNA. Studies indicate that irradiation of C_{60} in solution can be used to destroy virus contamination (Kasermann and Kempf, 1997). Fullerene conjugates have been investigated for use as drug delivery platforms for targeting mammary carcinoma cells (Lucafò *et al.*, 2012), as folate conjugates to target upregulated folate receptors on tumor cells (Shi *et al.*, 2012), and as conjugates to 5-fluorouracil to enhance the drug's effectiveness as an antitumor agent (Dou *et al.*, 2012).

Fullerene C_{60} also functions efficiently as an antioxidant, actually being better than other lipid-soluble antioxidants at scavenging reactive oxygen species (ROS) (Wang *et al.*, 1999). Water soluble derivatives of C_{60}, such as a poly-hydroxyl form, are able to function in the same respect in aqueous environments.

Pure fullerenes are insoluble in aqueous environments and only sparingly soluble in many organic solvents. Solutions of Buckminsterfullerene are a deep-purple color, whereas other sizes of fullerenes display a variety of other colors. The greatest solubility is found in 1,2,4-trichlorobenzene (20 mg/ml), carbon disulfide (12 mg/ml), toluene (3.2 mg/ml), and benzene (1.8 mg/ml) (Wikipedia.org). Solubility calculations have been performed on C_{60} in 75 different organic solvents (Silvaraman *et al.*, 2001).

1.2. Modification of Fullerenes

C_{60} contains exactly 30 double bonds in its ring structures that are chemically and electronically equivalent. The carbons at the double bond junctions do not possess any hydrogens, so substitution reactions are not feasible at these sites; however, addition reactions and redox reactions can occur to yield derivatives of the fullerene molecule. Many chemical derivatization

© 2013 Elsevier Inc. All rights reserved.

methods have been developed to afford fullerene solubility in particular environments and to provide functional handles for bioconjugation (Bosi *et al.*, 2003). The combination of adding polar groups and reactive functionalities to fullerenes, such as COOH, NH_2, and OH groups, provides water solubility and bioconjugation targets. Examples of these modifications include the method of Brettreich and Hirsch (1998) to add multiple carboxylates in a dendritic fashion and Wang *et al.* (1999), who added multiple pairs of carboxylates to the surface carbons. In addition, Cusan *et al.* (2002) developed a C_{60}–PEG dendrimer-based diamine derivative using a substituted fulleropyrrolidine modification linked to the surface. Polymer carriers have also been used to provide water solubility and sites of attachment. Cyclodextrins have been found to be excellent

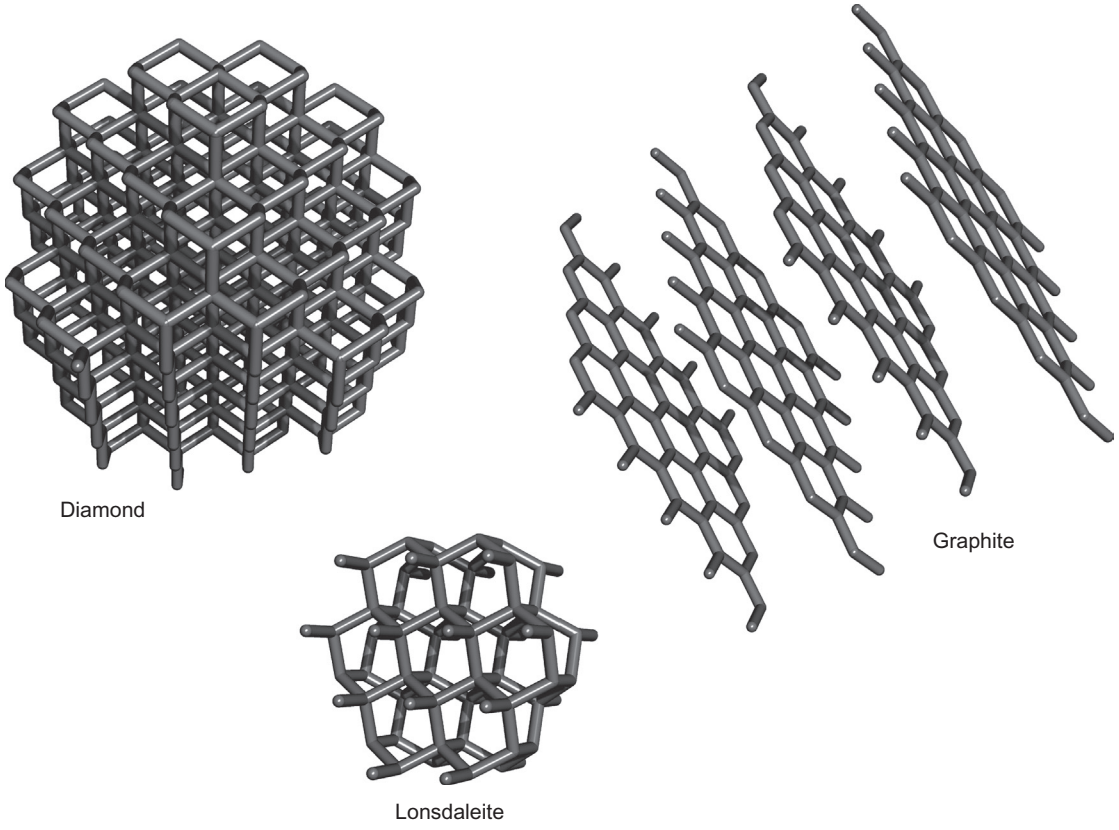

FIGURE 16.1 Three major allotropes of carbon.

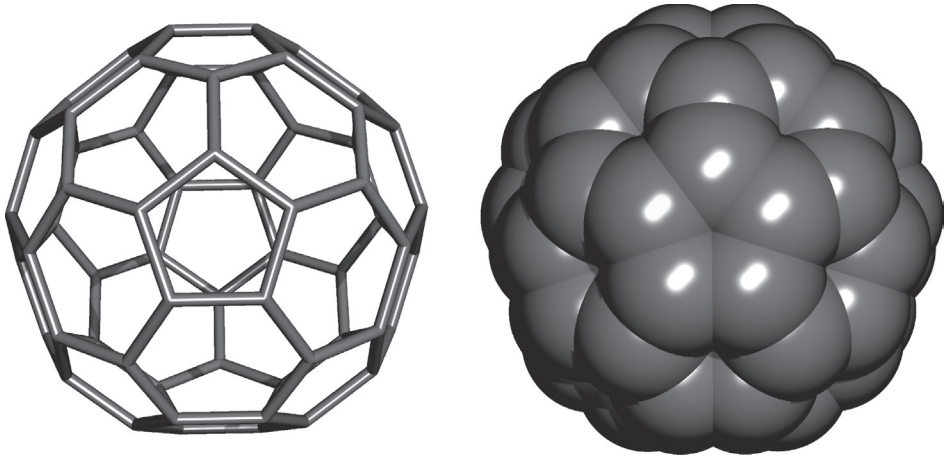

FIGURE 16.2 The structure of a C_{60} fullerene, also called a Buckyball.

carriers of C_{60} by holding the fullerene within its hydrophobic core (Andersson *et al.*, 1992; Braun, 1997; Filippone *et al.*, 2002; Samai and Geckeler, 2000) and covalent conjugates of C_{60} with alpha-cyclodextrin have been prepared (Xiao *et al.*, 2012) (Figure 16.3).

In many methods for derivatization of C_{60}, the initial modification is based on the reaction at a 6,6 ring junction on the fullerene with an azomethine ylide to form the 1,3-dipolar cycloaddition product (the "Prato reaction"), which creates a fulleropyrrolidine (Prato *et al.*, 1996; Bottari and Torres, 2011). The reaction is carried out overnight with heating to reflux in organic solvent. Typical reactants that combine with C_{60} in this reaction include an *N*-glycine derivative (with a constituent off the alpha-amino group) and an aldehyde derivative, which gives the fulleropyrrolidine compound according to Figure 16.4. By judicious choice of the right starting materials, the process provides a range of derivative possibilities to employ fullerenes in various bioconjugate applications. If the reactants are added in large excess over the concentration of the fullerene, then up to nine such pyrrolidine groups can be introduced per C_{60} molecule. The number of modifications actually ends up being a bell shaped curve from five to nine pyrrolidine derivatives, with a peak at seven modifications (Prato and Maggini, 1998). By controlling the length of the reaction, a mono-substituted product can be obtained in 40 to 50% yields.

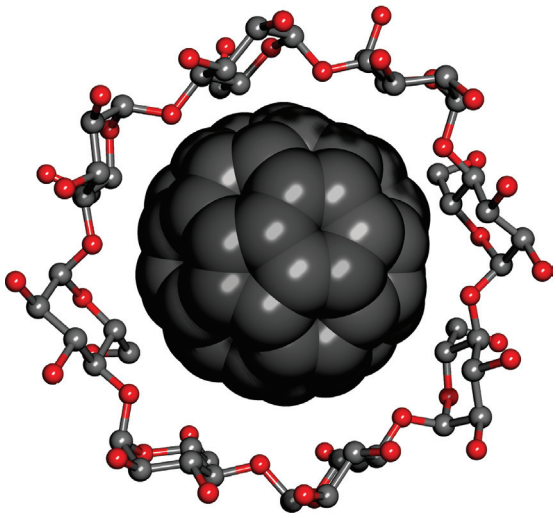

FIGURE 16.3 Gamma-cyclodextrin is able to accommodate a C_{60} fullerene within its core and solubilize it in aqueous solution.

In addition, the use of appropriate hydrophilic constituents on the aldehyde or glycine reactants can result in excellent water solubility of the C_{60} derivative. Two such modification arms can be added simultaneously to the pyrrolidine ring, thus providing a functional group for further conjugation and a hydrophilic arm for increased water solubility. PEG derivatives have been formed in this manner that create highly soluble fullerene derivatives.

The following procedure adapted from Prato *et al.* (1996) is an example of how glycine and formaldehyde derivatives may be used to create fullerene modifications for subsequent bioconjugation purposes.

Protocol

1. In a fume hood, prepare a solution of 100 mg of C_{60} dissolved in 100 ml of toluene.
2. Add to the fullerene solution with mixing, 25 mg of *N*-methyl glycine (sarcosine) and 20 mg of paraformaldehyde.
3. React by refluxing for 2 h with mixing.
4. Remove solvent under vacuum and purify the *N*-methyl-3,4-fulleropyrrolidine (Figure 16.5) by flash chromatography using toluene as eluent.

A similar preparative procedure can be used to form the *N*-(triphenylmethyl)-3,4-fulleropyrrolidine, which is a trityl protected amine derivative that may be deprotected using trifluoromethanesulfonic acid (TFMSA) to create a free secondary amine for conjugation. Kurz *et al.* (1998) used this C_{60} derivative to react with 3-maleimidopropionyl chloride to form a sulfhydryl-reactive fullerene. Although this derivative was not soluble in aqueous buffers, it was reactive enough as a micro-precipitate to be conjugated to thiol-containing proteins using the following procedure.

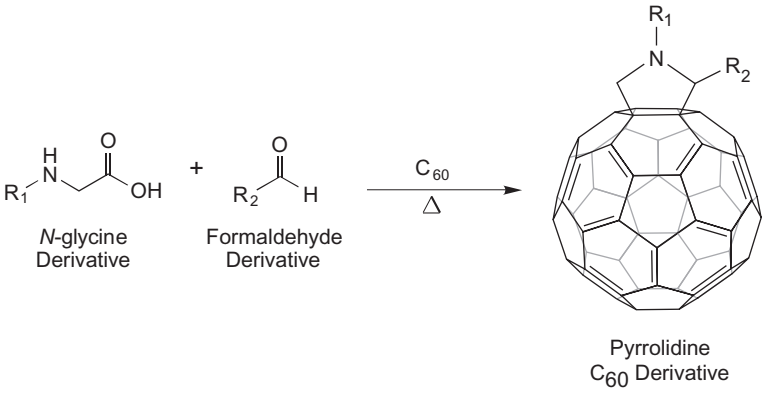

FIGURE 16.4 The reaction of a glycine derivative and a formaldehyde compound with a C_{60} molecule leads to the formation of a fulleropyrrolidine.

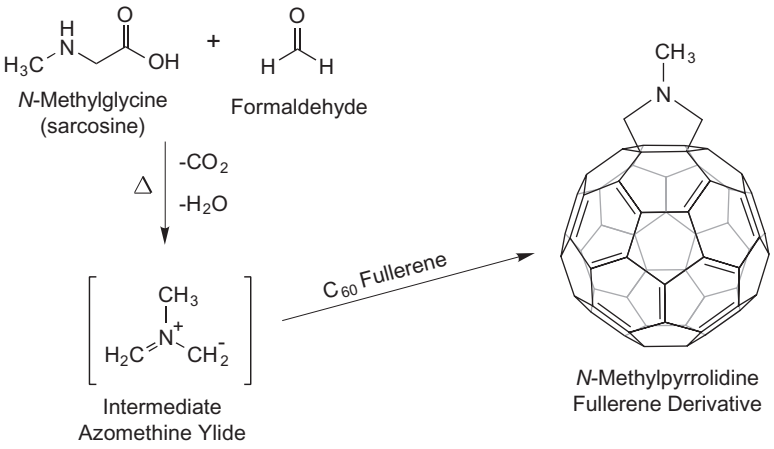

FIGURE 16.5 The synthesis of *N*-methylpyrrolidine–C_{60} proceeds through an intermediate azomethine ylide by the reaction of *N*-methylglycine plus formaldehyde upon heating.

Protocol

1. The thiol-containing protein is dissolved as a 60-μ*M* solution in 20-m*M* HEPES, pH 7.
2. Add the maleimide–C_{60} derivative to the protein solution at 100× mole excess with stirring. The addition of detergent to the solution may increase the solubility of the fullerene compound.
3. React with mixing at 4°C for 72 h.
4. Purify the labeled protein by size exclusion chromatography using a column with an exclusion limit of MW 5,000.

The nitrogen group in fulleropyrrolidines can be used for conjugation with crosslinking agents or hydrophilic biotinylation compounds for subsequent use in bioconjugation reactions. To create the free secondary amine group (NH) fulleropyrrolidine, an amine-protected starting material can be used in the reaction (Chai *et al.*, 2006). For instance, a trityl-oxazolidinone (using either triphenylmethyl- or, better, 4-methoxytriphenylmethyl-protecting groups) can be reacted with C_{60} to yield the trityl-protected pyrrolidine (Figure 16.6).

The following procedure for creating the NH fulleropyrrolidine is adapted from Maggini *et al.* (1994), Prato and Maggini (1998), and Prato *et al.* (1996). Extreme care should be taken when using TFMSA, as this acid is 30-times stronger than concentrated sulfuric acid.

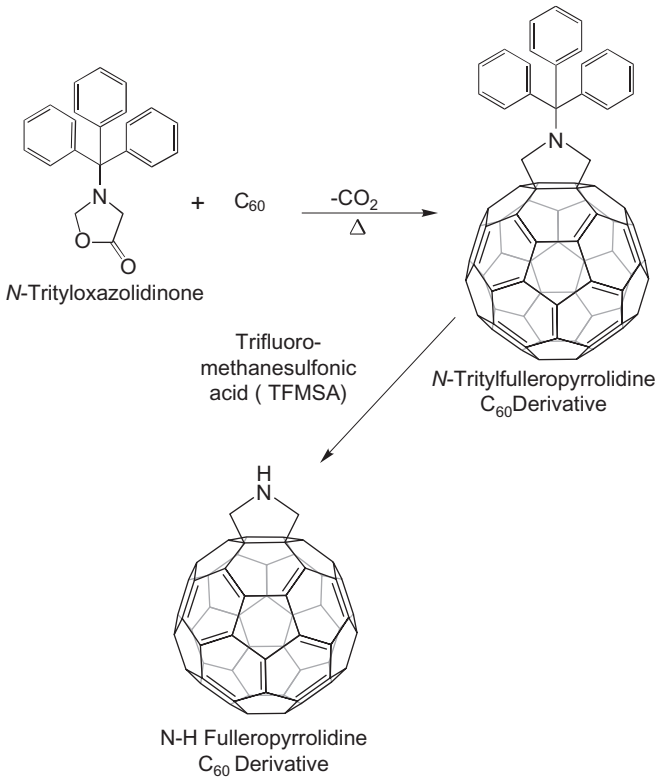

FIGURE 16.6 A trityl-protected pyrrolidine derivative of C_{60} can be prepared by the reaction of *N*-trityl-oxazolidinone with a fullerene. Deprotection of the trityl group using methanesulfonic acid gives the secondary amine, which can be used in further conjugation reactions.

Protocol

1. Dissolve 100 mg of C_{60} in 130 ml of chlorobenzene in a fume hood.
2. Add with mixing to the fullerene solution 54 mg of either *N*-(triphenylmethyl)-5 oxazolidinone or the same amount of the methoxytrityl oxazolidinone.
3. Reflux overnight in a fume hood with constant mixing.
4. Remove the solvent under vacuum and purify the residue using flash chromatography with an 8:2 mixture of petroleum ether/toluene as the eluent.
5. Remove the trityl-protecting group by dissolving the derivatized fulleropyrrolidine in 5 ml of dichloromethane in a fume hood and then adding 50 μl of TFMSA (caution!) with stirring.
6. React at room temperature for 1 h to remove the trityl protecting group, yielding the NH pyrrolidine derivative of C_{60}.

Capaccio *et al.* (2005) used the NH fulleropyrrolidine derivative to couple long-chain biotin to the C_{60} using the carbodiimide dicyclohexyl carbodiimide (DCC) in a pyridine/DMF/CH_2Cl_2 solvent mixture and reacting overnight at room temperature. This derivative was prepared using a hydrophobic, aliphatic long-chain biotin, but similar derivatives could be prepared using a biotin–PEG–carboxylate compound (e.g., NHS–PEG_4–biotin) to create a hydrophilic fullerene modification (Figure 16.7). The biotinylated fullerene could be used with streptavidin and another biotinylated enzyme to create a bioconjugate.

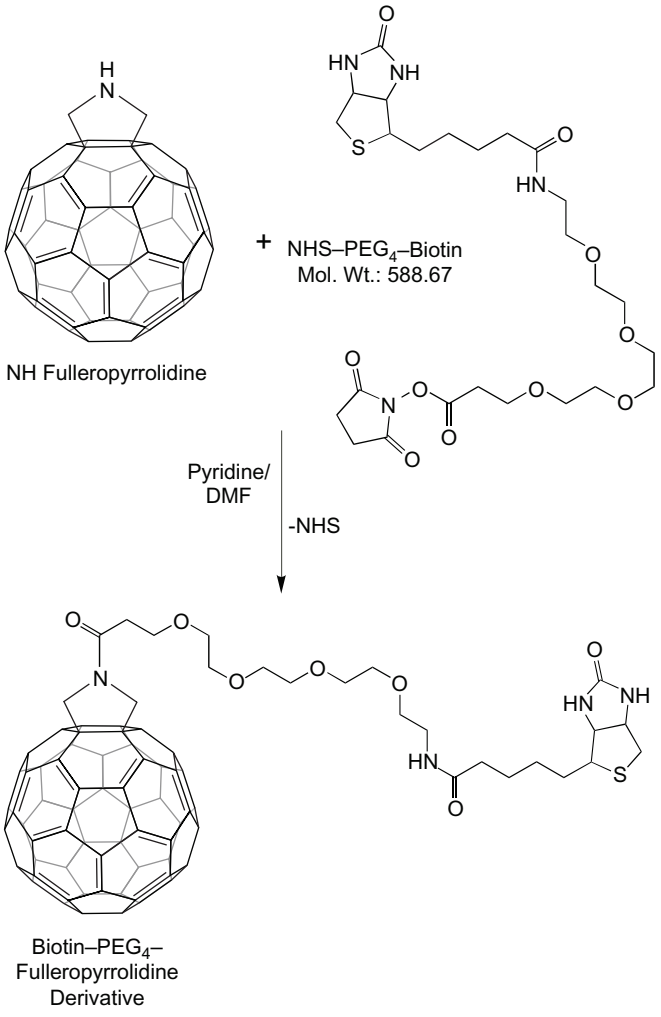

FIGURE 16.7 Reaction of an NH fulleropyrrolidine with NHS–PEG_4–biotin creates the biotinylated C_{60} derivative *via* an amide bond.

Similar to the fullerene modifications using either glycine/formaldehyde derivatives or oxazolidinone compounds, Maggini and Scorrano (1993) found that aziridines could yield similar pyrrolidine derivatives. Heating aziridine compounds in toluene was found to result in ring opening of the aziridine with subsequent covalent linking to the C_{60} ring system (Figure 16.8). Thus, synthesizing pyrrolidine derivatives of fullerenes can be done by several routes with success.

Another route to the preparation of C_{60} derivatives involves the reaction of a halogen derivative of diethylmalonate in the presence of a strong base with fullerenes, which results in a cyclopropanation product (Bingel, 1993; Isaacs *et al.*, 1993; Isaacs and Diederich, 1993). Using this reaction, various malonate derivatives of C_{60} can be made to facilitate production of bioconjugates (Zakharian, 2005). This reaction is often called the Bingel reaction (or Bingel–Hirsh addition) after the publication by the author in 1993 (see also Hirsch *et al.*, 1994). The reaction can yield carboxylate derivatives that then can be used to couple biomolecules through carbodiimide conjugation (Figure 16.9). Modifications of this reaction have been used frequently to produce important fullerene conjugates (Montellano *et al.*, 2011; Ruppert *et al.*, 2011; Tuktarov *et al.*, 2011; Xiao *et al.*, 2012).

The following protocol represents a C_{60} modification with an ethylmalonate derivative using the Bingel-type reaction, which creates an amine functional group on the fullerene surface, and is based on the method of Zakharian *et al.* (2005) (Figure 16.10). Ashcroft *et al.* (2006) used this method to create C_{60}

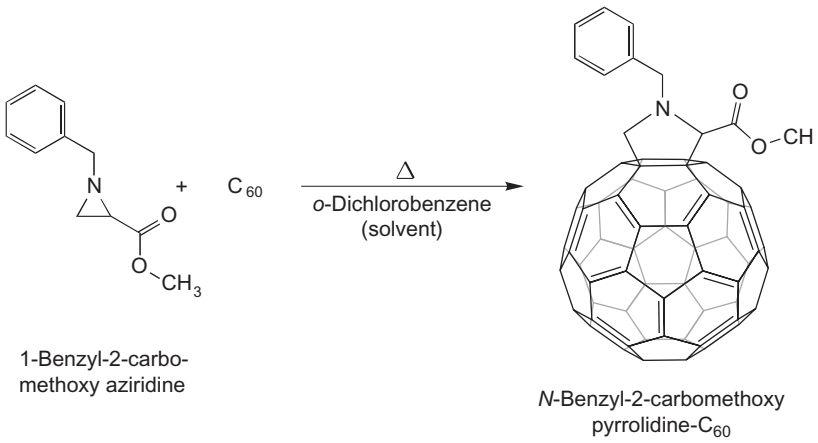

FIGURE 16.8 The reaction of aziridine derivatives with fullerenes can also give pyrrolidine derivatives useful for bioconjugation.

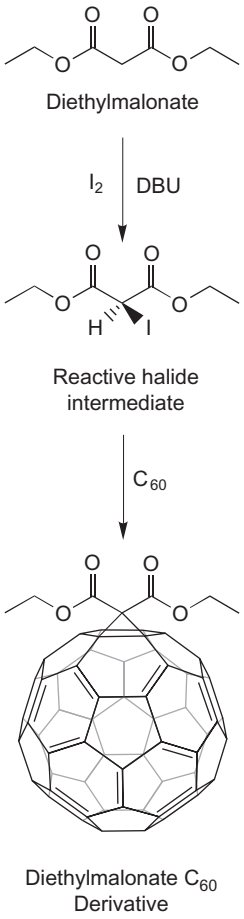

FIGURE 16.9 The Bingel reaction for the modification of fullerenes involves the *in situ* formation of a reactive halogen species in the presence of the strong base DBU. The cyclopropanation product can be used to create many bioconjugates.

immunoconjugates with the murine anti-gp240 melanoma antibody, which was made water soluble through the additional modification of the fullerene with hydrophilic malonodiserinolamide groups.

Protocol

1. In a fume hood, prepare a solution of 1.16 g *tert*-butyl-*N*-(3-hydroxypropyl)carbamate (Aldrich) in 100 ml of dry CH_2Cl_2 and add 1 ml of pyridine with stirring.
2. Cool the solution to 0°C and slowly add 1 g of ethylmalonyl chloride (Aldrich) under nitrogen with stirring.
3. React for 12 h with stirring at room temperature.
4. The resultant ethylmalonate–protected-amine compound is concentrated *in vacuo* and then purified using silica gel chromatography with a hexane/ethyl acetate (1 : 1) eluent.
5. In a fume hood, dissolve 400 mg of C_{60} in 700 ml of toluene with stirring.
6. Add to the C_{60} solution 100 mg of the purified ethylmalonate–protected-amine compound from step 4 along with 88 mg of I_2 and 105 mg of DBU (Aldrich).
7. React for 30 min at room temperature with mixing.
8. Remove the solvent *in vacuo* and purify the resultant mixture using silica gel chromatography. The initial eluent is toluene, which will remove the unreacted C_{60}, and then follow with a 10 : 1 mixture of toluene/ethyl acetate to elute the desired C_{60}–protected-amine derivative.
9. To remove the *tert*-butyl protecting group on the amine, in a fume hood add 190 mg of the C_{60}–protected-amine derivative from step 8 to 50 ml CH_2Cl_2 with stirring. Add to this solution with stirring 50 ml of TFA and mix for 30 minutes. Remove the solvent *in vacuo* to yield the final amine–C_{60} compound.

The amine group on the C_{60} fullerene may be used to couple carboxylate-containing spacers or affinity ligands using a carbodiimide conjugation reaction to form an amide linkage. The reaction may be performed in organic solvent or aqueous buffer, depending on the hydrophilicity of the fullerene derivative. A mixture of organic and aqueous solution also may be done if the ligand is more soluble in an aqueous environment.

A similar fullerene modification process developed by Hummelen *et al.* (1995) resulted in a number of phenyl C_{60} butyric acid methyl ester (PCBM) derivatives, which now are commercially available (Nano-C, Solenne). The reaction proceeds through the creation of a diazo derivative of methyl 4-benzoylbutyrate, which then is reacted with the aromatic ring system of C_{60} to give the cycloaddition product (Figure 16.11). The conjugate forms through the formation of both a 5,6 ring addition product (fulleroid) or a 6,6 ring addition product (methanofullerene). The fulleroid product results in breaking the 5,6 ring junction on the C_{60} molecule with dimeric bond formation to the aryl methyl group on PCBM.

The PCBM methyl ester can be used for coupling amine-containing ligands after removal of the methyl group and activation of the carboxylate using a number of different reaction strategies. Hummelen *et al.* (1995) successfully coupled cholestanol and histamine to the fullerene–PCBM derivative (after acid chloride formation) for use in fabrication of photodetectors and biological studies, respectively. For specific applications of PCBM-fullerenes, see Shaheen *et al.* (2001), Brabec *et al.* (2001), Yu *et al.* (1995), Mecher *et al.* (2002), Meijer *et al.* (2003), van Duren *et al.* (2004), and Anthopoulos *et al.* (2004).

Various commercial suppliers now offer fullerene derivatives with functionalities available for bioconjugation, including carboxylic and poly-hydroxylic derivatives, which are very hydrophilic and water soluble (BuckyUSA, NanoLab, NanoNB, Nano-C, and Aldrich).

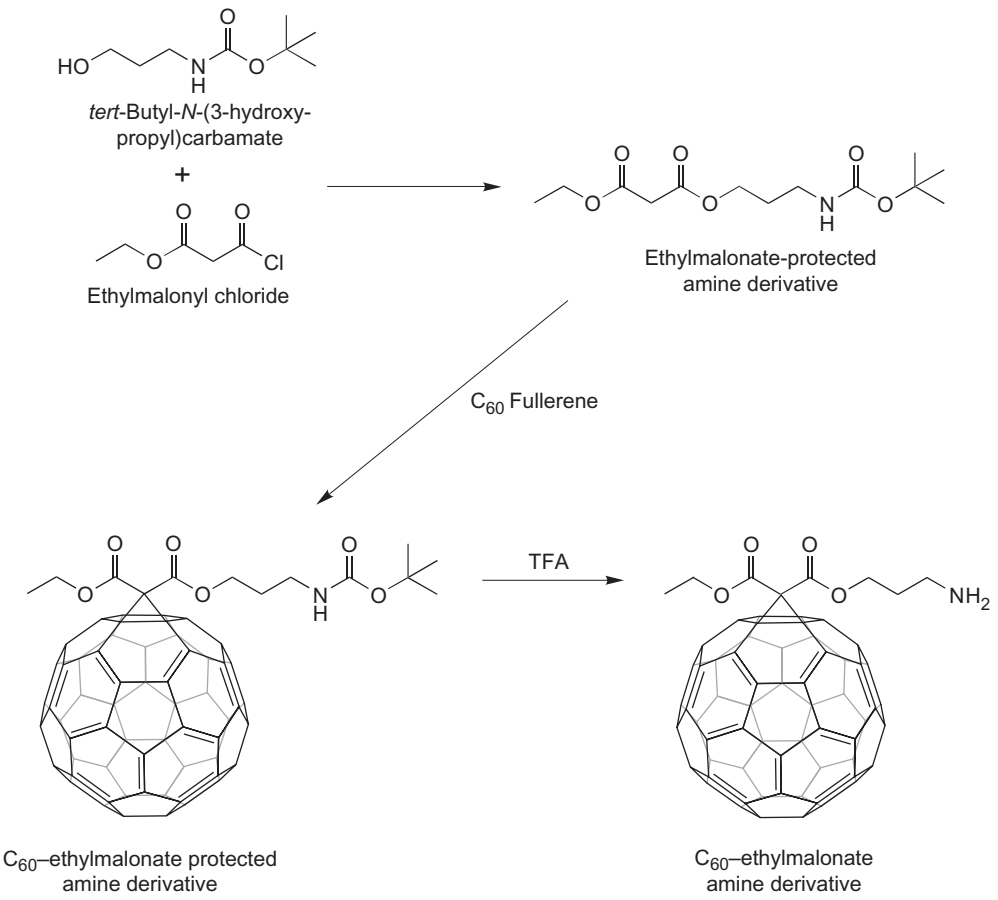

FIGURE 16.10 The reaction of the amine-blocked derivative of 3-hydroxypropylamine with ethylmalonyl chloride gives an ethylmalonate protected amine compound, which can be used in the Bingel reaction to create an amine group on a fullerene surface. Reaction with C_{60} in the presence of I_2 and DBU gives the cyclopropanation product that can be deprotected with TFA to yield the free amine.

2. CARBON NANOTUBES

2.1. Nanotube Properties

Cousins of the spheroidal fullerene molecules are carbon nanotubes. These are cylindrical graphene constructs with either open or closed ends and consist of carbon atoms arranged in a hexagonal pattern (Kit *et al.*, 2012). Similar to graphene, carbon nanotubes are being investigated and used as nanowires and sensors due to their electronic properties (Fam *et al.*, 2011; Zhang *et al.*, 2011 Tan *et al.*, 2012). There are two main families of carbon nanotubes that are distinguished by being either single-walled nanotubes (SWNTs) or multi-walled nanotubes (MWNTs). SWNTs are actually a graphene sheet that is seamlessly wound into a cylinder. MWNTs consist of multiple SWNTs that are concentrically wound around each other and nested together to create a tubes-within-tubes configuration (Figure 16.12). The type of nanotube is also determined by the manner in which the hexagonal pattern of carbon rings is arranged in the cylindrical structure.

In most publications, Iijima is given credit for the discovery in 1991 of the nanotube structure of carbon (Iijima, 1991; Bethune *et al.*, 1993; Iijima and Ichihashi, 1993). However, it has been said that Oberlin *et al.* (1976) also imaged carbon nanotubes, perhaps even SWNTs. Incredibly, nearly a century earlier, there was a study on the thermal decomposition of methane that resulted in the formation of long carbon strands, which were proposed at the time as a candidate for filaments in light bulbs (see Bacon and Bowman *et al.*, 1957).

SWNTs are typically only a few nanometers in diameter (0.4 to ~3 nm), but MWNTs can be from about 1.4 nm to over 100 nm in diameter, depending on the number of concentric nanotubes making up the bundle (Baughman *et al.*, 2007). However, carbon nanotubes can be from nanometers to millimeters or even microns in length, depending on how they are made. The length-to-diameter ratio typically exceeds 10,000 in most preparations. This unique molecular structure can result in fascinating properties, which include extremely high tensile strength, electrical conductivity

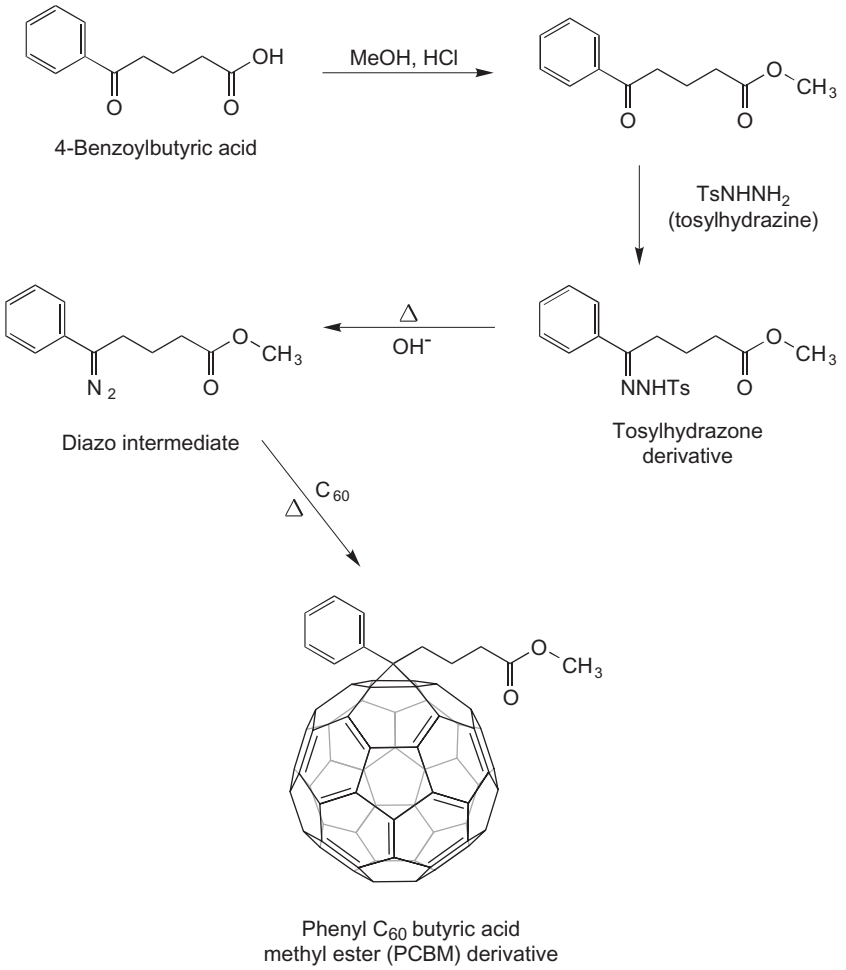

FIGURE 16.11 Fullerene–PCBM derivatives can be prepared using reactive diazo intermediates, which yield a cyclopropanation product similar to the Bingel reaction derivatives.

(or even semiconductor properties, depending on how the graphene sheet is wrapped), resistance to heat, and a great deal of chemical robustness. Nanotubes are being explored for use in applications ranging from electronics, optics, material science, biomedicine, biosensors, hydrogen storage, and nanoelectromechanical systems (NEMS) fabrication. The rate of growth in nanotube-related patents and publications has been increasing almost exponentially since the early 1990s, demonstrating the broad applications they can be used in (Baughman *et al.*, 2002; Park *et al.*, 2003).

The tensile strength of carbon nanotubes has been determined to be over 50 times that of high-carbon steel (Yu *et al.*, 2000). The strength of the bond structure in carbon nanotubes results from the fact that they are entirely sp^2 bonds, which are even stronger than the sp^3 carbon bonds in diamond. The addition of nanotubes to polymers, metals, and other structural materials has been used to add considerable strength to these materials. In fact, a carbon nanotube tether into low Earth orbit has been proposed as the only way of creating an elevator system into space.

The orbital bonding nature within carbon nanotubes creates unique electrical properties within a non-metallic molecule, which is a result of the delocalization of the pi-electron donated by each atom. Electrical conductivity can take place along the entire nanotube due to the freedom of pi-electron flow, making possible the design of circuits of extremely low-nanometer diameter.

Synthetic methods for the production of carbon nanotubes include arc discharge from graphite electrodes (Iijima, 1991; Collins and Avouris, 2000), pulsed laser ablation of a graphite substrate under high temperature (Guo *et al.*, 1995, 1995), chemical vapor deposition (José-Yacamán *et al.* 1993; Ren *et al.*, 1998), and high-pressure carbon monoxide (HiPco) method developed by Carbon Nanotechnologies, Inc. Methods for nanotube purification have been developed that result in 99.9% pure single-wall nanotubes (Chiang *et al.*, 2001).

Unlike the smaller, spheroidal fullerenes discussed previously, carbon nanotubes are not easily solubilized, even in organic solution. The reality is that all SWNTs and MWNTs are insoluble in all solvent systems. They also have a strong tendency to bind together and aggregate due to van der Waals attractive forces along the

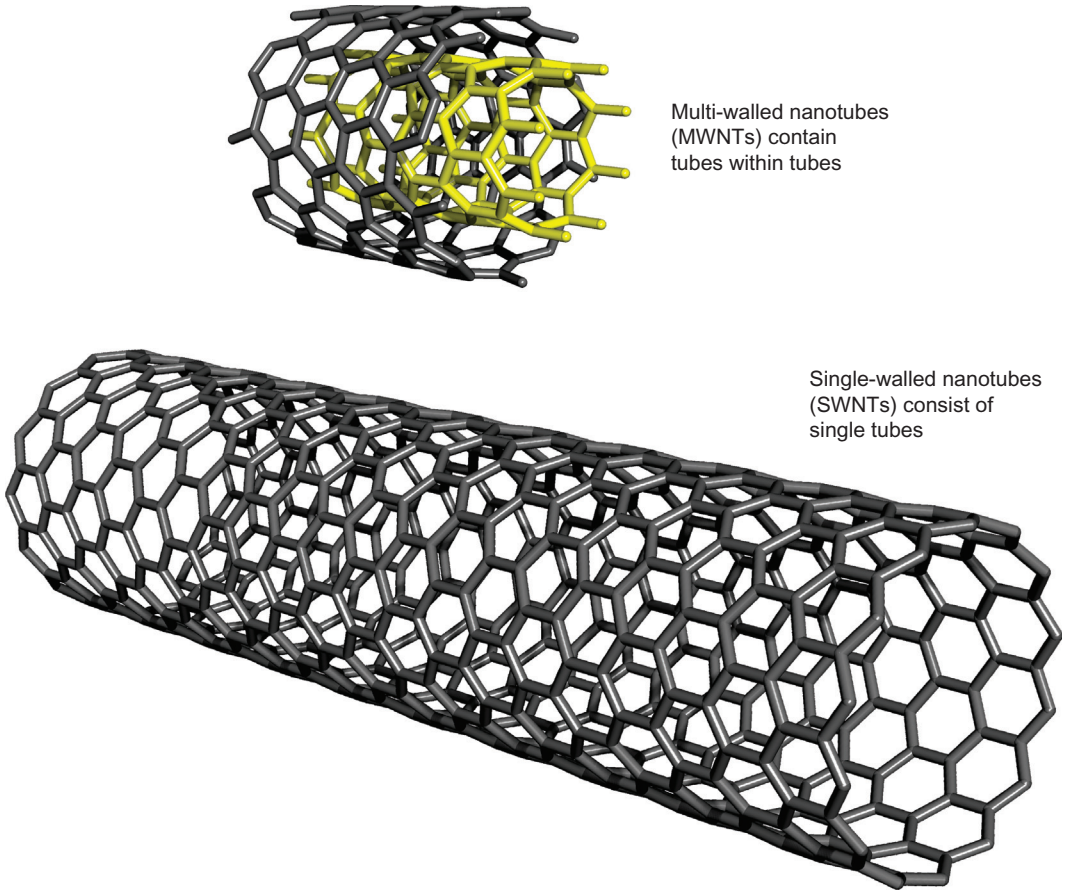

FIGURE 16.12 An example of a single-walled carbon nanotube and a multi-walled carbon nanotube. Multi-walled varieties of CNTs can consist of numerous tubes within tubes.

length of the nanotubes. Since the length-to-diameter ratio is so high for nanotubes, bundles are often observed to be knotted and tangled masses, which are very difficult to unravel. The best that can be done is to disrupt the bundle and form a dispersion of the nanotubes in a solvent medium.

Some of the better solvents for pure SWNTs are the amide-containing ones, like DMF or *N*-methylpyrrolidone, but they still do not permit full dissolution, just dispersion (Boul *et al.*, 1999; Liu *et al.*, 1999). The addition of surfactants to carbon nanotube suspensions can aid in their solubilization and even permit their complete dispersion in aqueous solution. The hydrophobic tails of surfactant molecules quickly adsorb onto the surface of the carbon nanotubes, while the hydrophilic parts permit interaction with the surrounding polar solvent medium.

2.2. Nanotube Functionalization

An important route to solubilization of carbon nanotubes is to functionalize their surface to form groups that are more soluble in the desired solvent environment. It has been shown that acid treatment of nanotube bundles, particularly with HCl or HNO_3 at elevated temperatures, opens up the aggregate structure, reduces nanotube length, and facilitates dispersion (An *et al.*, 2004; Kordás *et al.*, 2006). Nitric acid treatment oxidizes the nanotubes at the defect sites of the outer graphene sheet, especially at the open ends (Hirsch, 2002; Álvaro *et al.*, 2004), and creates carbonyl, carboxyl, and hydroxyl groups, which aid in their solubility in polar solvents.

Such carbonyls may be further oxidized using potassium permanganate ($KMnO_4$) and perchloric acid ($HClO_4$) to convert all of these groups into carboxylic acids. Once functionalized in this manner, the nanotubes can be fully dispersed in aqueous systems. Kordás *et al.* (2006) used these derivatives to print nanotube patterns on paper or polymer surfaces to create conductive patterns for potential use in electronic circuitry. The carboxylates may also be used as conjugation sites to link other ligands or proteins to the nanotube surface using a carbodiimide reaction as previously discussed (Section 1, this chapter; Chapter 3, Section 1.12; Chapter 4, Section 1).

Untreated carbon nanotubes nonspecifically adsorb protein in an irreversible manner much like the noncovalent adsorption of protein onto hydrophobic surfaces (Chen *et al.*, 2003). It is essential, therefore, to modify the surfaces of nanotubes to prevent hydrophobic binding of biomolecules, especially if the resultant conjugates are to be used in biological assays or systems. Two main strategies have been used to make nanotubes biocompatible: (1) the noncovalent modification of the graphene surface with amphipathic molecules, which have functional groups that can be used for conjugation; or (2) the covalent modification of the outer nanotube surface to promote hydrophilicity and create functional groups for coupling other molecules.

2.3. Detergent or Lipid Modification of Carbon Nanotubes

Detergents have been used for simple solubilization of SWNTs in aqueous solution. Ionic detergents such as SDS will coat the nanotube surface and expose the negatively charged sulfonate groups to the surrounding aqueous environment, thus allowing SWNT dispersion in aqueous environments. Similarly, nonionic detergents such as Triton X-100 will coat the tubes and present their hydrophilic groups to the aqueous phase. Fischer *et al.* found that coating SWNTs with sodium dodecylbenzene sulfonate resulted in the best solubilization properties with long-term stability of the nanotubes in aqueous buffers (Zhou *et al.*, 2004). The detergent molecules do not merely lie in a random pattern on the nanotube surface; they coat the SWNT in a series of half-micelle structures, which create small knobs along its length (Figure 16.13).

Detergents have also been exploited in the noncovalent modification of carbon nanotubes by using modified detergents containing a coupled affinity ligand, which is linked to the hydrophilic part of the detergent molecule. Detergents that contain both a hydrophobic portion and a hydrophilic part with at least one terminal functional group for conjugation can be used in this process. The hydrophobic tail of many detergents will strongly adsorb to the nanotube's outer graphene cylinder, leaving the hydrophilic portions pointing outward and available for conjugation, if they contain an appropriate functional group. The result is a hydrophilic surface that is completely masked to prevent nonspecific protein binding. This approach to nanotube functionalization also leaves the chemical structure of the graphene cylinder unaffected, thus avoiding defects that could alter its electronic properties.

As an example of this strategy, Chen *et al.* (2003) used an activated Tween 20 detergent to coat SWNTs for subsequent conjugation to biotin, protein A, and U1A antigen. Tween 20 is a polyoxyethylene sorbitan monolaurate compound with 20 ethylene oxide units, 1 sorbitol unit, and 1 lauric acid group esterified as the hydrophobic tail. The fatty acid group avidly adsorbs to the carbon nanotube surface, leaving the three PEG arms, each containing terminal hydroxyl groups, sticking out from the coating to create an extremely biocompatible construct (Figure 16.14). The hydroxyl groups on the Tween molecules can be activated for coupling to biomolecules using many of the methods discussed for hydroxylic particles in Chapters 14 and 15.

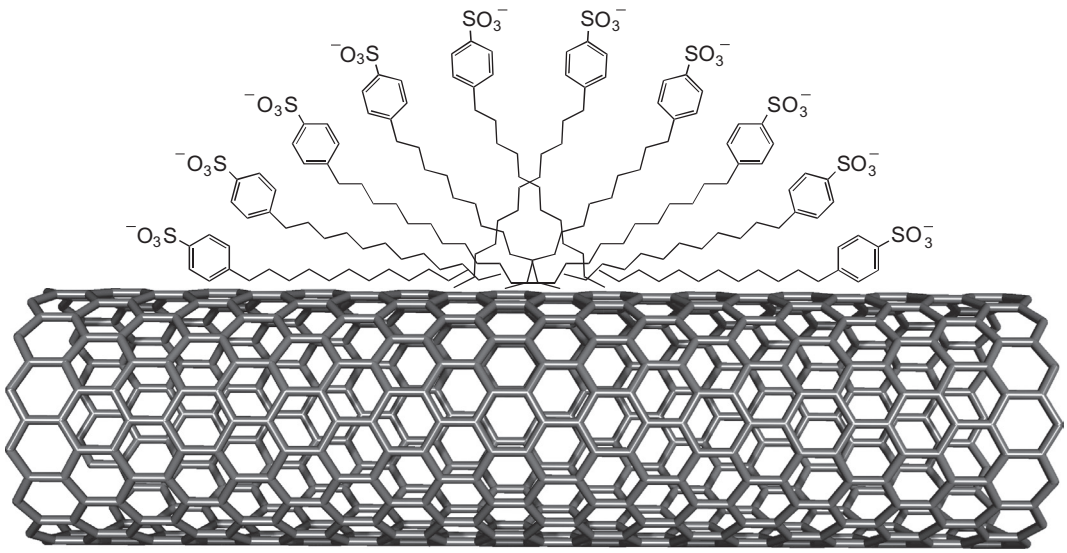

FIGURE 16.13 Detergent molecules can be used to solubilize carbon nanotubes by adsorption onto the surface through hydrophobic interactions and create half-micelle structures with the hydrophilic head groups facing outward into the aqueous environment.

For instance, activation of Tween 20 with carbonyl diimidazole (CDI) or disuccinimidyl carbonate (DSC) in a nonaqueous solution provides a reactive derivative suitable for coupling to amine-containing molecules, such as proteins.

The following protocol for the activation of Tween 20 with CDI and its subsequent use in modifying a carbon nanotube and coupling an affinity ligand is based on the method of Chen *et al.* (2003).

Protocol for Activation of Tween 20

1. Dissolve 5 mg of Tween 20 in 25 ml of dry DMSO with stirring.
2. Add 4 g of CDI with mixing and react for 1 h at room temperature.
3. Precipitate the CDI-activated Tween 20 by the addition of ethyl ether, and then isolate the precipitate using centrifugation or filtration. Redissolve the precipitated product in DMSO and

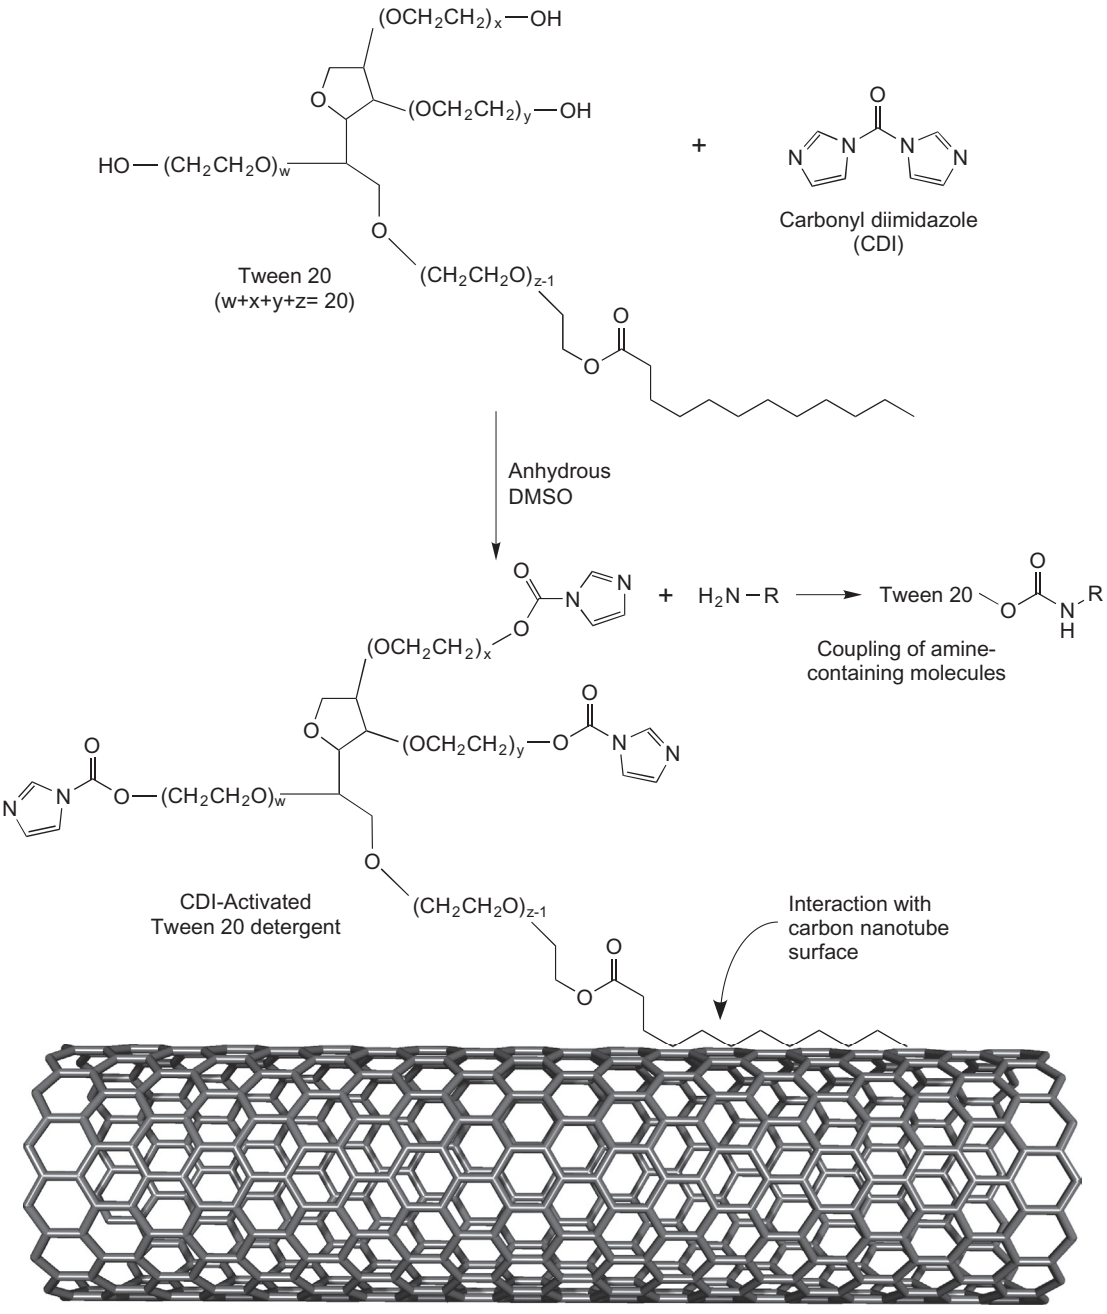

FIGURE 16.14 Tween-20 can be activated with CDI using its hydroxyl groups to create an amine-reactive imidazole carbamate intermediate that then can be used to coat a carbon nanotube. The result is an activated nanotube that can be used to couple proteins and other amine-containing molecules.

repeat the precipitation process two more times to ensure removal of excess reactants and reaction byproducts. After the final precipitation, dry the isolated precipitate overnight *in vacuo* to remove remaining solvent.

Protocol for Coating Nanotubes with CDI-Activated Tween 20

4. Suspend the SWNTs in 1% (w/w) CDI-activated Tween 20 solution in water using sonication and allow the detergent molecules to bind for 30 min at room temperature.
5. Quickly remove excess detergent by filtration on a 0.2-µm filter and washing the modified nanotubes with water.

Protocol for Coupling Activated Tween 20 to an Amine-Containing Ligand

6. Dissolve an amine-containing ligand in 0.1-*M* sodium carbonate, pH 9.5. If coupling a small ligand, such as a biotin–PEG–amine compound (Chapter 18, Section 1.3), then use a concentration of about 5 to 10-m*M* in the carbonate buffer. For proteins, concentrations of 10 n*M* to 1 µ*M* can be used with success.
7. Resuspend the activated nanotubes in the ligand-containing carbonate buffer and react with mixing overnight at room temperature or 4°C (e.g., for sensitive proteins).
8. Wash the coupled nanotubes with water or a suitable buffer using filtration and finally store them in buffer containing a preservative at 4°C.

In a similar approach to the noncovalent modification of carbon nanotubes with detergent molecules, Kam *et al.* (2005) used phospholipid derivatives to coat SWNTs for photo-therapeutic agents against tumor cells *in vivo*. A phospholipid containing a PEG–NH_2 group was used to couple folic acid as an affinity ligand (using EDC to form an amide bond), which preferentially can be taken up by cancer cells. SWNTs were modified by the lipid derivative in aqueous solution using sonication for 1 h and centrifuged to remove insoluble material. The aqueous fraction contained modified nanotubes, which contained the surface-adsorbed lipid derivative. After the modified SWNTs were incubated with cells, the solution was irradiated using an 808-nm laser. The nanotubes absorb light in this region of the spectrum and heat up to the point of causing cell death.

2.4. Pyrene Modification of Carbon Nanotubes

Another method for the noncovalent modification of carbon nanotubes involves the interaction of pyrene derivatives with the graphene sidewalls, presumably due to pi-stacking (Nakashima *et al.*, 2002) (Figure 16.15). This interaction forms tight complexes that completely coat the nanotube surface, and if the pyrene contains a hydrophilic portion, it can impart water solubility to the SWNT, as well. The additional presence of reactive groups or functional groups on a pyrene side chain permits conjugation to affinity ligands for biological applications.

Nakashima *et al.* (2002) found that a pyrene derivative containing a single side chain terminating in a positively

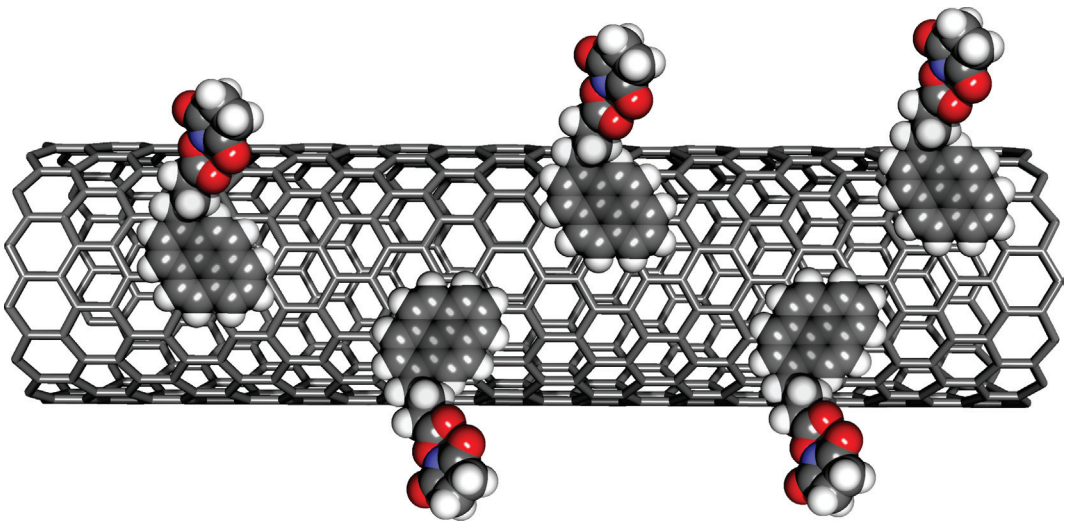

FIGURE 16.15 The NHS ester of a pyrene butyric acid derivative can be used to modify a carbon nanotube by adsorption of its rings onto the surface of the tube. The NHS ester groups then can be used to couple amine-containing molecules to form amide bonds.

charged quaternary amine imparted water solubility to SWNTs treated with the compound. The application of other pyrene derivatives can be performed to contribute both water solubility and an appropriate functionality for bioconjugation. Examples of pyrene derivatives that are suitable for the noncovalent modification of carbon nanotubes include those that have a single modification to the pyrene ring structure. Derivatives that contain multiple modifications off the pyrene group may affect its interaction potential for the SWNTs and should be avoided. For instance, water soluble poly-sulfonated derivatives of pyrene, such as the Cascade Blue fluorescent dyes described in Chapter 10, Section 5, should not be used, because the pyrene structure is too hydrophilic to associate with the nanotube surface due to the three negative charges contributed by the sulfonic acids.

Some commercially available pyrene compounds that may be used to functionalize a carbon nanotube by this method include 1-pyrenebutyric acid and 1-aminopyrene (from Acros or Aldrich) as well as *N*-(1-pyrenyl) maleimide, 2-(1-pyrenyl)ethyl chloroformate, 1-pyrenebutyric acid *N*-hydroxysuccinimide ester, 1-pyrenecarboxaldehyde, and 1-pyreneacetic acid (from Aldrich). Each of these compounds provides a single site of derivatization off the basic pyrene rings to contain either a functional group or reactive group for coupling ligands. Molecules modified with these pyrene derivatives may be used to treat a carbon nanotube to form a stable noncovalent complex.

The pyrene derivatives containing a carboxylate group, chloroformate, aldehyde, or an NHS ester can be used to couple to amine-containing ligands, including proteins. The maleimide–pyrene derivative may be used to couple with thiol-containing ligands, while the amine–pyrene compound may be used to conjugate with carboxylate-containing ligands. Also available are (1-pyrenyl)butyic acid hydrazide and pyrene-1-isothiocyanate from Molecular BioSciences, which react with aldehydes and amines, respectively. Once a ligand is conjugated to a pyrene derivative, the complex may be incubated with a carbon nanotube to produce the final noncovalent complex. Since the initial modification is done on a water-insoluble nanotube, it is best to perform the primary coating of the pyrene derivative in an organic solvent, such as DMF. It then is desirable to make the nanotube water soluble by linking a hydrophilic spacer arm to the pyrene–nanotube complex. If a hydrophilic spacer is built into the resultant pyrene conjugate, such as the use of a short-chain PEG compound, then the resultant SWNT complex will be completely water soluble (for example, see Figure 16.16). The PEG spacer chosen for this purpose should contain a terminal functional group for coupling to another molecule. At this point, the water soluble complex can be reacted with a protein or other affinity ligand in aqueous buffer to make the desired bioconjugate. This multi-step process will result in a biocompatible carbon nanotube that retains its electronic properties, is water soluble, and has added fluorescent properties due to the pyrene molecules coating its surface.

Maehashi *et al.* (2007) used pyrene adsorption to make carbon nanotubes labeled with DNA aptamers and incorporated them into a field effect transistor constructed to produce a label-free biosensor. The biosensor could measure the concentration of IgE in samples down to 250 p*M*, as the antibody molecules bound to the aptamers on the nanotubes. Felekis and Tagmatarchis (2005) used a positively charged pyrene compound to prepare water soluble SWNTs and then electrostatically adsorb porphyrin rings to study electron transfer interactions. Pyrene derivatives have also been used successfully to add a chromophore to carbon nanotubes using covalent coupling to an oxidized SWNT (Álvaro *et al.*, 2004). In this case, the pyrene ring structure was not used to adsorb directly to the nanotube surface, but a side-chain functional group was used to link it covalently to modified SWNTs.

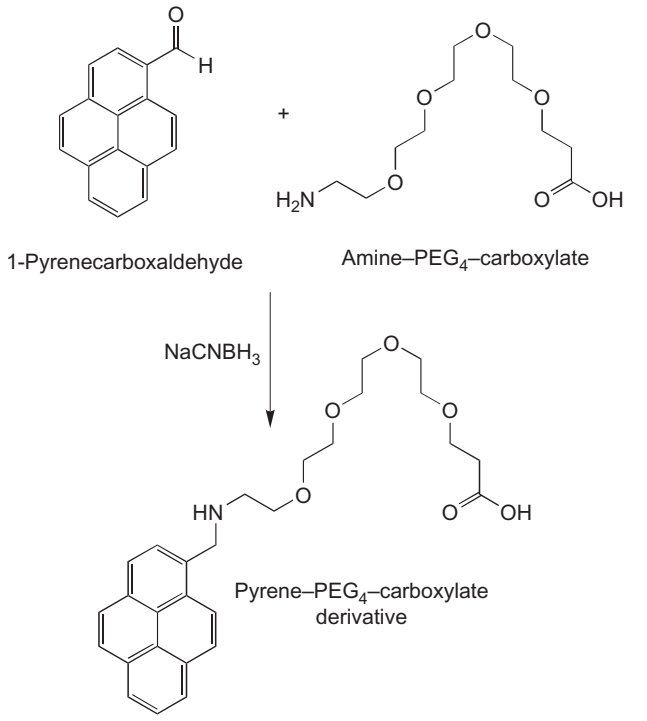

FIGURE 16.16 An aldehyde derivative of pyrene can be used to couple a hydrophilic amino–PEG–carboxylate spacer by reductive amination. The resultant derivative then can be used to coat a carbon nanotube through pyrene ring adsorption and result in a water soluble derivative containing terminal carboxylates for coupling amine-containing ligands.

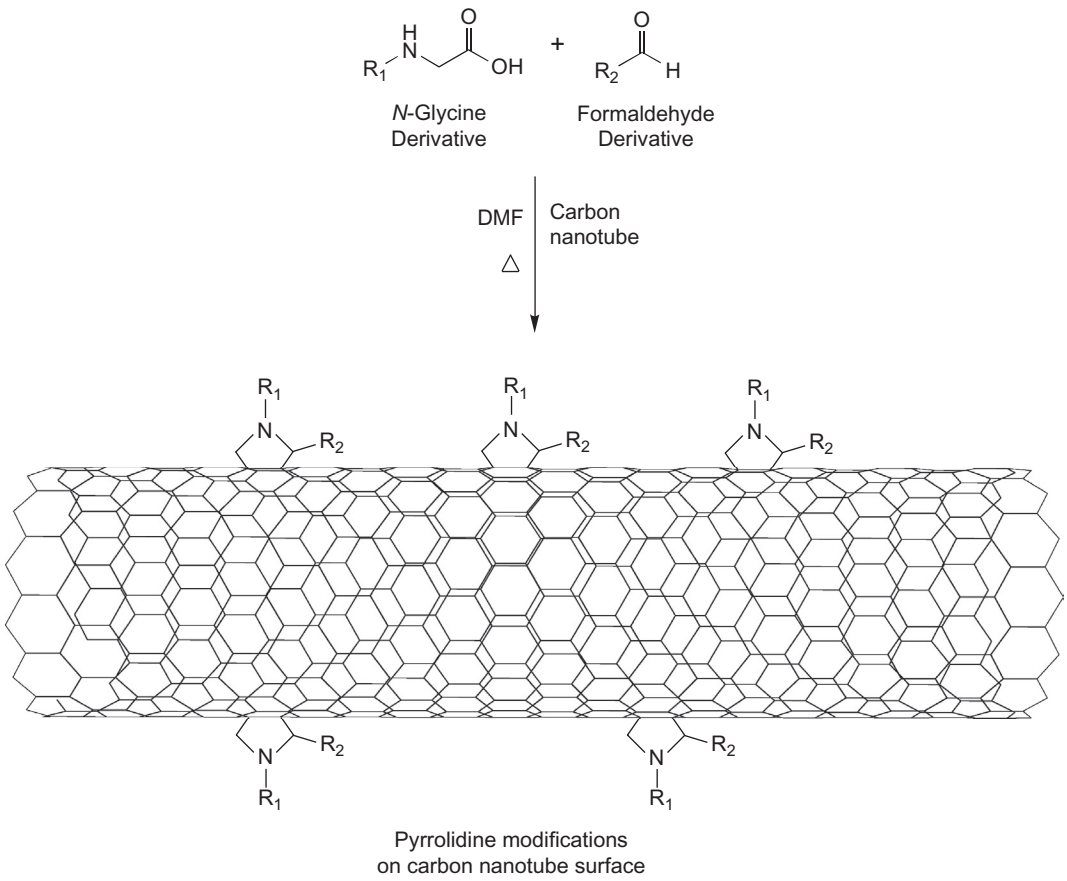

FIGURE 16.17 Some modification methods that are useful for fullerenes also can be used with carbon nanotubes. The reaction of an *N*-glycine compound with an aldehyde derivative can result in cycloaddition products, which create pyrrolidine modifications on the nanotube surface.

2.5. Modification of Carbon Nanotubes by Cycloaddition

The covalent methods previously discussed for fullerene modification using cycloaddition reactions also can be applied to carbon nanotubes (Kumar *et al.*, 2011). This strategy results in chemically linking molecules to the graphene rings on the outer surface of the cylinder, resulting in stable conjugates that can be designed to include hydrophilic groups for water solubilization. Georgakilas *et al.* (2002) described the use of a 1,3-dipolar cycloaddition process to carbon nanotubes with azomethine ylides, generated by condensation of an amino acid derivative and an aldehyde. The reaction occurs in organic solvent at high temperature over a time period of several days.

Typically, SWNTs are suspended in DMF using sonication and the aldehyde and glycine derivatives are added to the mixture with stirring. The alpha-amine derivative of glycine can include hydrophilic spacers to make the resultant nanotube water soluble as well as include protected functional groups to couple affinity ligands after deprotection (Kurz *et al.*, 1998). The aldehyde also can include R groups that add water solubility or functionality to the nanotube. A combination of a glycine derivative with an aldehyde derivative can result in both hydrophilicity and a functional group to conjugate ligands (Figure 16.17).

Felekis and Tagmatarchis (2005) used this cycloaddition process to prepare SWNT derivatives possessing photoactive components, such as the addition of ferrocene groups. They used a short PEG-type spacer on the glycine to impart water solubility at the same time.

Singh *et al.* (2006) also used cycloaddition to prepare carbon nanotubes containing indium-labeled diethylenetriamine pentaacetic acid (DTPA derivatives (Figure 16.18). In the initial modification, an SWNT was derivatized to contain a primary amine at the end of a short PEG spacer. The resultant water soluble nanotube then was reacted with DTPA to create a metal-chelating group at the end of the chain. Subsequent loading of the chelate with ^{111}In created a radionuclide–SWNT complex for *in vivo* biodistribution studies.

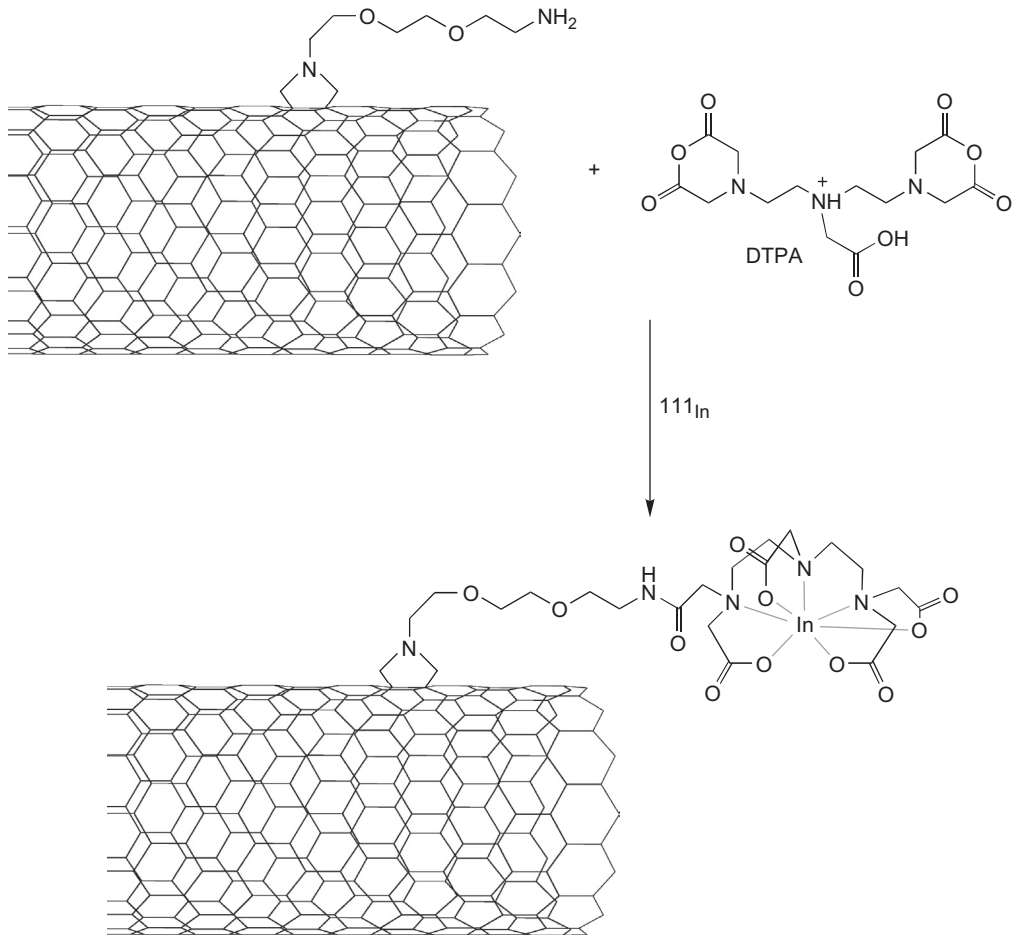

FIGURE 16.18 An amino–PEG–pyrrolidine derivative of carbon nanotubes can be used to couple metal-chelating groups, such as DTPA. Subsequent coordination of ^{111}In results in an indium chelate that can be used for imaging applications.

The demonstration that the 1,3-dipolar cycloaddition process with azomethine ylides works with nanotubes implies that similar reactions developed for use with fullerenes also will be successful with carbon nanotubes. In particular, the cyclopropanation reactions discussed previously for the modification of C_{60} also have been used for derivatization of SWNTs and MWNTs (Zakharian *et al.*, 2005; Umeyama *et al.*, 2011).

CHAPTER

17

Chemoselective Ligation; Bioorthogonal Reagents

The many dozens of reactions that are available for bioconjugation purposes generally are designed to work with biological molecules and the functionalities they contain. The main goal of most bioconjugate techniques is to use the functional groups on biomolecules to label with another type of biomolecule or link to synthetic probes. However, it is often desirable to couple one molecule to another without the potential for cross-reactivity with biomolecules. The term "chemoselective ligation" has been coined to describe the coupling of one reactive group specifically with another reactive group without side reactions in aqueous solution or in the presence of biological material (Lemieux and Bertozzi, 1998).

The incredible diversity of biomolecules in cells and organisms often presents problems for the goal of total chemoselectivity and bioorthogonality, as the number and variety of reactive sites on the molecules of life are extraordinary. Even the best crosslinkers or labeling reagents designed to be somewhat site specific in their reactions often display cross-reactivity with functional groups on biomolecules other than the ones intended for coupling. For instance, *N*-hydroxysuccinimide (NHS) esters usually are considered amine reactive, but they also can react with cysteine, histidine, serine, threonine, and tyrosine side chain groups. Maleimide groups too are touted as being thiol specific, but amines can also react with maleimides given the right conditions.

Bioorthogonal reagents ideally should contain a reactive group that will only react with another specific reactive group without any potential for cross-reactivity with biomolecule functionalities. In other words, a bioorthogonal reactive group could be added to a complex mixture of biological molecules in aqueous solution without reacting with any of them. Moreover, the ideal bioorthogonal system should be immune to instability in aqueous solutions, such as the tendency to hydrolyze or easily oxidize. True bioorthogonal reagents of this type will link to each other and only to each other in the presence of intracellular environments or in cell lysates or in defined biomolecule solutions.

The reality is that there are few options in this category of bioconjugate reagents and the systems or reactant pairs that have been developed for bioorthogonal applications have differing degrees of how well they perform in this task. The following sections describe the major chemoselective ligation reactions that can be considered to have a degree of bioorthogonal characteristics. In each system, the chemoselective pair of reactants can be separately linked or built into the design of crosslinkers or labeling reagents and used to modify biomolecules, surfaces, particles, or organic compounds. Subsequently, these labeled components can be brought together, even in complex solutions, to facilitate conjugation between the two bioorthogonal reacting species.

In addition, for several reactant strategies in chemoselective ligation, one of the reagent pairs can be designed into a biological monomer that can be utilized by cellular processes to become incorporated into biopolymers. This advantage provides a unique *in vivo* labeling capability through the feeding of monomer analogs to cells or organisms, such as modified amino acids or sugar derivatives, which then get selectively added into proteins, carbohydrates, or lipids. Thus, the ultimate application of bioorthogonal chemoselective ligation is to label specifically the molecules of life directly within living systems and without cross-reactions with other biological functional groups. For a review on the use of chemoselective reactions in living systems, see Prescher and Bertozzi (2005), as well as van Berkel *et al.* (2011).

1. DIELS–ALDER REAGENT PAIRS

The Diels–Alder reaction has long been a staple for forming carbon–carbon bonds in organic synthesis (Smith and March, 2007). The typical reaction proceeds through the 2 + 4 cycloaddition of a double bond (alkene) and a diene to give a six-member ring product. The double-bond reactant is often called a dienophile, and electron-withdrawing constituents next to the alkene are used to accelerate the reaction (such as COOH, CHO, and COR groups, among others). Conversely, electron-donating groups on the diene are important for increasing reaction rates (Figure 17.1).

Some reports indicated that the Diels–Alder reaction could be done in aqueous environments with a potential for accelerated reaction rates under the right conditions (Rideout and Breslow, 1980; Blokzijl and Engberts, 1992; Pai and Smith, 1995; Otto *et al.*, 1996; Wijnen and Engberts, 1997), and the addition of $InCl_3$ was determined to act as a catalyst in aqueous environments (Loh *et al.*, 1996). For a review of organic reactions that can be done in aqueous media, see Li (2005).

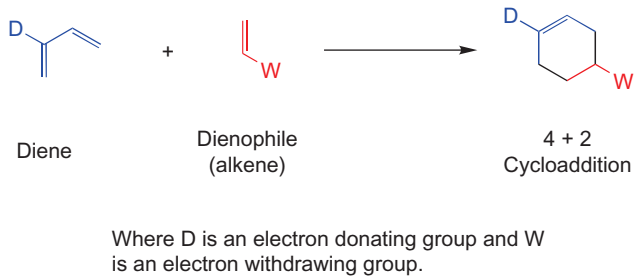

FIGURE 17.1 A general Diels Alder reaction consists of a 4 + 2 cycloaddition between a diene and an alkene, often called a dienophile. The reaction rate and yield increase if the diene contains an electron donating group and the alkene contains an electron withdrawing group.

In addition, it has been discovered that there are naturally occurring enzymes that facilitate Diels–Alder type reactions within certain metabolic pathways and that enzymes are also instrumental in forming polyketides, isoprenoids, phenylpropanoids, and alkaloids (de Araujo *et al.*, 2006). Agresti *et al.* (2002) identified ribozymes from RNA oligo libraries that catalyzed multiple-turnover Diels–Alder cycloaddition reactions.

In 2001, Hill *et al.* extended the use of aqueous-phase Diels–Alder reactions for the bioconjugation of diene-modified oligonucleotides. The dienophile that was used consisted of a simple maleimide derivative, which is present on a broad range of commercially available bioconjugation reagents. Modified oligonucleotides were prepared by solid-phase synthesis using a 3,5-hexadiene phosphoramidite derivative, which could be incorporated into the oligo at the 5′ end. Maleimide compounds investigated for oligo bioconjugation include *N*-ethylmaleimide, biotin–BMCC, fluorescein–maleimide, coumarin–maleimide, maleimide-PEG_2-biotin, and an mPEG–maleimide. Figure 17.2 shows the reaction of maleimide–PEG_2–biotin with the diene-modified oligo to yield the cycloaddition product.

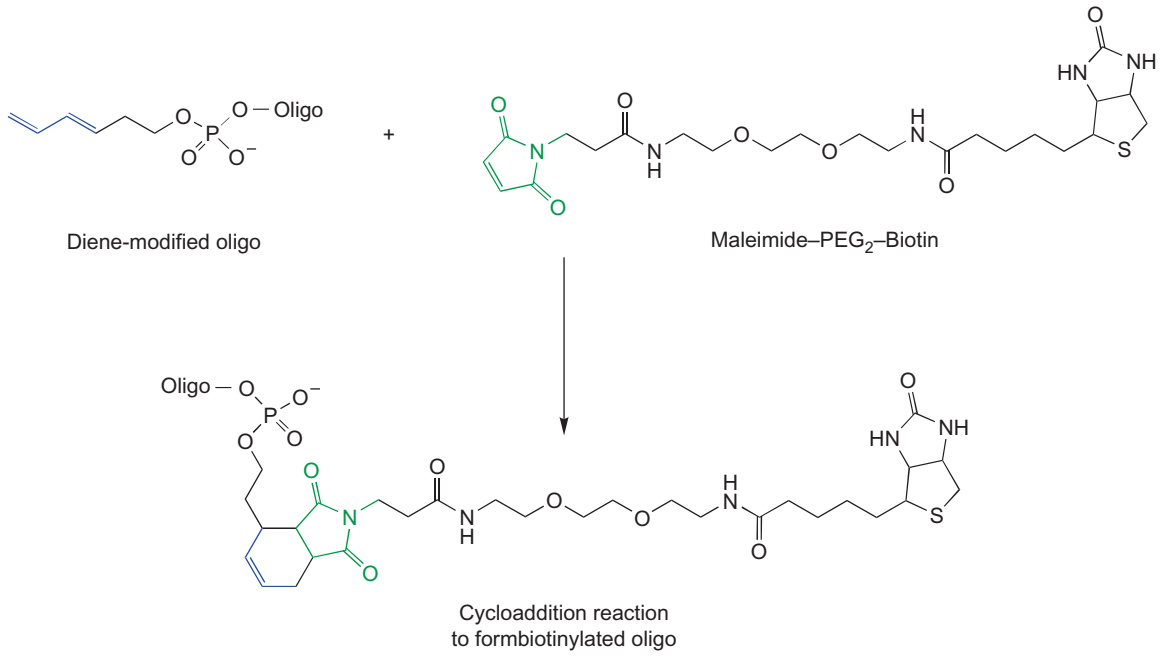

FIGURE 17.2 Maleimide groups provide good dienophiles for a Diels–Alder reaction. Biotin–PEG_2–maleimide can react with an oligo-diene molecule to form a covalent cycloaddition product, which adds the biotin tag to the oligo.

The reaction kinetics between a maleimide derivative and a 3,5-hexadiene derivative varies depending on the maleimide compound being reacted. Cycloaddition yields of greater than 80% and often as much as 90 to 95% can be expected within 1 to 18 h at room temperature or slightly elevated reaction conditions (e.g., 30°C).

The conjugation of oligonucleotides with peptides can also be carried out using Diels–Alder cycloadditions in water (Tona and Häner, 2005). Marchan *et al.* (2006) used the same 3,5-hexadiene phosphoramidite derivative as Hill *et al.* (2001), but in this case used a maleimide-modified peptide sequence. A mild, aqueous Diels–Alder reaction between them resulted in the formation of the cycloaddition product.

The Diels–Alder reaction for bioconjugation has been used for the chemoselective ligation of peptides and proteins in aqueous solution (de Araujo *et al.*, 2006). Peptides modified using a 2,4-hexadienyl ester were derivatized to contain a diene and were found to be reactive toward other peptides containing an N-terminal maleimide group to give the cycloaddition product in high yield. The hexadienyl group was also attached to biotin and allowed to interact with streptavidin, which could then be conjugated with peptides containing a maleimide group.

Diels–Alder cycloaddition reactions have also been used to link carbohydrates covalently to proteins (Pozsgay *et al.*, 2002), carbohydrates to surfaces (Beckmann *et al.*, 2012), for the immobilization of proteins onto surfaces (Chen *et al.*, 2011), as well as for the immobilization of oligonucleotides on glass surfaces to create arrays (Latham-Timmons *et al.*, 2003). In an application that used two chemoselective ligation reactions, Sun *et al.* (2006) employed sequential Diels–Alder and azide–alkyne (click chemistry) cycloaddition reactions to immobilize protein, biotin, or carbohydrate ligands on solid surfaces. In this case, glass slides containing maleimidocaproyl groups were used as the dienophiles and a PEG_4 spacer containing an alkyne on one end and a cyclopentadiene at the other end was the reactive linker. A Diels–Alder reaction coupled the maleimide groups to the cyclopentadiene groups on the spacer, while the alkyne groups at the other end were used in a click chemistry reaction to attach azide-containing ligands (Figure 17.3). The cycloaddition reaction between the maleimide groups on the slides and the cyclopentadiene group on the spacer was done in a 1:1 solution of water:*tert*-BuOH at room temperature for 12 h. After washing with the same water/solvent mixture, the slides contained hydrophilic spacers terminating in alkyne groups, which then could be coupled with the azide-containing ligands using click chemistry (see Section 6).

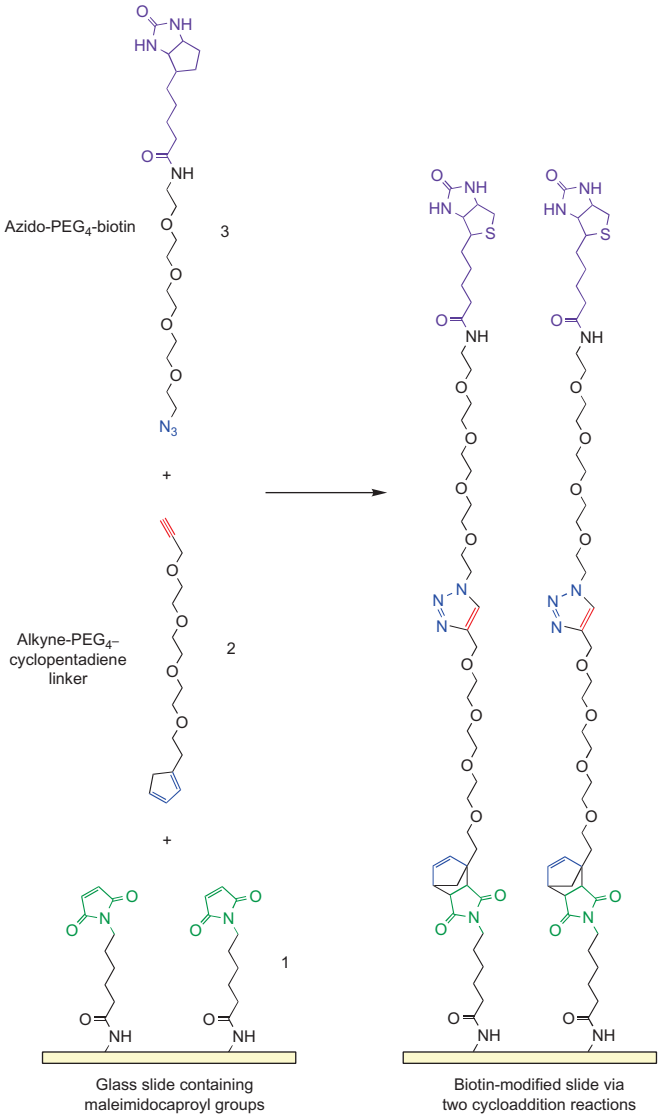

FIGURE 17.3 Maleimide-modified glass slides (1) can be derivatized using two chemoselective ligation reactions to create biotin modifications. In the first step, alkyne–PEG_4–cyclopentadiene linkers (2) are added to the maleimide groups using a Diels–Alder reaction. In the second reaction, an azido–PEG_4–biotin compound (3) is reacted with the terminal alkyne on the slide using click chemistry to result in another cycloaddition product, a triazole ring.

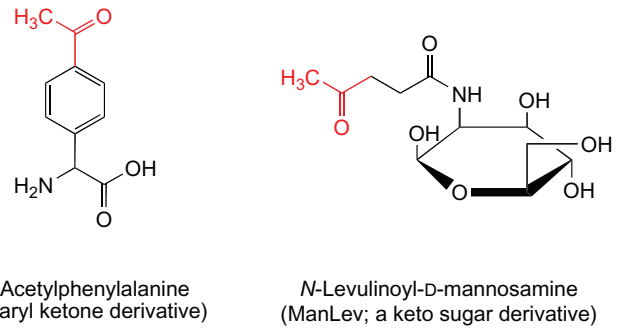
Chemoselective ligation reactions using the Diels–Alder cycloaddition process offer another bioconjugation route using a reactive component available commercially (maleimide-containing reagents). However, their use as true bioorthogonal reactants is limited due to the cross-reactivity of maleimides toward thiols. For instance, in the modification of a Rab protein, a cysteine residue had to be protected prior to cycloaddition using a maleimide compound (de Araujo *et al.*, 2006); otherwise, the maleimide would have coupled to the sulfhydryl, too.



2. HYDRAZINE–ALDEHYDE REAGENT PAIRS

The reaction between an aldehyde or ketone and a hydrazide or hydrazine derivative to form a hydrazone bond has been frequently used for bioconjugation purposes (Chapter 3, Section 5.1). The reaction is appealing from a bioorthogonal perspective, because natural biopolymers do not normally contain these reactive groups. Although aldehydes may form temporary Schiff base interactions with amines on proteins and other biomolecules, in aqueous solution they are fully reversible and will rapidly exchange with a hydrazide or hydrazine, if present. This also holds true of aminooxy (hydroxylamine) derivatives, which form stable oxime bonds with aldehydes, although the number of reagents available with an aminooxy functionality is limited, these reagents are growing in popularity.

The only potential problem of cross-reactivity for this chemoselective reaction pair with molecules of biological origin might occur from a hydrazine reacting with aldehyde- or ketone-containing metabolic intermediates, reducing sugars, or similar small organic molecules present within cells or cell lysates. However, if the hydrazine reagent is added in sufficient excess, the desired coupling reaction will still occur in such environments, as evidenced by the many successful bioconjugation reactions carried out with oxidized glycoproteins on cell surfaces or in lysates (Bayer and Wilchek, 1990; Bayer *et al.*, 1987a,b; 1990).

The hydrazine–aldehyde reaction has been used intracellularly to deliver nontoxic drug components, which when linked to form a hydrazone bond *in situ*, become cytotoxic (Rideout, 1986, 1994; Rideout *et al.*, 1990). This same approach has been used to generate enzyme inhibitors *in vivo*, wherein the hydrazine and aldehyde precursors are not active, but when coupled together within cells to form a hydrazone linkage, become active site binders (Rotenberg *et al.*, 1991).

Ketone-containing bio-monomer analogs have been used successfully to incorporate these functionalities into biopolymers, such as proteins and carbohydrates (glycans). For example, a phenylalanine analog containing a *para*-substituted aryl ketone group is able to be transformed into an aminoacyl t-RNA and then introduced with sequence specificity into a protein by cellular ribosomal machinery (Datta *et al.*, 2002). In addition, the post-translational glycosylation process within cells is tolerant of certain sugar analogs, and ketone derivatives of monosaccharides have been used to incorporate these functions into glycans. In particular, growing cells in the presence of *N*-levulinoyl-D-mannosamine (ManLev; Figure 17.4) was found to result in the incorporation of this ketone sugar into cell surface carbohydrates through enzymatic transformation into a keto sialic acid (Mahal *et al.*, 1997; Lemieux and Bertozzi, 1999). Since sialic acid residues are terminal sugars on most mammalian cell surface glycoproteins, the addition of pendent ketone groups allows for specific targeting of these glycans with hydrazine (hydrazide/aminooxy) based reagents.

p-Acetylphenylalanine (an aryl ketone derivative)

N-Levulinoyl-D-mannosamine (ManLev; a keto sugar derivative)

FIGURE 17.4 Ketone derivatives of phenylalanine and mannose can be fed to cells to incorporate the monomers into proteins and glycans. The resultant modifications can be probed using hydrazide-containing reagents.

There are many bioconjugate reagents and probes available with aldehyde or hydrazide functional groups that may be used for hydrazone bond formation. However, the best choices for making this reaction as chemoselective and bioorthogonal as possible are aromatic aldehyde and aromatic hydrazine derivatives due to their extremely low reactivity with biological functional groups, minimal nonspecific interactions with biomolecules (charge or Schiff base formation), and their highly efficient hydrazone bond formation in complex aqueous solutions (Solulink). Reagents of this type typically contain reactive groups consisting of either an aryl aldehyde (benzaldehyde) or a 6-hydrazinium nicotinate (Schwartz *et al.*, 1993, 1995).

These aldehyde and hydrazine functionalities can be associated with virtually any other reactive group or tag, such as heterobifunctional crosslinkers, fluorescent labels, or biotin compounds. Two reagents frequently used to chemically introduce the aldehyde and hydrazine groups include SANH (succinimidyl 4-hydrazinonicotinate acetone hydrazone) and SFB (succinimidyl 4-formylbenzoate) (Figure 17.5). Long-chain analogs of these two compounds also exist, which contain either a 6-aminocaproyl spacer arm in the cross-bridge or a short PEG spacer to promote increased water solubility. The SFB and SANH NHS ester compounds are amine-reactive and form amide bonds with the molecules modified by them (Figure 17.6). Other reactive groups or tags are also available having the benzaldehyde or hydrazinium nicotinate groups, including maleimide (thiol-reactive), biotin, and various fluorescent probes (Solulink).

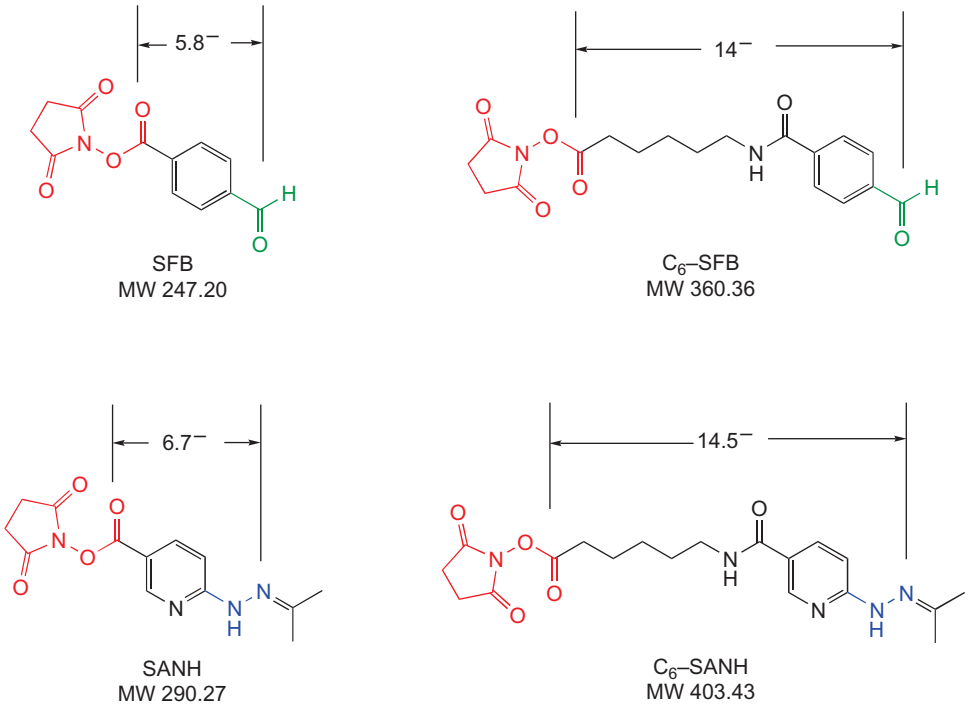


FIGURE 17.5 Structures of aldehyde-containing and hydrazine-containing heterobifunctional crosslinkers that can be used in chemoselective hydrazone conjugation procedures.

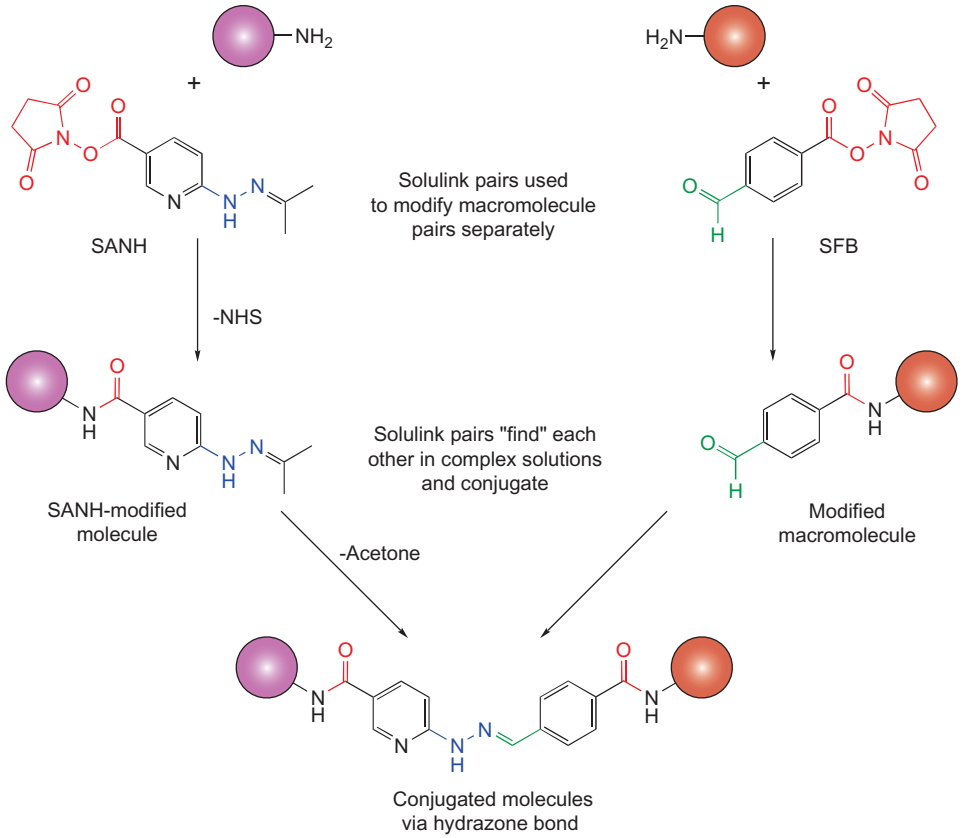

FIGURE 17.6 The reaction of SANH with amine-containing proteins or other molecules results in amide bond modifications containing terminal hydrazine groups. The reaction of SFB with amine-containing proteins or other molecules results in amide bond modifications containing terminal aldehyde groups. Subsequently, the two modified molecules can be reacted together to create a conjugate via hydrazone bond formation.

The hydrazinium nicotinate group on these reagents commonly is protected against reaction with the active ester by the addition of acetone to form the acetone hydrazone derivative. This hydrazone protective group is readily reversible at neutral or mildly acidic pH and will immediately exchange with a benzaldehyde on the corresponding chemoselective partner to form a stable hydrazone linkage.

Proteins, other molecules, or surfaces that are activated to contain either the benzaldehyde functionality or the hydrazinium nicotinate group can be quantified as to the number of these groups present using certain chromophoric reactants. For instance, 2-hydrazinopyridine can be reacted with a benzaldehyde-containing molecule to give a UV-absorbing derivative with $\lambda_{max} = 350\,nm$ and an extinction coefficient of $18{,}000\,M^{-1}\,cm^{-1}$. Conversely, the hydrazinium nicotinate-activated molecules can be reacted with *p*-nitrobenzaldehyde to create another UV detectable derivative having $\lambda_{max} = 390\,nm$ with an extinction coefficient of $24{,}000\,M^{-1}\,cm^{-1}$.

The aromatic nature of the SFB and SANH reactants create a hydrazone structure with unique absorptivity for monitoring the course of the ligation process. The aromatic hydrazone bond has a maximal absorbance at 354 nm and a molar extinction coefficient equal to 29,000/M. If the conjugation reaction is carried out with sufficient amounts of benzaldehyde and hydrazinium nicotinate reactants, then the yield of the reaction can be directly measured by monitoring the change in absorbance at this wavelength over time.

The *bis*-aryl hydrazone bond formed by this reaction is stable in aqueous solution over a broad pH range (pH 2–11) and under elevated temperature conditions (up to 94°C) (Solulink website).

Kozlov *et al.* (2004) used SANH and SFB to create DNA–antibody conjugates for highly sensitive detection in immunoassays using PCR amplification with fluorescently labeled primers. They also investigated hydrazone bond formation and its stability in aqueous solution using 3′- and 5′-labeled DNA pairs, wherein one oligonucleotide contained a benzaldehyde group and the other contained the hydrazinium nicotinate group. It was found that the most efficient pH for the creation of the hydrazone bond was pH 5.0 to 7.0, with an optimum at about pH 6 and yields dropping off at lower or higher pH. In addition, once the hydrazone bond was formed and the conjugate purified, it was stable in PBS buffer, pH 7.2, with or without 10 mg/ml BSA for 12 weeks at 4°C. The hydrazone linkage was also found to be stable at pH values between 2.3 and 11.3 without hydrolytic breakdown.

When reactions between the benzaldehyde and hydrazinium nicotinate groups are done in relatively dilute solution, for example using a modified antibody molecule at 1 mg/ml (~6 μ*M*) containing one of the two reactants, then to obtain maximal yield of the hydrazone conjugate, the second component should be added in sufficient excess to drive the reaction to completion. Kozlov *et al.* (2004) found that at least an 8-fold molar excess or above of the second reactant over the first reactant is necessary to obtain a yield of about 80% hydrazone bond formation.

The practical use of chemoselective ligation reactions for bioconjugation purposes involves the attachment of one of the reactants to a first biomolecule using a standard coupling chemistry (e.g., NHS ester) to an available functional group, while the second reactant is coupled to a second molecule or a surface, depending on the final conjugate desired. In this regard, the following protocols for modification of oligonucleotides or proteins can be carried out with either the benzaldehyde component or the hydrazine component and the opposite reactant is used to modify another molecule or surface that will be coupled in the final conjugation step.

Protocol for Modification of Amine–Oligo with SANH or SFB

1. Dissolve a 5′-amine modified oligonucleotide at a concentration of 0.5-m*M* in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4.
2. Dissolve SANH (or SFB) in DMF at a concentration of 100-m*M*. Note: Both reagents are soluble in this solvent to about 50-mg/ml concentration.
3. Add a quantity of SANH or SFB solution to the oligo to provide a 40-fold molar excess of crosslinker over the amount of amine–oligo present. Mix well.
4. React at room temperature for 2 h to overnight with gentle mixing.
5. Purify the modified oligo from unreacted crosslinker and reaction byproducts using a micro-spin concentrator with a membrane having a molecular weight cutoff able to retain the size of the DNA being modified.

A similar method can be used to modify proteins, such as antibodies, to contain either benzaldehyde or hydrazinium nicotinate groups for subsequent conjugation with another molecule modified by the opposite functionality. The following protocol is based on the methods of Solulink, and Kozlov *et al.* (2004).

Protocol for Modification of Protein or Antibody with SANH or SFB

1. Dissolve the protein or antibody to be conjugated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4. The antibody solution should be as concentrated as possible, given the amount of antibody available for modification. This general protocol will work for protein or antibody concentrations ranging from

about 0.5 mg/ml to 10 mg/ml, but an increase in the molar excess of either SANH or SFB may have to be made at lower antibody concentrations to provide the same modification yields obtained at higher concentrations.
2. Dissolve SANH or SFB in DMF at a concentration of 2 mg/100 µl DMF.
3. Add a quantity of the crosslinker solution of choice (SANH or SFB) to the antibody solution to obtain the desired molar excess of reagent over the antibody. Typically, antibody modification procedures are done with 10- to 20-fold molar excess, but for dilute antibody concentrations, this may have to be doubled, depending on how many hydrazine or aldehyde groups are desired to be introduced on the modified antibody.
4. React for 2 to 3 h at room temperature with gentle mixing.
5. Purify the modified antibody by use of size exclusion chromatography or dialysis, using a molecular weight exclusion limit of 5000 to 10,000 Daltons. The modified antibody may be stored at 4°C or frozen until used to make a conjugate. The protected hydrazine on SANH is stable for several months and the SFB benzaldehyde group is stable indefinitely. For longer storage, the modified antibody can be lyophilized.

Once a molecule is modified with a hydrazine reagent and another molecule is modified with the benzaldehyde compound, they may be combined to form the final conjugate, which will result in a hydrazone linkage between the two molecules. In addition, chemoselective ligation using aldehyde/hydrazine reactions may be carried out to immobilize biomolecules. In this regard, one modified component may be a surface and the other one an antibody, protein, or oligonucleotide destined for immobilization onto the surface.

2.1. Conjugation using the Aldehyde/Hydrazine Reaction

1. Separately dissolve the SFB-modified molecule and the SANH-modified molecule in citrate buffer (100-m*M* sodium citrate, 150-m*M* NaCl, pH 6.0) at concentrations of at least 1 mg/ml. Note that pH 6 is an optimal pH for the formation of the hydrazone bond, but pH values slightly lower (to pH 4.7) or higher (to pH 7.4) may also work, but they will result in lower reaction rates and lower yields.
2. Mix a portion of the SFB-modified molecule with the SANH-modified molecule to obtain a molar ratio that will give the desired conjugate properties. The optimal ratio of reactants may have to be determined experimentally by performing a series of conjugations using different molar ratios and testing the performance of the final conjugate in the intended application.
3. React for at least 2 h at room temperature, longer if pH values other than pH 6 are used.
4. To purify the conjugate from reactants that did get incorporated into the conjugate, size exclusion chromatography may be used with resins having a molecular exclusion limit able to accommodate both the labeled molecules and the final conjugate.

3. AMINOOXY–ALDEHYDE REAGENT PAIRS

The chemoselective ligation of an aminooxy group ($R–ONH_2$) with an aldehyde is similar to that of the reaction of a hydrazide with an aldehyde (see previous section), except instead of giving a hydrazone bond it yields an oxime linkage. This aminooxy–aldehyde pair of reactants has been used in many bioconjugation reactions, including the coupling of ligands to surfaces, for the synthesis of radiohalogenated compounds, and in the synthesis of drug candidates (Thumshirn *et al.*, 2003; Poethko *et al.*, 2004; Liu *et al.*, 2007; Colombo and Bianchi, 2010; Mezö *et al.*, 2011). The reaction of aminooxy groups with ketones is also quite efficient and generally gives better yields than the reaction of hydrazide groups with ketones.

The simplest form of this reaction occurs with aldehydes or ketones as they react with the small molecule hydroxylamine (Figure 17.7). An organic hydroxylamine derivative is typically called an aminooxy group, which can also be termed an aminoxy or alkoxyamine group. The aminooxy compound of this reaction contains an organic substituent off the oxygen of hydroxylamine, which can consist of virtually any organic compound that terminates in the ONH_2 group. Oxime formation usually occurs more rapidly than in the reaction between a hydrazide group and an aldehyde or ketone and it typically provides a more stable oxime bond than a hydrazone bond. The bioorthogonal nature of this reaction is not absolute, however, as a number

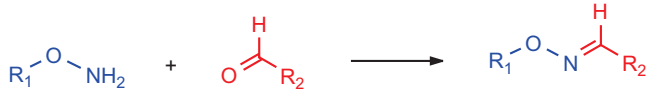

FIGURE 17.7 The reaction of an aminooxy derivative with an aldehyde (or ketone) compound forms a stable oxime linkage.

of small metabolites in biological systems contain aldehyde or ketone groups, which may participate in the reaction with an aminooxy group. The reaction can be used to probe unnatural aldehyde-containing sugar or amino acid derivatives in glycans, carbohydrates, or proteins within cells using aminooxy reagents.

The presence of an aminooxy group on a crosslinking reagent can be used to chemoselectively react with other compounds or biomolecules containing an aldehyde or ketone group. In particular, hydrophilic discrete PEG-based reagents are available that contain a protected aminooxy group, such as the phthalimidooxy–dPEG$_{12}$–NHS ester (Quanta Biodesign). This crosslinker has a phthalimide-protected aminooxy group on one end and an amine-reactive NHS ester on the other end that can be used to modify amine molecules to contain the protected aminooxy group. Without the protecting group being present, the NHS ester end of the compound would simply react with the aminooxy end. The phthalimide group prevents this from occurring until the NHS ester end is first used to label an amine-containing molecule. The result of this reaction will be the formation of an amide bond with the amine-containing molecule, which will create a derivative with hydrophilic PEG$_{12}$ chains that terminate in the protected aminooxy function. The subsequent removal of the phthalimide protecting group can be done with 0.5-*M* hydrazine (toxic) in aqueous solution, which then yields the free aminooxy-modified molecule (Figure 17.8).

The creation of aminooxy groups on surfaces or substrates has been used to covalently array proteins to form nano-patterns on silicon wafers and other surface materials. In one example, the aminooxy functionalities were coated on the surface of wafers using 8-arm PEG derivatives (Christman *et al.*, 2008). Coupling proteins to the surface aminooxy groups could be carried out after modification of the protein with an aryl aldehyde-containing crosslinker, such as 4-formyl-benzamido–dPEG$_{12}$–TFP ester (Quanta Biodesign). The reaction of this compound with the amine groups on proteins will create amide bonds through the reaction of the TFP ester side of the crosslinker and thus leave the aryl aldehyde groups available to react with an aminooxy-modified surface or another aminooxy-modified molecule (Figure 17.9). Both the aminooxy and aryl aldehyde groups have little to no reactivity with biological macromolecules, thus ensuring that a bioorthogonal reaction will occur only with each other to form the oxime linkage. In addition, aryl aldehyde groups only have a weak tendency to form Schiff base interactions with amines, so side reactions usually do not occur with this aldehyde.

The reaction of an aminooxy group with an aldehyde- or ketone-containing molecule can be accelerated by the addition of an aniline catalyst. As in the formation of

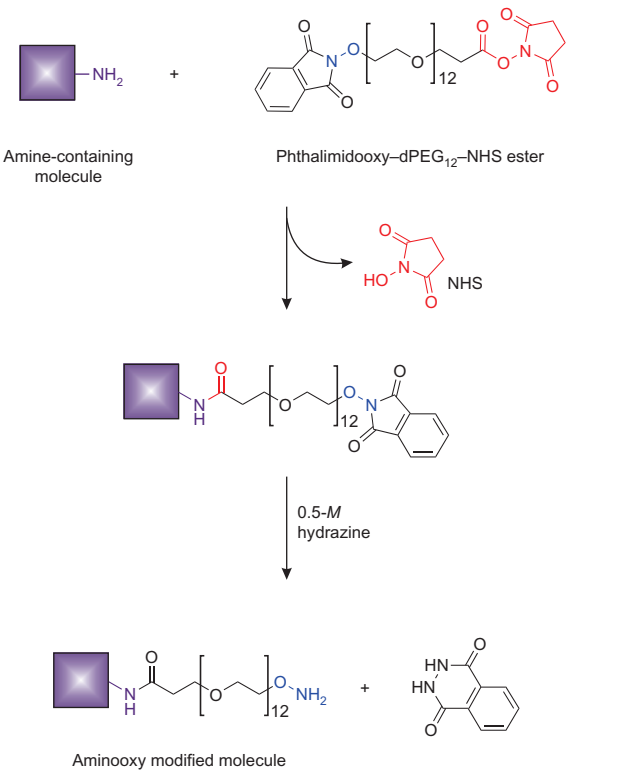

FIGURE 17.8 The modification of an amine-containing molecule with phthalimidooxy-dPEG$_{12}$-NHS ester proceeds through the reactive ester end to form an amide bond derivative. The protected aminooxy group can be removed using an aqueous solution of hydrazine to yield the aminooxy group available for further conjugation with aldehyde- or ketone-containing reagents.

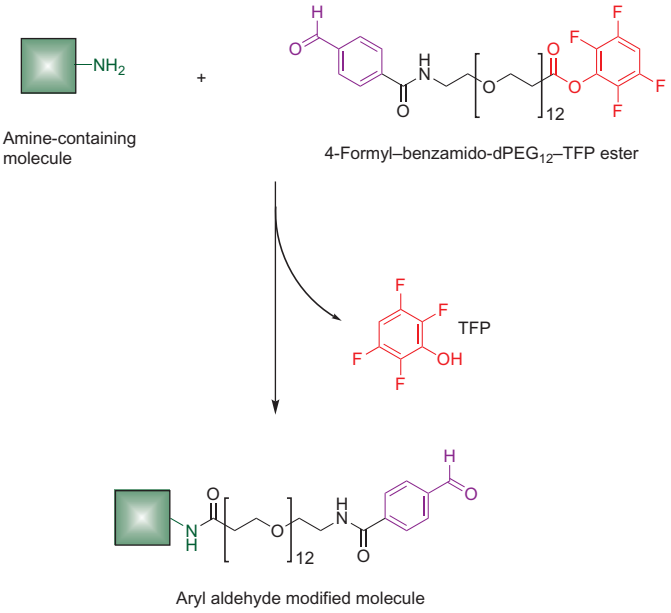

FIGURE 17.9 The modification of an amine-containing molecule with 4-formyl-benzamido–dPEG$_{12}$–TFP ester occurs by reaction at the ester end to form an amide bond derivative with loss of the TFP group. The aryl aldehyde can then be used to conjugate with aminooxy-containing reagents.

hydrazone linkages between aldehydes and hydrazides, the formation of an oxime bond between an aldehyde or ketone and an aminoxy is dramatically increased in rate and yield by the presence of aniline (Cordes and Jencks, 1962; Dirksen *et al.*, 2006a,b; Dirksen and Dawson, 2008; Byeon *et al.*, 2010). During this reaction, the aromatic amine on aniline first reacts with the aldehyde or ketone group to form an intermediate imine, which then reacts with the aminooxy group to create the final oxime linkage (Figure 17.10) (Kohler, 2009).

The aniline-catalyzed reaction was studied in detail to determine its kinetics under various conditions (Lempens *et al.*, 2009). A peptide was modified to contain an N-terminal aldehyde residue made via the pyridoxyl 5′-phosphate/sodium periodate method of Gilmore *et al.* (2006a,b) (see also Scheck and Francis, 2007; Scheck *et al.*, 2008). It was found that the aniline catalyst dramatically increased the reaction rate and coupling efficiency at all pH values studied, with the greatest rate and yield obtained at pH 4.5. The rate at pH 6.0 was less than half that observed at the lower pH condition; however, the positive difference between a catalyzed and an uncatalyzed reaction was significant at all the acidic pH environments studied.

The aminooxy–aldehyde chemoselective ligation reaction has been used to make peptide–drug conjugates (Mezö *et al.*, 2011), to label aldehyde-containing unnatural glycans with aminooxy reagents (Hudak *et al.*, 2011), for tethering bioactive molecules to platinum prodrugs for cancer therapy (Wong *et al.*, 2012), for immobilization of peptides and proteins on biosensor surfaces (Lempens *et al.*, 2011), and for the detection of sialic acid groups on glycans using an aminooxy derivative of nitrobenzoxadiazole fluorophore (Key *et al.*, 2012).

The conditions and methods for performing the reaction of an aminooxy-containing molecule with an aldehyde- or ketone-containing molecule can be found in Chapter 15, Section 2.4, including the use of aniline as a catalyst. The modification of proteins and other molecules

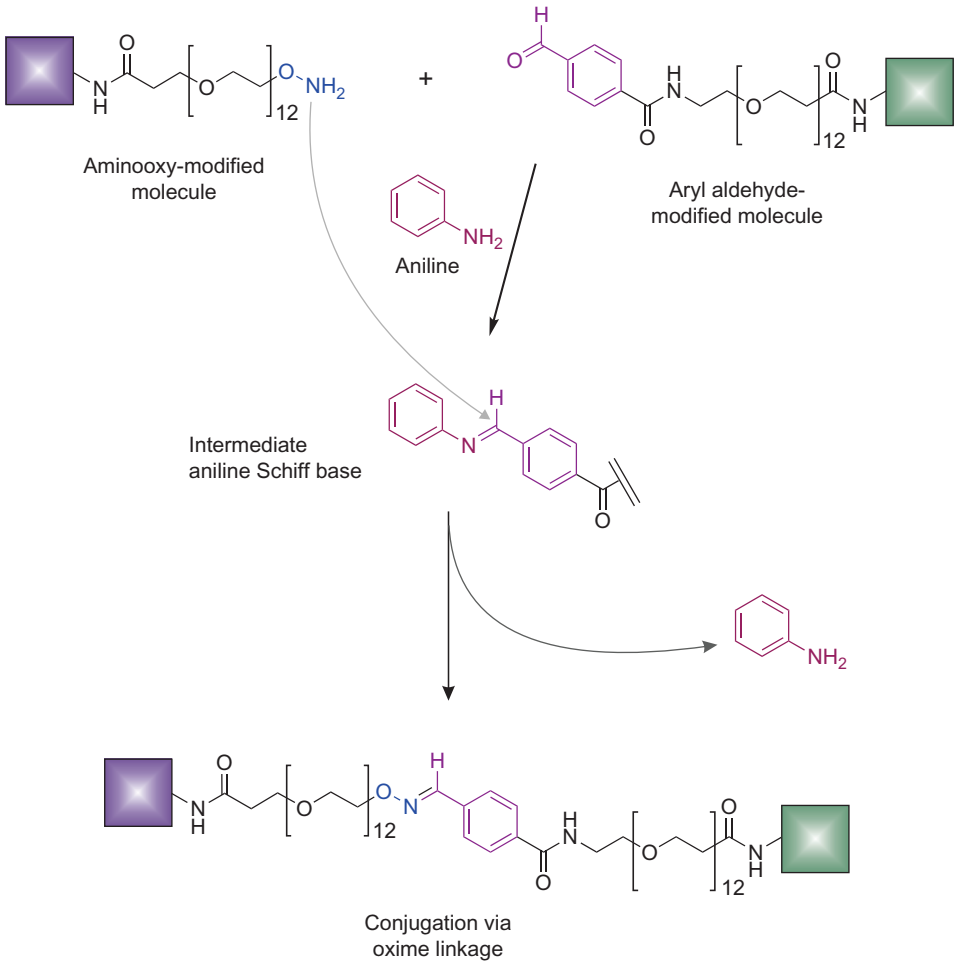

FIGURE 17.10 The chemoselective reaction between an aminooxy-modified molecule and an aryl aldehyde-modified molecule using aniline as the catalyst. With aniline in excess, the initial reaction is to form an imine intermediate (Schiff base) with the aniline amino group. This imine is subsequently displaced by the aminooxy group to form the oxime bonded conjugate in high yield.

using the crosslinking reagents 4-formyl-benzamido–$dPEG_{12}$–TFP ester and phthalimidooxy–$dPEG_{12}$–NHS ester can be found in Chapter 18, Section 1.2.

4. BORONIC ACID–SALICYLHYDROXAMATE REAGENT PAIRS

Phenylboronic acid (PBA) groups can interact with a variety of polar constituents on adjacent or nearby carbon atoms to result in a complex consisting of a 5- or 6-member heterocyclic ring. This process has been used for the affinity chromatographic purification of carbohydrates, glycoproteins, RNA, AMP (from cAMP), glycated proteins (such as glycated hemoglobin formed in diabetes; Klenk *et al.*, 1982), and a range of small molecules containing 1,2- or 1,3-diols, 1,2- or 1,3-hydroxy acids, 1,2- or 1,3-hydroxylamines, 1-2- or 1,3-hydroxyamide, 1,2- or 1,3-hydroxyoxime, as well as various sugars containing these species (Weith at al., 1970; Rosenberg and Gilham, 1971; Rosenberg *et al.*, 1972; Pace and Pace, 1980; Singhal *et al.*, 1980). For a review on the use of phenylboronic acid in affinity separations, see Scouten (1983). In addition, bioconjugate labeling reagents containing a PBA group have also been used as probes of these species in biological molecules, including fluorescent reagents for targeting glycans on cell surfaces (Burnett *et al.*, 1980; O'Shannessy and Quarles, 1987).

The interaction of PBA derivatives with molecular species having the above functional groups occurs optimally in the pH range of 8 to 9, but it is typically reversible at acid pH or in the presence of a high concentration of competing ligand. However, the heterocyclic boronic acid complex is relatively stable under optimal conditions of formation.

Stolowitz (1997) exploited this interaction potential in the design of a new chemoselective bioconjugation reagent pair consisting of a PBA group on one reagent and a salicylhydroxamic acid (SHA) group on a second reagent. Each reactant of the pair can be used to modify biomolecules, surfaces, or other compounds for subsequent conjugation or immobilization through specific PBA–SHA ring formation (Springer *et al.*, 2002). The major product of this reaction forms a 6-membered ring structure consisting of the PBA's boron atom along with one of its oxygens coordinated with the SHA's hydroxyl oxygen and hydroxamate nitrogen atoms (Figure 17.11). It also is possible that a 5-membered ring structure can form from interaction of the PBA boron with the hydroxamate hydroxyl and carbonyl oxygens on SHA, but this is a minor product as proven by NMR (Stolowitz *et al.*, 2001).

A significant advancement in the PBA reagent was to add another boronic acid group to the phenyl ring and thus allow two cycloaddition products to form from a single complexation. The phenyldiboronic acid (PDBA) group effectively increases the affinity constant of the interaction if reacting with SHA-modified molecules or surfaces that have more than one near-neighbor SHA group available. The resultant formation of two 6-membered rings per conjugation reaction assures that the bond will not hydrolyze even under high or low pH conditions. This is particularly useful for using the reaction to couple proteins or other molecules to surfaces for arrays, because multiple linkages maintain stability of the immobilized molecule without the possibility for leaching off. A single SHA–PBA bond reportedly has an affinity constant in the range of $10^6 M^{-1}$, which is relatively weak for affinity binding properties. Two such bonds, however effectively raise the avidity to an observed affinity constant of $>10^{10} M^{-1}$ (Lonza product information). Note that multiple single PBA groups also can combine with multiple SHA groups when conjugating proteins together or proteins to surfaces and thus increase the effective avidity of the resultant bonding interaction. Springer *et al.* (2003) described the use of SHA membranes in this process for the immobilization

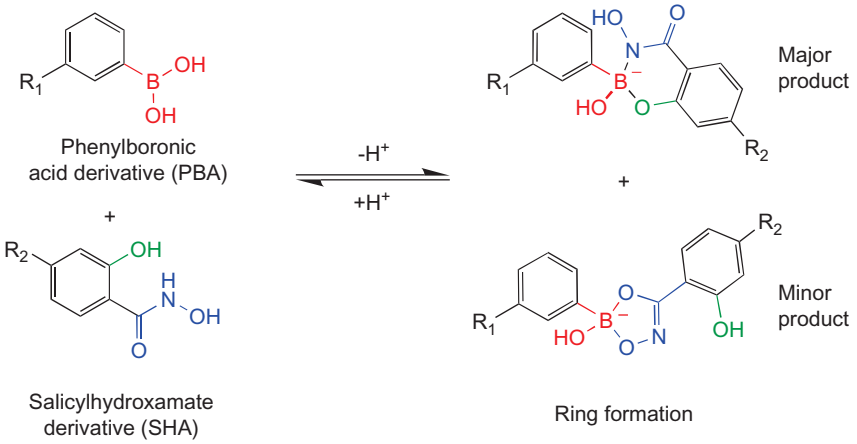

FIGURE 17.11 Phenylboronic acid derivatives react with salicylhydroxamate derivatives to form 5-membered or 6-membered ring structures, with the 6-membered ring the major product.

of PDBA-modified molecules, including nucleic acids and proteins.

Complex formation between PBA or PDBA groups and the SHA group occurs in a wide range of buffer types from pH 5 to 9, and it can tolerate high salt conditions (to 1.5-*M*) or the presence of moderate amounts of water-miscible solvents, detergents, chaotropes, and denaturing agents commonly used when working with protein solutions.

Ring formation between SHA groups coupled to solid-phase matrices and ligands containing either PBA or PDBA groups have been investigated for the immobilization of affinity molecules for protein purification (Wiley *et al.*, 2001). Using the dimeric PDBA group, immobilization of modified alkaline phosphatase onto SHA–agarose resulted in good retention of enzyme activity plus high stability of the coupled protein. The immobilized protein was also stable to elution conditions of acidic (pH 2.5) or basic (pH 11) buffers without cleavage of the boronic acid complexes or leakage of coupled protein. This indicates that multivalent attachment points using PDBA instead of PBA result in high tolerance for extreme environmental conditions without hydrolysis.

Bergseid *et al.* (2002) also reported on the use of SHA-activated chromatography supports for the coupling of boronate-containing affinity ligands. In this case, immobilized RNase A was used to purify anti-RNase antibodies from antiserum samples. RNase A was modified with an NHS–PDBA crosslinker at a molar ratio of 100:1 (crosslinker:protein), purified to remove excess crosslinker, and then coupled to an SHA-agarose support in 0.1-*M* sodium bicarbonate, pH 8.0.

Prolinx originally developed the technology utilizing the SHA–PBA interaction and later portions of it were commercialized by Invitrogen and then Lonza (Cambrex; Versalinx reagents). A number of PDBA crosslinking agents are now available to introduce the diboronic acid group into biomolecules. These include heterobifunctional compounds containing an NHS ester (amine reactive), a hydrazide group (aldehyde reactive), a maleimide group (thiol reactive), a pyridyl disulfide group for reversible linkage to thiols or for thiolation of target molecules, and an iodoacetyl group for creating thioether bonds. SHA crosslinkers include a hydrazide-containing compound, an NHS ester, and a *bis*-SHA compound containing a hydrazide group. Some examples of these reagents are shown in Figure 17.12.

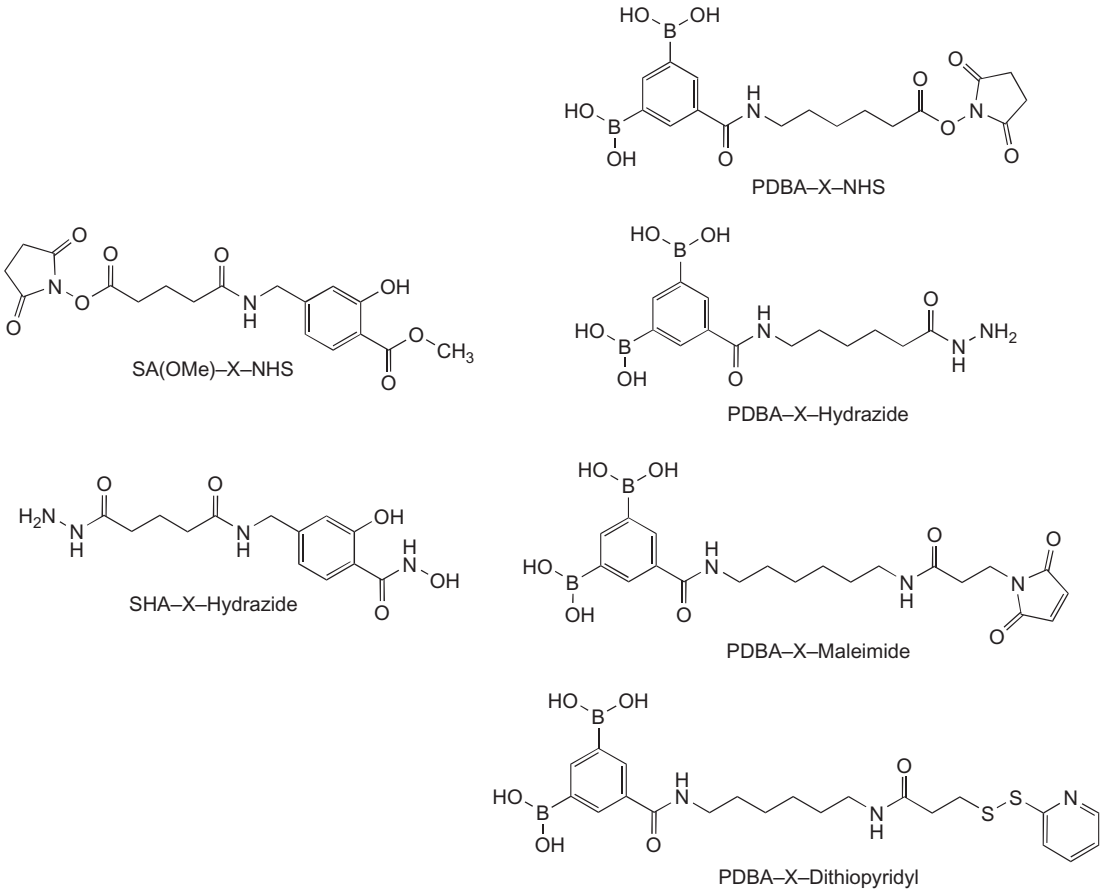

FIGURE 17.12 Heterobifunctional crosslinking agents containing the phenylboronic acid or salicylhydroxamate group for chemoselective conjugation purposes.

Conjugation reactions between phenylboronates and salicylhydroxamates entail the formation of a low-affinity interaction involving a reversible heterocyclic ring formation. Conjugates formed as a result of this reaction are relatively stable provided the pH is maintained within the optimal range and there are no competing species in solution, which may exchange for the SHA group. This may include sugars or carbohydrates containing diols or other organic constituents mentioned previously. The creation of dimeric or multivalent interactions with two or more SHA groups and a phenylboronate-modified molecule (using PBA or PDBA) will dramatically increase the stability of the linkage over that observed with a single PBA–SHA linkage. Wiley *et al.* (2001) found that modification of alkaline phosphatase with PBA or PDBA for subsequent immobilization on an SHA–agarose support resulted in stable immobilization if six PBA groups were present on each alkaline phosphatase molecule or the equivalent of three dimeric PDBA groups. This difference reflects the dimeric nature of the PDBA group in forming more than one boronate ring structure per modification.

The use of the PBA–SHA conjugation in a bioorthogonal mode will probably be problematic due to the potential side interactions that could occur involving the phenylboronate groups with biological molecules in cells or cell lysates. In addition, there are no reports of using SHA or PBA bio-monomer analogs (e.g., amino acids containing these groups) to incorporate into biopolymers *in vivo* as there are with other chemoselective reacting groups. However, the use of the PBA–SHA reaction as a chemoselective immobilization process for attaching proteins or other molecules to surfaces may have advantages over other bioconjugation reactive groups, because the reactive groups are very stable and will not hydrolyze in aqueous solution. In addition, the PBA–SHA reaction can be used with success for the conjugation of two pure biomolecules, such as in the creation of a protein–protein conjugate (Le Roch *et al.*, 2000).

The following protocol describes the immobilization of a protein on an amine-surface using the P(D)BA–SHA chemistry.

Protocol for Preparation of P(D)BA-Modified Protein

1. Dissolve a first protein to be modified at a concentration of 1 to 10 mg/ml in 0.1-*M* sodium bicarbonate buffer, pH 8.5. PBS buffer at physiological pH may also be used as the reaction medium.
2. Add a quantity of PDBA–NHS ester to the protein solution to provide the desired molar excess of crosslinker over the protein. A suggested starting point is to use a 10- to 15-fold molar excess of reagent, but the optimal amount to be added should be determined by experimentation to provide a final conjugate having the best possible properties for the intended application. The PDBA–NHS ester may first be dissolved in DMF as a concentrated stock solution and then an aliquot added to the reaction mixture. Mix well to dissolve.
3. React for at least 1 h at room temperature with gentle mixing.
4. Purify the modified protein by gel filtration or dialysis using a molecular weight cutoff that will be appropriate for the protein being modified.

Protocol for Preparation of SHA-Modified Surface

An amine-containing surface, such as an APTS-modified glass slide (see Chapter 13, Section 2), may be modified with a long-chain NHS–salicylic acid methyl ester derivative (Lonza), which then can be converted to the SHA group for coupling to a P(D)BA-modified protein. The following protocol describes this method.

1. Thoroughly wash the amine-containing slide with deionized water and then with 0.1-*M* sodium bicarbonate, pH 10 (coupling buffer).
2. Add a quantity of NHS–salicylic acid methyl ester reagent dissolved in coupling buffer to the slide surface to provide at least a 2 fold molar excess of crosslinker over the quantity of amines present on the surface. The surface of the slide may be coated with a minimum solution volume of the crosslinker by layering the solution over the surface. Slide masks or gaskets may be used to isolate only certain regions for modification. Alternatively, the slide may be immersed in the crosslinker solution. The NHS–salicylic acid methyl ester may first be dissolved in DMF as a concentrated stock solution and then an aliquot added to the reaction mixture to prepare the final concentration desired. Mix well to dissolve before immediately exposing the solution to the slide surface.
3. React for at least 1 h at room temperature with gentle mixing.
4. Wash the slide with 10 volumes of water.
5. Prepare a 1-*M* solution of hydroxylamine in coupling buffer sufficient to again treat the slide. The pH of the coupling buffer should be adjusted to pH 10 after dissolving the hydroxylamine into it. Expose the slide to the hydroxylamine solution in the same manner as the crosslinker treatment.

The hydroxylamine will react with the methyl ester groups on the salicylic acids and form hydroxamate functionalities suitable for conjugation with the P(D)BA-modified protein from above.

6. React the slide with the hydroxylamine solution for 16 to 24 h at room temperature.
7. Thoroughly wash the slide with coupling buffer and at least 10 volumes of water.

Protocol for Coupling PDBA-Modified Protein to SHA-Modified Slide

Proteins modified with boronic acid groups may be covalently linked to SHA-modified slides simply by spotting the PDBA-modified protein onto the slide surface in 0.1-*M* sodium bicarbonate buffer, pH 8.0. The arraying technique may use pin spotters, piezoelectric contactless printers, or even pipette dispensing into masked wells on the surface. The quantity of PDBA-modified protein placed on the surface should at least be in 2-fold molar excess to the theoretical density of SHA groups present. A large quantity of protein spotting may obviate a covalent attachment strategy by building up a "mountain" of dried protein, as is typically done using simple surface adsorption of protein to form array spots.

5. CLICK CHEMISTRY: CU(I)-PROMOTED AZIDE–ALKYNE [3 + 2] CYCLOADDITION

The 1,3-dipolar cycloaddition reactions to unsaturated carbon–carbon bonds have been known for quite some time and have become an important part of strategies for organic synthesis of many compounds (Smith and March, 2007). The 1,3-dipolar compounds that participate in this reaction include many of those that can be drawn having charged resonance hybrid structures, such as azides, diazoalkanes, nitriles, azomethine ylides, and aziridines, among others. The heterocyclic ring structures formed as the result of this reaction typically are triazoline, triazole, or pyrrolidine derivatives. In all cases, the product is a 5-membered heterocycle that contains components of both reactants and occurs with a reduction in the total bond unsaturation. In addition, this type of cycloaddition reaction can be carried out using carbon–carbon double bonds or triple bonds (alkynes).

The reaction between an azide and an alkyne has been referred to as the Huisgen cycloaddition reaction, after the name of its originator (Huisgen *et al.*, 1964). This type of reaction, shown in Figure 17.13 for both alkenes and alkynes, results in similar heterocycles only differing in a single carbon–carbon double bond within the ring. The Sharpless group has coined the term "click chemistry" to describe these reactions, because of the seemingly "spring-loaded" nature of the electrophiles that participate in it (for review, see Kolb *et al.*, 2001). It was also noticed that such reactions appear to be accelerated in aqueous solution compared to the same reactions carried out in organic solvent.

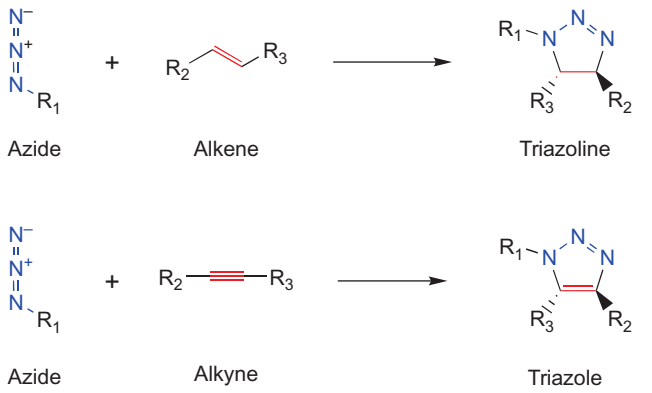

FIGURE 17.13 A general Huisgen reaction involves the cycloaddition of an azide with an alkene or an azide with an alkyne. The products of these reactions are a triazoline ring or a triazole ring, respectively.

Click chemistry reactions historically are done at elevated temperatures, and sometimes elevated pressures, to increase the rate of reaction and make the yield of heterocycle formation acceptable. However, it was discovered that in the presence of Cu(I), the reaction kinetics are dramatically accelerated to provide high yields even at room temperature and ambient pressures (Rostovtsev *et al.*, 2002; Tornøe *et al.*, 2002 Sharpless *et al.*, 2005). There was an early indication that Cu(I) could catalyze this process (L'Abbé, 1984), but it was not pursued further at that time, especially as a potentially useful bioconjugation method. In fact, in aqueous solution, the presence of only a small catalytic amount of Cu(I) in a click chemistry reaction can increase the rate of cycloaddition by about a million-fold, making the reaction biocompatible.

The copper-catalyzed azide–alkyne cycloaddition process has resulted in a proliferation of applications in organic synthesis and bioconjugation. There are hundreds of references to the use of this conjugation reaction for small molecule synthesis, protein conjugation, activity-based protein profiling, nucleic acid conjugation, surface modification, detection schemes, and *in vivo* targeting of molecules on cells. One of the primary reasons for the increasing popularity of the click chemistry reaction is the bioorthogonal nature of the two reacting groups.

Azides in particular are convenient electrophilic participants in the click chemistry reaction due to their ease of formation and stability. Alkyl azides undergo nearly no side reactions and are extremely stable in aqueous solution, even in the presence of complex biological material. Note that the aryl azides, which often are used as photoreactive crosslinking agents, are highly unstable to UV light or reducing agents and probably should be avoided for this purpose (although they may be perfectly good substrates for the click reaction).

Alkyne groups are also remarkably stable in biological solutions, provided they do not have an activating group adjacent to them, such as a carbonyl, which would make them predisposed to Michael-type addition reactions, especially with thiols. Adding an alkyne group to a modification reagent or a crosslinker can be as simple as coupling an activated carbonyl group with propargylamine, which forms the propargylamide linkage and creates a terminal acetylene group for conjugation. Link *et al.* (2004) synthesized a biotin–PEG–alkyne modification reagent using this strategy, which then could be used to modify proteins containing azide amino acids (Figure 17.14).

The functional groups used for click chemistry conjugations are completely unreactive toward biological molecules and virtually free of side reactions that otherwise would cause reagent instability in aqueous environments. This means that a molecule modified to contain an azide functionality would be able to react specifically with another molecule containing an alkyne group, even in the presence of biological fluids, cells, or cell lysates. In addition, without the presence of Cu(I), the azido-molecule and the alkyne-molecule would not react to an appreciable extent at room temperature even when placed together in solution. Only upon the addition of Cu(I) in sufficient concentration would the cycloaddition reaction take place and a triazole linkage be formed.

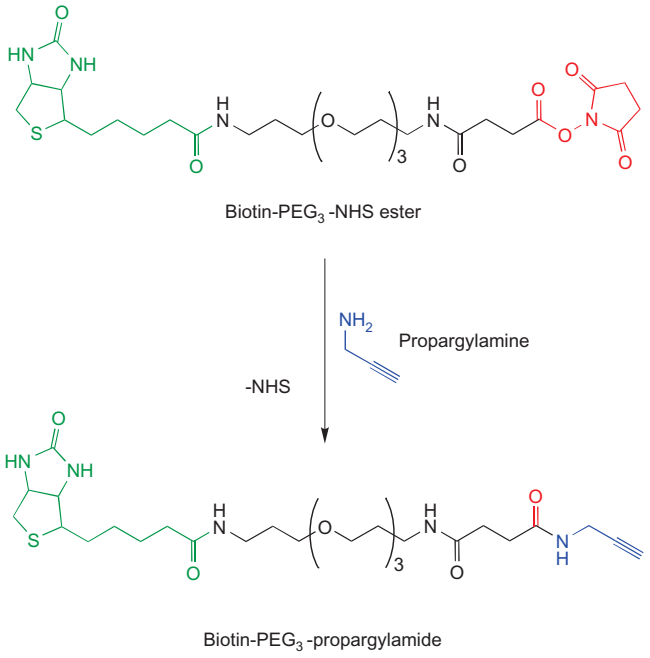

FIGURE 17.14 Propargylamine can be used to add an alkyne group to amine-reactive reagents, such as the NHS ester group on the biotin-PEG_3 compound.

The Cu(I) source used to drive the click reaction can be generated in several ways. The use of CuBr can be carried out to add Cu(I) directly to the reaction; however, Cu(I) salts are relatively impure and in solution they are labile and may degrade by oxidation to a significant extent over the time course of the reaction. The use of Cu(I) salts has also been found to result in some degree of side reaction products as well as needing an organic base and organic co-solvent during the reaction to efficiently drive the cycloaddition process. For these reasons, the source for Cu(I) typically is generated *in situ* using Cu(II) in the presence of a reducing agent.

The Cu(II) salt, $CuSO_4$, is particularly convenient, as it is readily available and easily converted to Cu(I) with a reducing agent, such as sodium ascorbate or TCEP. In solution, Cu(II) is reduced to Cu(I) by ascorbate with concomitant oxidation of ascorbate to dehydroascorbate. For reactions between pure click chemistry components in solution, the amount of catalyst addition only has to be from about 0.25 mole percent to 2 mole percent relative to the amount of reactants present, with a 5-fold molar excess of ascorbate over the amount of Cu(II). Therefore the reaction is initiated by production of only a small amount of Cu(I), which catalytically gets oxidized and then regenerated by reduction during the cycloaddition process. The proposed mechanism for the click chemistry reaction has been illustrated as a catalytic cycle by both the Meldal group (Tornøe *et al.*, 2002) and the Sharpless group (Rostovtsev *et al.*, 2002), giving a cyclic intermediate azide–Cu(I)–alkyne complex, which then goes on to form the 5-membered triazole ring.

Another source for Cu(I) in the click reaction is to use elemental copper metal filings, which generate Cu(I) ion in solution slowly by oxidation. This last option, however, is considerably slower in generating the necessary Cu(I) than the other methods and will result in reactions needing to be done for at least 24 h.

For click reactions made in complex solutions, such as in the presence of biological molecules, the amount of Cu(II) and ascorbate addition typically is at a concentration of at least 0.1-m*M* $CuSO_4$ and 0.2-m*M* ascorbate. In this type of environment, the labeling reaction usually is done on azide or alkyne

targets at very low concentration levels and for extended times. At this concentration of metal salt and ascorbate, cells may not remain viable for long periods and may die.

In some cases, click chemistry ligation reactions may not be appropriate for labeling within cells if continued cell viability is important. Live cell labeling requires that the conjugation chemistry not adversely affect cell viability or dramatically alter protein expression or pathway activation. Due to this limitation, the click chemistry reaction has been said to be undesirable for performing conjugations within a living cell, and only useful for labeling targets on live cell surfaces (Link and Tirrell, 2003; Prescher and Bertozzi, 2005).

However, some groups have worked around these issues and developed strategies for live cell labeling wherein the first step occurs *in vivo*, but then subsequent steps use *in vitro* cycloaddition for detection. Speers and Cravatt (2004a,b) used a click chemistry reactant to label enzymes *in vivo* at their active sites with an azide-substrate analog. Activity-based protein profiling (ABPP) typically involves using a binding probe along with a reactive group and a detectable tag, which is able to target specifically the binding site of an enzyme. The reactive group covalently links the affinity molecule to the active site, while the tag is used to image the enzyme *in vitro*. Using the click chemistry strategy, the active site binder in ABPP does not contain the detectable tag, but only possesses an azide group. The azide functionality is extremely stable *in vivo*, so the affinity reagent can be used in living cells or whole organisms. After incubation with the azide affinity component, the probe specifically interacts with the enzymes being targeted. Subsequently, the tissue or cells can be lysed (or fixed) and probed for bound enzyme using an alkyne-labeled reagent. This can be a fluorescent probe or an affinity handle, such as biotin, for purification.

In fact, most cell-based assays are done using fixed cells, not live cells, which makes click chemistry reactions eminently practicable. In this approach, a test population and a control population of cells is grown and after treating the test population of cells with a potential drug candidate or another modulator of cellular processes, they are compared relative to the expression of a biological component or the activity of a biomolecule. Most high-content screening assays are done on cells after a formaldehyde fixation step followed by a permeabilization process to allow passage of molecular probes into the cells (refer to Thermo Fisher Scientific, Cellomics). For these applications, the use of azide–alkyne reagents in a click chemistry strategy is entirely appropriate and may be the best choice of all conjugation reactions, because of its exquisite chemoselectivity, bioorthogonality, and excellent reaction kinetics.

The triazole ring generated by the reaction of an azide and an alkyne is a very stable linkage and not likely to undergo hydrolysis or any other breakdown reaction to cleave the linkage. Even under relatively extreme conditions used in some biological operations involving the addition of denaturants, detergents, chaotropic agents, organic solvents, or acidic or basic conditions, the triazole ring will survive and remain intact. Click chemistry reactions are thus highly chemoselective and result in strong conjugation bonds for use in any application.

Another important advantage to the use of click chemistry for cell-based targeting is the ability to create bio-monomer analogs containing either azido or alkyne functionalities, which then can be incorporated into biopolymers using a cell's native enzymatic machinery. Methionine and phenylalanine analogs containing side-chain alkyne or azide groups have been synthesized and proven able to be introduced into proteins at normal methionine sites in a sequence-specific manner (Link *et al.*, 2004; Prescher and Bertozzi, 2005). Kiick *et al.* (2002) also demonstrated that both azido and alkynyl amino acid derivatives could be used as methionine surrogates and get integrated into proteins with nearly the same efficiency as normal methionine. In addition, azide-sugar derivatives have been prepared that are capable of being incorporated into glycans and glycoconjugates using normal enzymatic biosynthetic pathways in cells (Saxon and Bertozzi, 2000). Thus, proteins and carbohydrates can be specifically tagged to contain non-canonical amino acids or sugars for subsequent bioconjugation using reagents containing the opposite click chemistry reactant (Figures 17.15 and 17.16). Cells grown in the presence of azido or alkyne monomer analogs will utilize these as building blocks for creating biopolymers. Proteins and glycans within the cells and on cell surfaces afterward display discrete bioconjugation targets for subsequent detection, cross-linking, or capture using click chemistry applications.

Lin *et al.* (2006) used click chemistry combined with site-specific labeling of recombinant protein using expressed protein ligation (EPL) (Muir, 2003) to couple proteins to array surfaces. A propargylamido-cysteine reagent was used to modify an expressed protein containing a thioester intein at its C-terminal. Reaction of the free thiol on the propargylamido–cysteine with the thioester linkage on the protein resulted in transthioesterification followed by an immediate S→N shift to give an amide bond between the alkyne compound and the protein (Figure 17.17).

Once the protein is modified to contain an alkynyl group at its C-terminal it can be used to covalently link to its click chemistry reactant partner, an azide on the surface of an array. Other azido molecules can also be

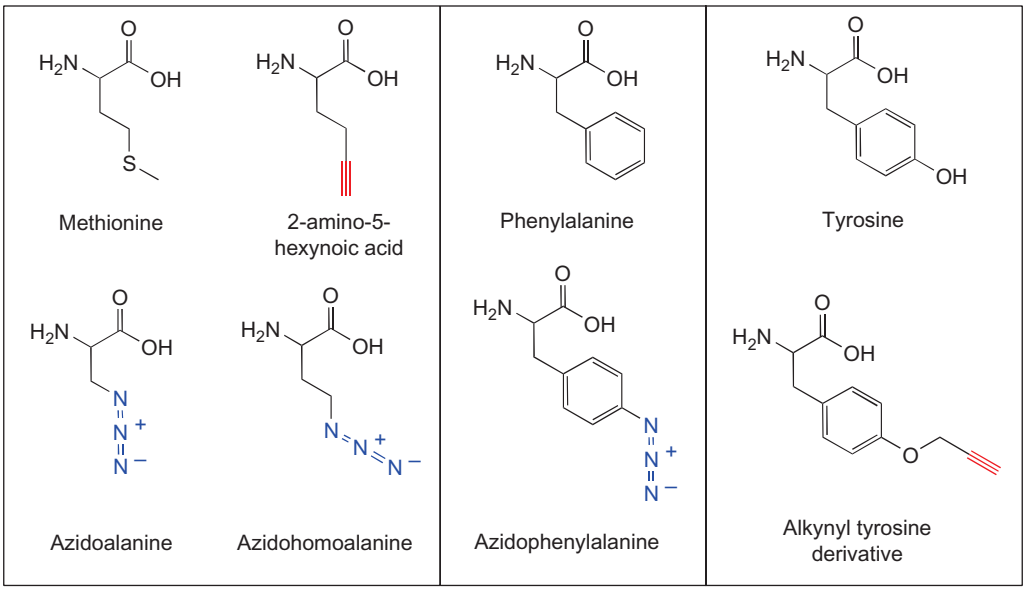

FIGURE 17.15 Amino acid analogs containing either azido or alkyne modifications can be fed to cells and these monomers incorporated into expressed proteins.

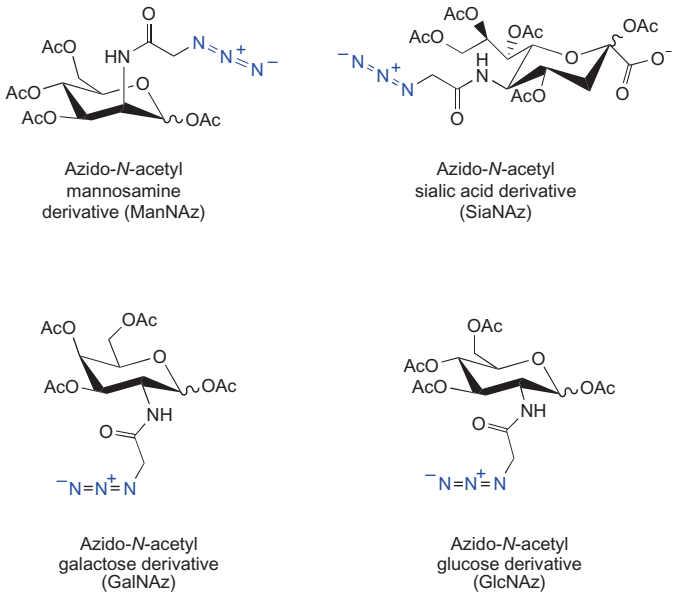

FIGURE 17.16 Azido derivatives of sugars can be used as monomers for glycan and carbohydrate synthesis by cells. Such modifications can be probed using click chemistry or Staudinger ligation reactions.

conjugated with an alkyne-labeled protein to facilitate the detection or capture of the protein using affinity techniques. For instance, an azido–fluorescein reagent can be used to detect fluorescently the expressed protein in complex samples or an azido–biotin derivative can be used to biotinylate the protein at its C-terminal for subsequent purification or detection (Figure 17.18).

In another application of coupling proteins to surfaces using click chemistry, Duckworth *et al.* (2006) carried out prenylation of a protein using a farnesyl azide derivative and the enzyme farnesyl transferase for subsequent chemoselective ligation to alkyne-functionalized agarose beads. The result is a highly discrete, site-specific attachment of the protein to the solid phase at a single location.

Bonnet *et al.* (2006) used the click chemistry reaction to synthesize receptor ligands containing fluorescent probes or biotin groups to specifically tag and detect or isolate receptor proteins. The efficiency of the click cycloaddition reaction catalyzed by Cu(I) presented many benefits over carrying out such synthesis by other routes. If receptor ligands can be modified to contain an alkyne group or an azide, then the opposite click chemistry reactant can be used on any number of probes to conjugate with the ligand for subsequent receptor probing applications.

Nanoparticles can also be modified with one of the click chemistry reactants to facilitate protein or ligand coupling to them in high yield. Brennan *et al.* (2006) modified gold nanoparticles with a thiol–azido spacer to produce azide functional groups on the particles for subsequent coupling of alkynyl–lipases. The thiol end formed a dative bond with the gold surface, which produced a long, hydrophilic, PEG-containing spacer terminating in an azide (Figure 17.19). Interaction of the alkynyl–lipase with the modified particles in the presence of Cu(I) resulted in triazole linkages, which efficiently immobilized the enzyme on the surface. The resultant enzyme–gold particles retained high enzymatic activity with an average of seven protein molecules conjugated per nanoparticle.

The following protocol adapted from Brennan *et al.* (2006) describes the coupling of alkyne-modified protein to 14-nm gold nanoparticles. The lipase enzyme

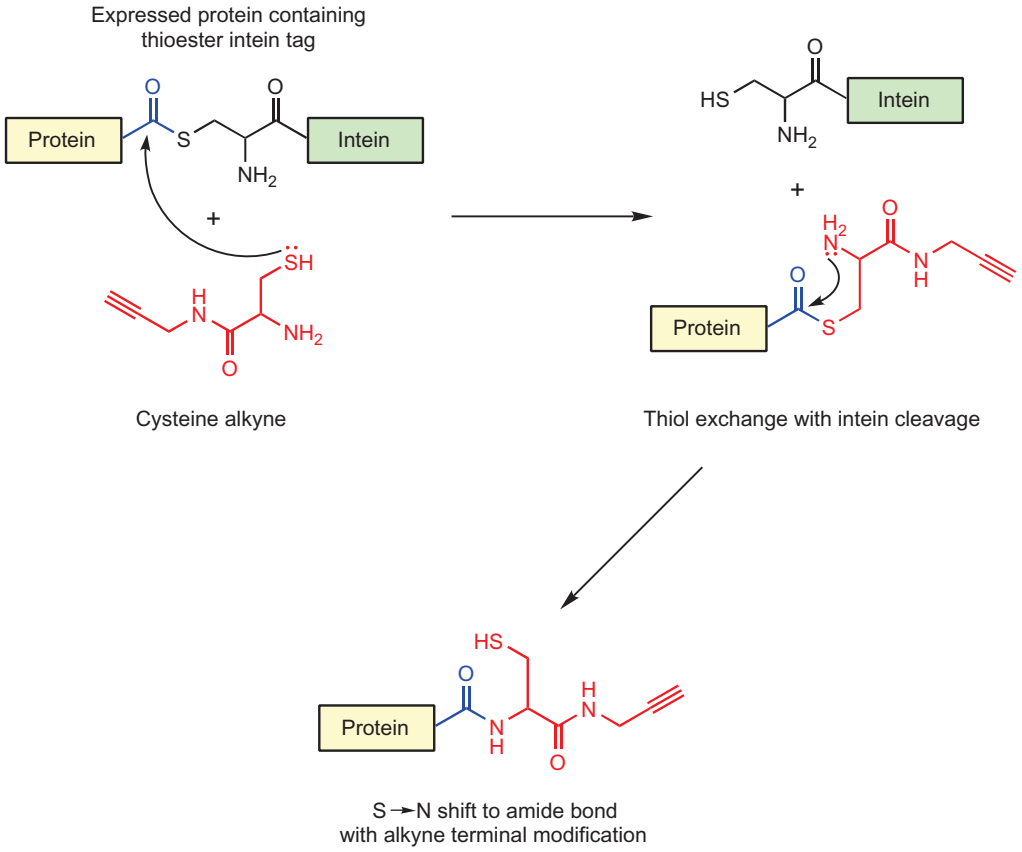

FIGURE 17.17 Expressed proteins containing a thioester intein tag can be specifically modified using a cysteine–alkyne derivative by trans-thioesterification followed by an internal S→N shift.

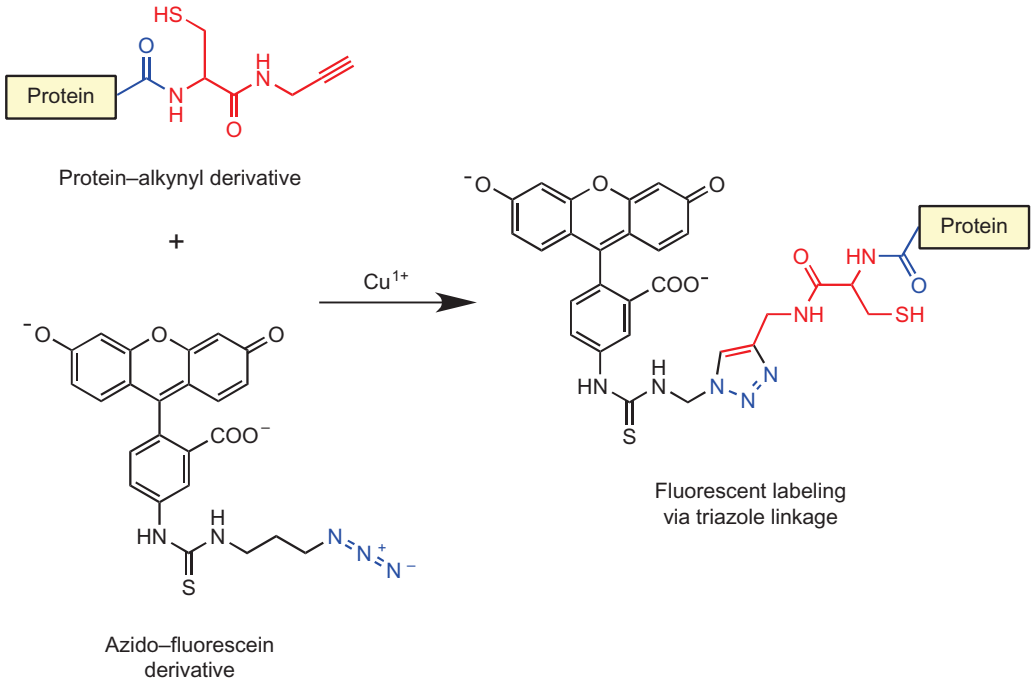

FIGURE 17.18 An expressed protein containing a thioester intein tag that was subsequently modified by native chemical ligation to contain an alkyne group can then be labeled using an azido–fluorescein probe by the click chemistry reaction in the presence of Cu^{1+}.

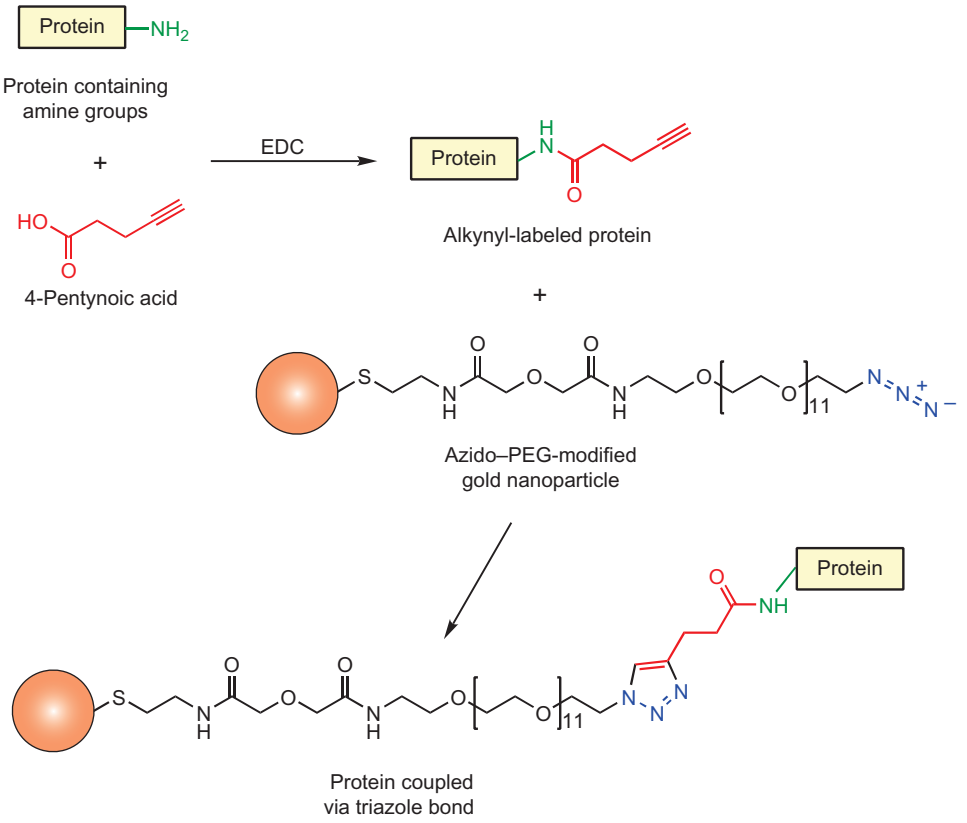

FIGURE 17.19 The small carboxylate–alkyne compound 4-pentynoic acid can be used to modify proteins at their amine groups with EDC to provide alkyne sites for click chemistry-mediated conjugation. The subsequent reaction of an azido–PEG-modified gold nanoparticle with the alkynyl-labeled protein in the presence of Cu^{1+} yields the triazole-coupled protein.

was engineered to contain a single lysine residue that was accessible to the aqueous environment for labeling with 4-pentynoic acid using carbodiimide coupling. This procedure is also applicable to other proteins containing lysine residues to add alkynyl groups for subsequent click chemistry conjugation procedures.

An alternative method of modifying proteins to contain alkyne groups is to use the propargyl–PEG_1–NHS ester compound described in Chapter 18, Section 1.2. This reagent will react spontaneously with available amine groups in proteins to form an amide bond without the need to use EDC, as in the following protocol.

Protocol for Modification of Protein with Alkynyl Groups

1. Dissolve a protein to be modified with an alkynyl group in 1.2 ml of 20-m*M* sodium phosphate, pH 7.0 (PBS), at a concentration of at least 20 µ*M*.
2. Prepare a stock solution of 4-pentynoic acid by dissolving it at a concentration of 100-m*M* in 50% THF/PBS. Add 6.7 µl of this solution to the protein solution with mixing.
3. Prepare a stock solution of EDC just prior to use by dissolving it in PBS at a concentration of 50-m*M*. Note: EDC is unstable in aqueous environments and should be used immediately after the solution is made. Quickly add 13 µl of the EDC solution to the protein solution with mixing.
4. Add to the reaction solution with mixing 150 µl of THF and 130 µl of PBS.
5. React with mixing in a fume hood overnight at room temperature. Note: This reaction may be complete within 2 to 4 h, as carbodiimide conjugations usually proceed to completion within this time frame.
6. Purify the alkynyl-protein by dialysis or gel filtration using PBS to remove excess reactants and solvent.

Protocol for Modification of Gold Nanoparticles with Thiol–PEG–Azide Linker

1. Gold nanoparticles (or other metallic or semiconductor particles) are functionalized with azide groups by suspending a 2.8-nm concentration of particles in 20 ml of water and adding a 20-µmole amount of a thiol–PEG–azide spacer ligand to the suspension with stirring.
2. Mix for 18 h at room temperature.
3. Purify the modified particles from excess linker by repeated centrifugation (at least three times at 15,000 *g*) and resuspending each time with water.

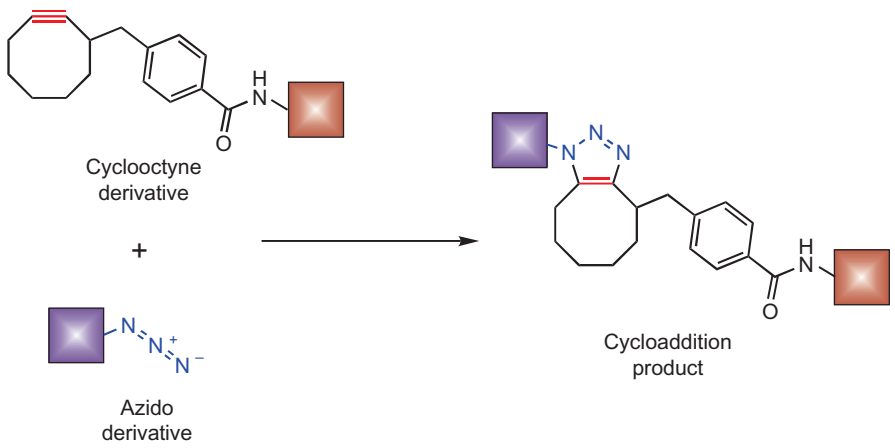

FIGURE 17.20 Cyclooctyne derivatives can be used as alternative click chemistry reactants, as they are capable of reacting with an azide group without the presence of Cu^{1+} to form a cycloaddition product. This reaction proceeds at a slower rate than the Cu^{1+}-catalyzed process, but it avoids the cytotoxic effects that copper addition can have on cells.

Protocol for Coupling Alkyne-Modified Protein to Azide-Nanoparticles

1. Suspend the azide-nanoparticles in water at a concentration of 13 nm.
2. With mixing, add a quantity of alkyne-modified protein to the particle suspension to provide at least a 10-fold molar excess over the quantity of azide groups present on the particles. The high molar excess is important to prevent particle aggregation if the modified protein has more than one alkyne group, which could crosslink more than one particle with a single protein, if the protein concentration is too low. However, if the modified protein only has a single alkyne modification, reacting it at a lower molar ratio is okay. For example, Brennan *et al.* (2006) added 36 µl of alkyne–lipase (69 µ*M*) in PBS buffer to 192 µl of azide-nanoparticles (13 nm).
3. Add 2.5 µl of 10-m*M* $CuSO_4.5H_2O$, 50-m*M* ascorbic acid dissolved in water per ml of the protein and particle mixture. Mix to dissolve.
4. React at room temperature for up to 3 days (or at 4°C, if the protein is not stable at ambient temperature). The optimal time of reaction is dependent on the protein being coupled and the number of alkyne reactive groups available. An alkynyl-protein added to the nanoparticles at a high molar ratio would probably reach maximal coupling yield in a matter of hours.
5. Purify the protein particles by repeated centrifugation (at least three times at 15,000 *g*) and resuspending each time with water.

In another application to couple ligands to surfaces, Sun *et al.* (2006) used two chemoselective ligation reactions, a Diels–Alder cycloaddition followed by an azide–alkyne (click chemistry) reaction, to immobilize protein, biotin, or carbohydrate ligands on glass slides. In this strategy, glass slides were prepared containing maleimidocaproyl groups, which were used in the Diels–Alder reaction to couple a PEG_4 spacer containing an alkyne on one end and a cyclopentadiene at the other end. The Diels–Alder reaction was used to link the cyclopentadiene to the maleimide groups, while the alkyne groups at the other end were used in the click chemistry reaction to attach the azide-containing ligands (see Figure 17.3).

Click chemistry reactant pairs used for surface immobilization have the advantage of being stable to aqueous conditions and long-term storage. Unlike many of the other coupling chemistries used with surfaces (e.g., NHS esters, EDC conjugation), which suffer from hydrolysis and degradation over time, the alkyne or azide components can be used to activate a surface and stored indefinitely until needed. A ligand modified with the opposite reactant can then be spotted on the array surface in the presence of Cu(I) to initiate covalent attachment through triazole ring formation.

Another version of the click chemistry azide/alkyne reaction has been developed to eliminate the requirement for Cu(I) to be added to catalyze the triazole ring formation. Agard *et al.* (2004) used a cyclooctyne ring to take the place of the typical linear alkynes used as the reactant partner for azides in the Cu(I) catalyzed reactions. This cyclic triple bond reactant is activated, because of ring strain, to produce better kinetics in the 3 + 2 cycloaddition reaction (Prescher and Bertozzi, 2005; Agard *et al.*, 2006). The reaction with an azide lessens the ring strain of the alkyne within the cyclooctyne structure, and thus drives the reaction without the addition of cytotoxic copper (Figure 17.20). This cycloaddition reaction is still much slower than a copper-catalyzed reaction, but its usefulness on living cells may give it an advantage in this application.

6. STAUDINGER LIGATION

Early in the last century, the Nobel Prize-winning chemist Hermann Staudinger discovered a reaction between phosphines and azides which became known as the Staudinger reaction (Staudinger and Meyer, 1919). Triphenylphosphine reacts with azides to form an intermediate iminophosphorane with the release of nitrogen gas. This intermediate quickly breaks down in aqueous environments to yield triphenylphosphine oxide and a primary amine (Figure 17.21). This reaction has since been used successfully to synthesize amines in countless numbers of organic compounds and still remains one of the most common organic reactions performed today. Often azides are thought of as hidden amines, because the azide is relatively inert to other reactants until it is revealed through the Staudinger reaction.

A significant modification to the Staudinger reaction was developed by Saxon and Bertozzi (2000) that effectively turns it into a covalent coupling reaction with bioconjugation potential (see also Saxon and Bertozzi, 2003, 2006). Termed "Staudinger ligation," this reaction is carried out using a triphenylphosphine derivative that contains an electrophilic group next to the phosphorus core. *Ortho* positioning of an electrophilic benzyl methyl ester group on one of the phenyl rings provides a reactive site for the nucleophilic nitrogen from an azide group that temporarily forms an aza–ylide interaction with the phosphorus atom core. Nucleophilic attack of the nitrogen on the carbonyl "electrophilic trap" releases methanol and forms a stable amide bond (Figure 17.22).

Thus, using the Staudvinger ligation process, a triphenylphosphine derivative containing a benzyl methyl ester group can be covalently conjugated to an azide derivative through the formation of an amide linkage. The two derivatives can have attached to them virtually any other molecules, such as proteins,

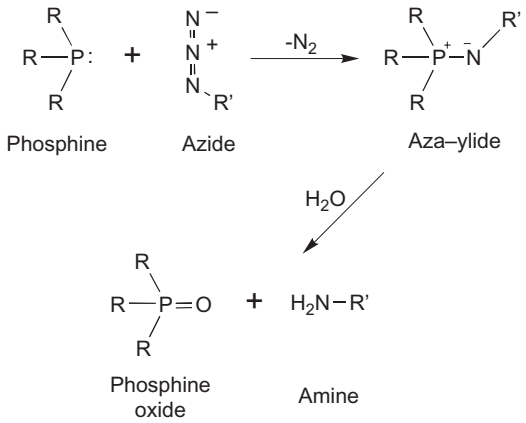

FIGURE 17.21 The Staudinger reaction involves the reduction of an azide to a primary amine with loss of N_2 and the concomitant oxidation of a phosphine derivative to a phosphine oxide.

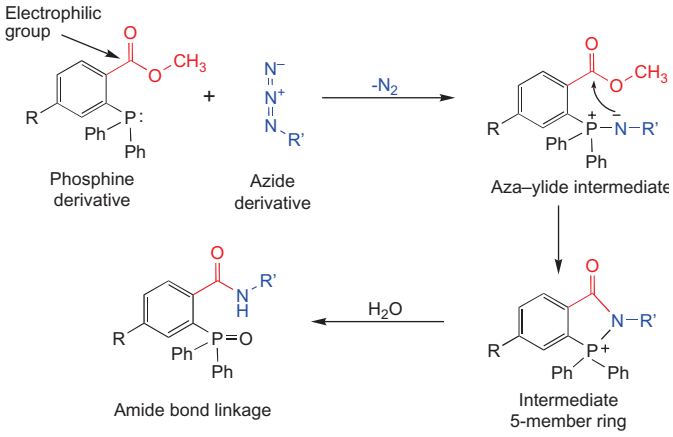

FIGURE 17.22 The Staudinger ligation reaction uses a modified phosphine derivative containing an electrophilic group that acts as a trap for the nucleophilic nitrogen in the intermediate aza–ylide. The resultant shift yields an amide bond derivative between the phosphine-containing molecule and the azide-containing molecule.

carbohydrates, other biological molecules, fluorescent tags, biotin groups, or other organic compounds, to create a conjugate between them.

The Staudinger ligation reactants are also extremely bioorthogonal. As discussed previously in the section on click chemistry, the (aliphatic) azide component is extremely stable in aqueous or biological solution and will not cross-react with other functional groups. The azide derivative is not appreciably reduced even given the reducing potential inside cells. In addition, the aryl derivative of triphenylphosphine used as a partner in this reaction has also been shown to be very stable in complex solutions, even to the point of not being an effective reducing agent for disulfides, as are many other phosphine compounds, including triphenylphosphine (Saxon and Bertozzi, 2000).

A number of alkyl–azide compounds that may be used in click chemistry reactions and the Staudinger ligation processes are now available. It is not recommended, however, to use aryl–azide compounds, as these are light sensitive and photoreactive as well as highly susceptible to reduction in the presence of thiols. More choices for obtaining commercial aryl–phosphine compounds to participate in this reaction are becoming available, as the applications for Staudinger ligation grow (Thermo Fisher).

The reaction between an alkyl–azide and the aryl–triphenylphosphine occurs without the requirement for other catalysts or activators, such as the need for Cu(I) in the click reaction. This provides an advantage for working with biological samples, since there is no possibility for toxicity or side reactions with added components being present. For this reason, the Staudinger ligation reaction is very amenable to being carried out with living cells without affecting cell viability.

Additionally, the azide group can be incorporated into amino acids, sugars, and lipids to label cellular molecules *in vivo* prior to reacting with a phosphine probe (see Figures 17.15 and 17.16). Kiick *et al.* (2002) demonstrated that both azido– and alkynyl–amino acid derivatives could be used as methionine surrogates and get integrated into proteins with nearly the same efficiency as normal methionine. Growing cells in the presence of one of these azido monomers will result in their incorporation into biopolymers at specific sites. In this manner, biomolecules can be purposely tagged using Staudinger ligation with a detectable phosphine probe, which is all done within living cells to track or locate them within their native environment. For instance, Prescher *et al.* (2004) used azido-sugar derivatives to modify cell surface glycans with azide groups at sialic acid residues, which are typically the outermost sugars on glycoproteins. It was found that cells took up these compounds most effectively if the hydroxyl groups were acetylated, presumably due to the easy transport of such hydrophobic derivatives through lipid membranes. The acetyl groups are removed within the cells by esterases, thereby providing the azido-sugar to the cell machinery for synthesizing glycoconjugates. The azido–glycan modifications produced on the cell surface using this process could then be labeled by the Staudinger ligation reaction with a phosphine–Flag tag derivative and subsequently detected using fluorescently labeled anti-Flag tag antibody and flow cytometry.

Due to the bioorthogonal nature of the reactants used for Staudinger ligation as well as the ability to incorporate azido analogs in biopolymers *in vivo* and the mild effect the reagents have on living cells, the process has been termed "a gift to chemical biology" (Köhn and Breinbauer, 2004). For the first time, efficient labeling of biomolecules within cells can be done with very small modifications to the biopolymers *in vivo*. Staudinger ligation permits discrete chemical tagging with detectable probes or affinity handles that facilitate purification.

The methods used for *in vivo* incorporation of azido monomers and performing a labeling reaction with live cells are relatively simple. The following protocol is based on the methods of Saxon and Bertozzi (2000), which use acetylated azidoacetylmannosamine as the azido-monomer source and a biotin–PEG–phosphine compound to biotinylate cell surface glycoproteins at the specific azide–sialic acid incorporation sites (Figure 17.23).

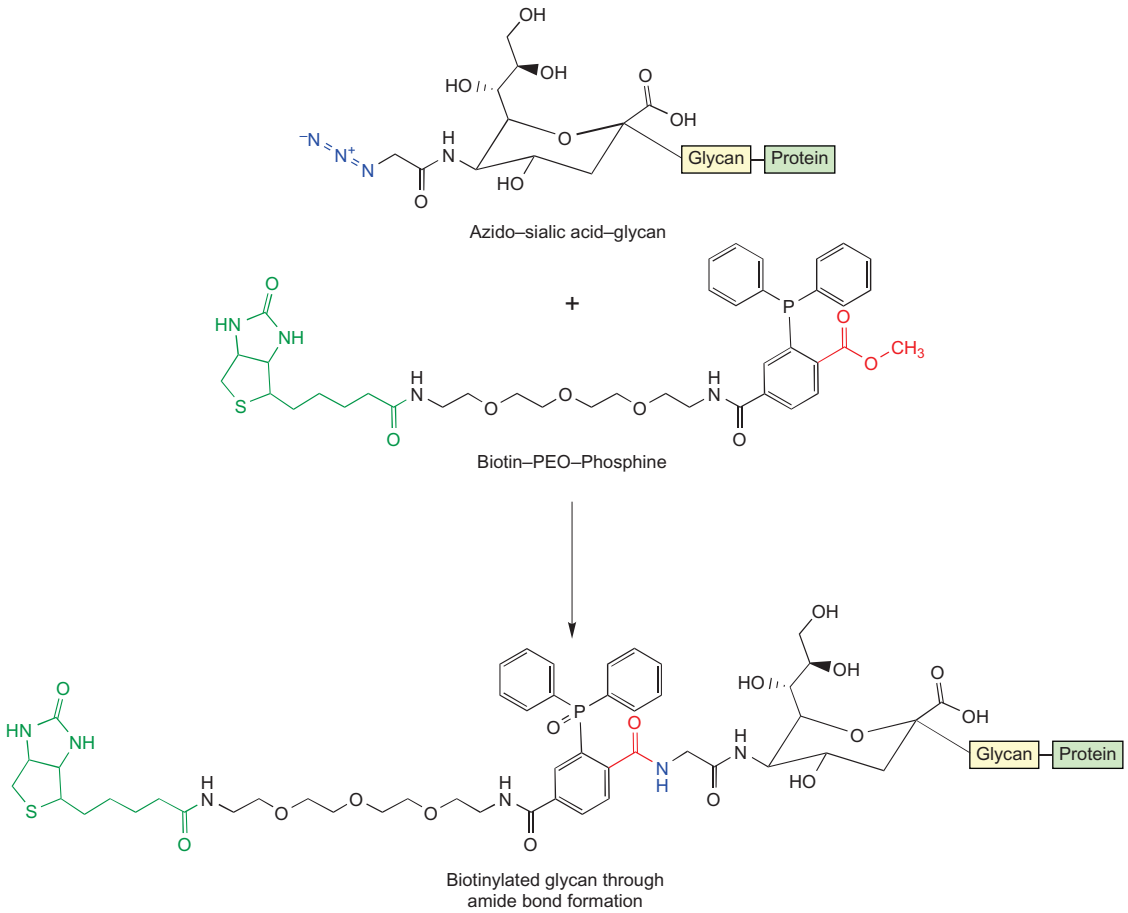

FIGURE 17.23 An azido–sialic acid derivative that gets incorporated into glycans in cells can be labeled specifically with a biotin–phosphine tag using the Staudinger ligation process. The result is an amide bond linkage with the glycan.

Protocol

1. Grow cells (~1×10^5 cells/ml) for 3 days in appropriate media containing a 20-μ*M* concentration of acetylated azidoacetylmannosamine.
2. Wash the cells at least twice with 0.1% fetal bovine serum in 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4 (PBS), to remove excess azido-sugar.
3. Suspend the washed cells in 0.25 ml of PBS, pH 7.4.
4. Add to the washed cells 60 μl of a 5-m*M* concentration of the phosphine derivative to couple to the azido-sugar groups on the cell surface (e.g., biotin–PEG–phosphine).
5. Incubate for 1 h at room temperature with gentle mixing.
6. Wash the cells with PBS, pH 7.4, to remove excess biotinylation reagent.

The biotinylated glycans on the cell surfaces subsequently may be probed with (strept)avidin reagents to detect the azido–sialic acid modifications. Alternatively, the cells may be lysed and the glycoproteins isolated using an immobilized (strept)avidin or monomeric avidin affinity resin.

The same approach to *in vivo* labeling may be carried out using azide derivatives of sugars administered intraperitoneally in mice (once per day for 7 days) (Prescher *et al.*, 2004). Tissue samples can then be taken of particular organs and reacted *ex vivo* with a phosphine derivative to undergo Staudinger ligation. This process can facilitate probing of glycans on the cell surfaces of organs or cells within an animal. Various treatment procedures can be carried out, such as administering drug candidates to test animals, to determine the effect on glycosylation of proteins *in vivo*.

Staudinger ligation techniques can also be used to detect post-translational modification of proteins *in vivo*. Hang *et al.* (2007) developed a method to monitor fatty acid acylation of proteins using azido-fatty acids fed to cells. The two major types of fatty acid acylation, *N*-myristoylation and *S*-palmitoylation, could be detected with terminal (ω-)azido-labeled myristic acid or palmitic acid. Mammalian cells grown in the presence of these fatty acid azide derivatives resulted in certain proteins being modified to contain ω-azido-fatty acid modifications. Subsequent Staudinger ligation with a biotin–PEG–phosphine reagent resulted in covalent attachment to any post-translationally modified protein containing these groups (Figure 17.24). The biotin group could then be used for detection or purification of *N*-myristoylated or *S*-palmitoylated proteins using (strept)avidin reagents.

In a similar application, Kho *et al.* (2004) were able to detect post-translationally modified proteins using an azido–farnesyl analog. Cells grown in the presence of this derivative enzymatically incorporated the azido

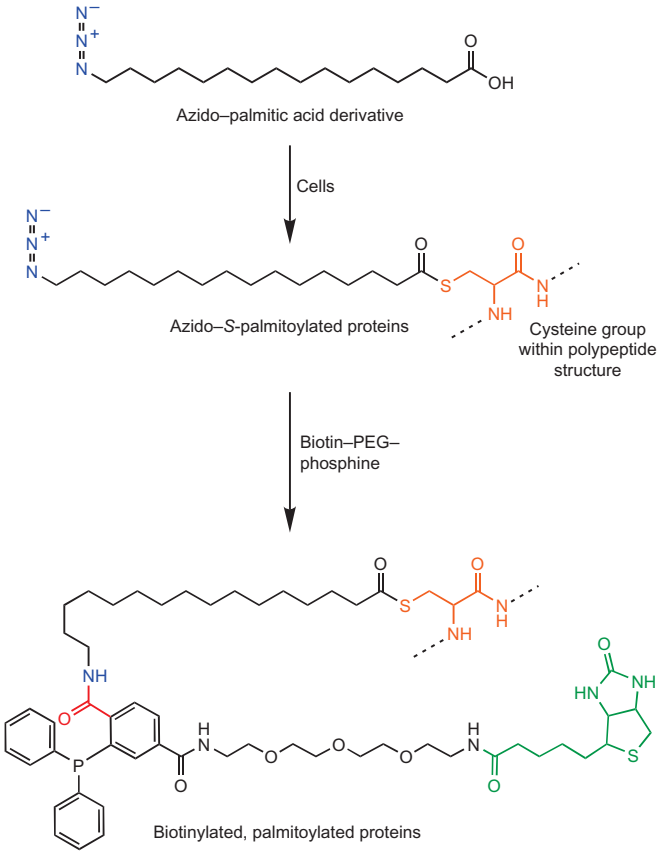

FIGURE 17.24 An azido–palmitic acid derivative can be added to cells to obtain palmitoylated proteins that contain an azide group able to participate in the Staudinger ligation reaction. Biotinylation of these post-translationally modified sites can then be carried out *in vivo* using a biotin–phosphine reagent.

group into farnesylated proteins through the action of farnesyl transferase. These modifications could then be targeted through Staudinger ligation using the same biotin–PEG–phosphine reagent (Figure 17.25).

Protein farnesyl transferase can also be used to add a geranylazide derivative to a synthetic peptide by incorporating the enzyme recognition sequence "CAAX" at the C-terminal of any peptide. This enzyme uses a farnesyl diphosphate derivative to transfer covalently the lipid to the cysteine residue via a thioether bond. Xu *et al.* (2006) found that the use of 6,7-dihydrogeranylazide diphosphate resulted in appending the terminal azido derivative onto such peptides, yielding an azido functionality for subsequent conjugation using Staudinger ligation. This process enabled targeted coupling through the C-terminal of any peptide or protein containing the CAAX box sequence.

Another important variation of the Staudinger ligation reaction described above involves the use of cleavable aryl groups on the triphenylphosphine

component, which allows for a "traceless" ligation reaction to occur. This strategy results in a zero-length amide bond between the phosphine derivative and the azide derivative, thus removing the triphenylphosphine component from the final conjugate and linking the two molecules together directly (Saxon *et al.*, 2000; Nilsson *et al.*, 2000, 2001; Soellner *et al.*, 2002; Saxon and Bertozzi, 2003, 2006). The phosphanes useful in this process are built from acyl derivatives of compounds such as those shown in Figure 17.26. During

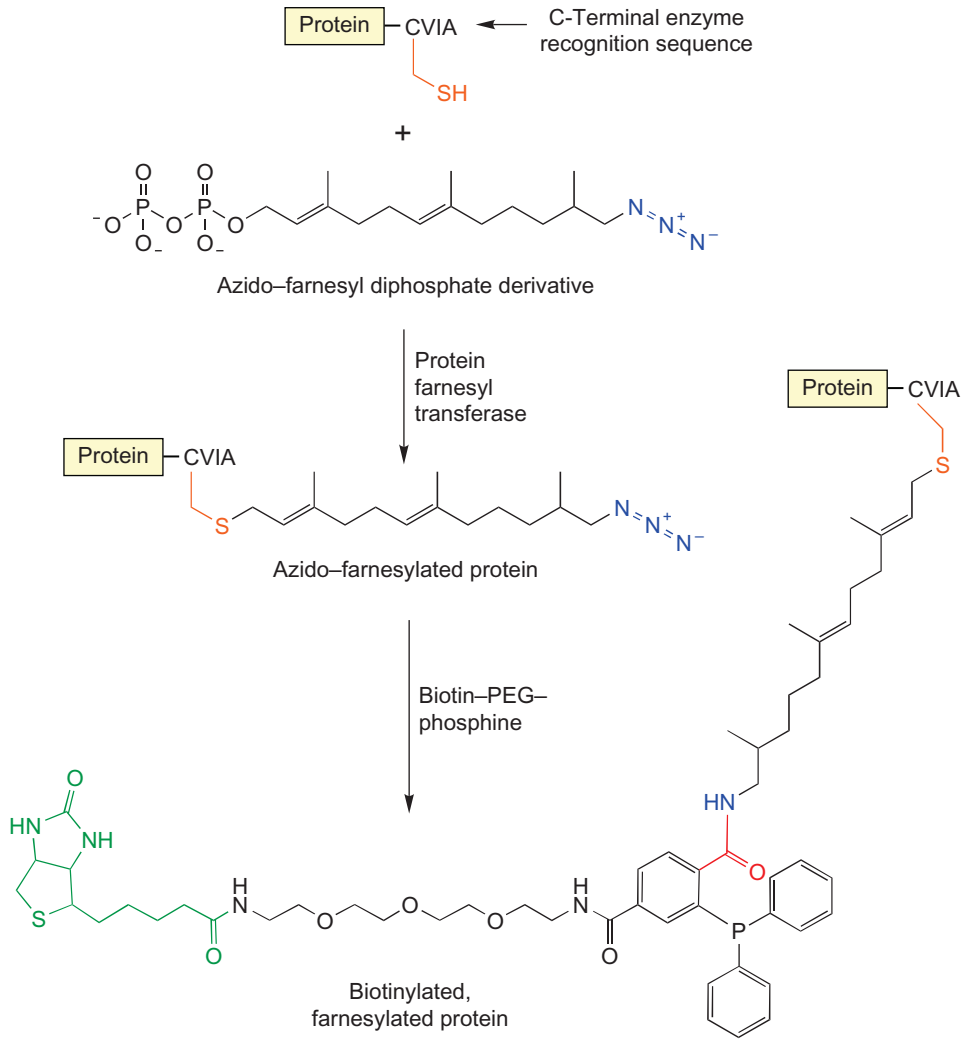

FIGURE 17.25 An azido–farnesyl diphosphate derivative can be added to cells to obtain farnesylated proteins containing terminal azide groups that can be targeted in a Staudinger ligation reaction. Biotinylation of these post-translationally modified proteins can be done *in vivo* using a biotin–phosphine derivative.

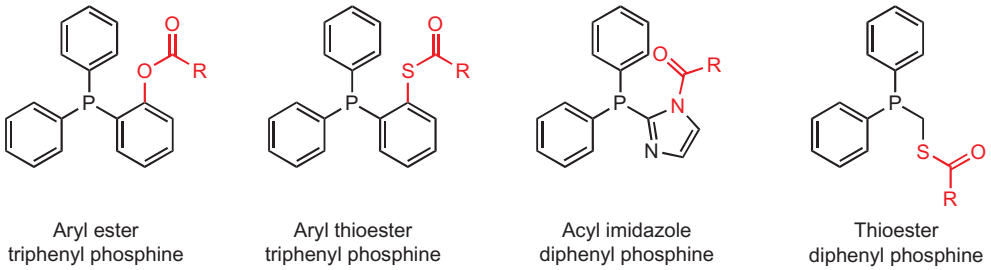

FIGURE 17.26 Certain unique phosphine derivatives can be used in the design of modification or conjugation reagents to create a traceless Staudinger ligation process, wherein the phosphine group is lost and an amide bond between an azide-containing molecule and the phosphine-containing molecule results.

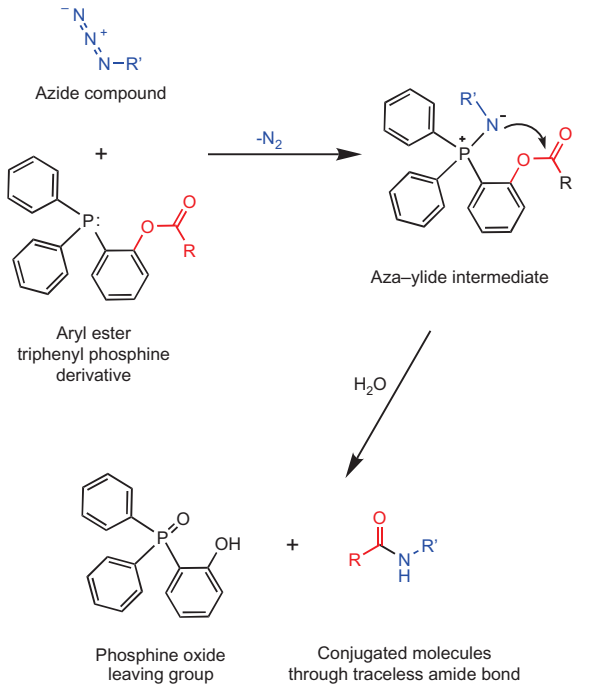

FIGURE 17.27 A traceless Staudinger ligation process involves the formation of an intermediate aza–ylide with subsequent attack of the nucleophilic nitrogen atom on the neighboring electrophilic group. The formation of an amide bond then occurs concomitant with the loss of the phosphine component, thus forming a zero-length crosslink between the two molecules.

the Staudinger ligation process, once the azide reactant forms the aza–ylide with the phosphine, electrophilic attraction induces the nitrogen to attack the electron deficient carbonyl, which in turn causes release of the phosphonium group and forms the amide bond (Figure 17.27).

The most useful phosphane derivatives in a traceless Staudinger ligation reaction include the acyl-modified 2-diphenylphosphanylphenol and the acyl-modified diphenylphosphanylmethanethiol. These two core structures provide the best rate of reaction and efficiently form the amide bond conjugate (Köhn and Breinbauer, 2004). The traceless Staudinger ligation method no doubt will become a popular choice to avoid retention of the bulky phosphane species in bioconjugates. The reaction can be used with success to produce long polypeptide chains by linking together azido-containing peptides with phosphine-containing peptides to form the appropriate biological peptide bond between them (Nilsson *et al.*, 2003). This makes it possible to synthetically create polypeptides that are too long to create using standard solid-phase peptide synthesis procedures (Figure 17.28). In addition, the traceless Staudinger ligation reaction can be used to link biomolecules containing azide groups to surfaces containing the traceless phosphane derivative (Soellner *et al.*, 2003).

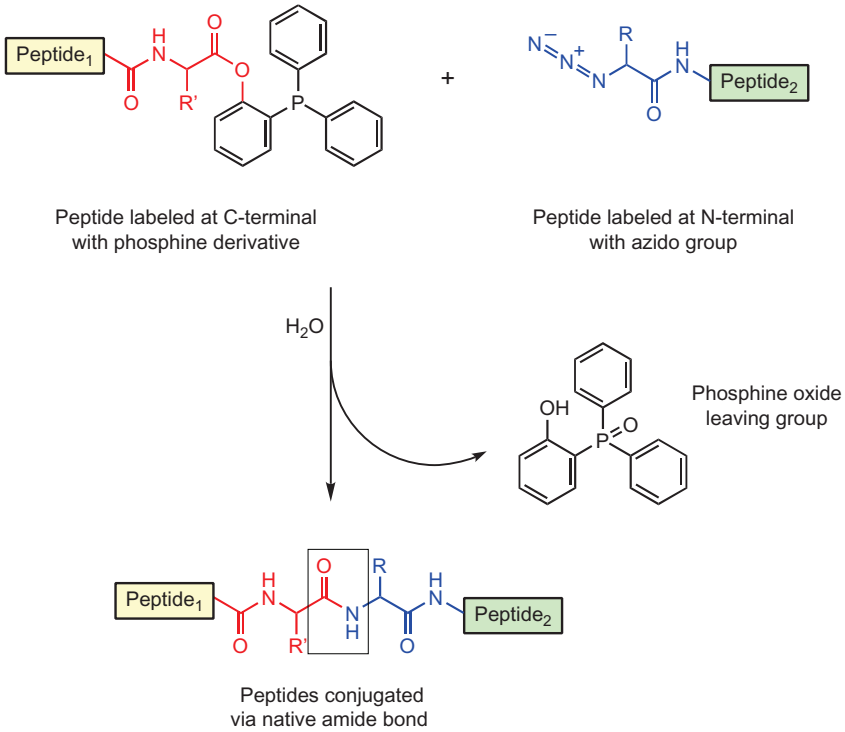

FIGURE 17.28 The traceless Staudinger reaction can be used to form larger peptides from smaller peptides, if one contains an azido group at the N-terminal and the other one contains a phosphine ester at its C-terminal. The reaction gives a native peptide (amide) bond with loss of the phosphine group.

7. NATIVE CHEMICAL LIGATION

Native chemical ligation is an important alternative chemoselective peptide conjugation technique to the previously discussed non-native methods (Dawson *et al.*, 1994). This system can provide discrete coupling of the N-terminal of one peptide to the C-terminal of another peptide using a unique reaction process, essentially extending a peptide chain while maintaining native sequence and bonding characteristics. The reactant partners are prepared through typical peptide synthetic procedures, wherein one peptide is made to contain an alpha-thioester on its C-terminal carboxylate and the other peptide is synthesized to contain a cysteine amino acid residue at its N-terminal. The reaction of these two derivatives proceeds through nucleophilic attack of the cysteine thiol of one peptide onto the carbonyl group of the alpha-thioester at the C-terminal of a second peptide. The result forms an intermediate thioester by transthioesterification, which then spontaneously rearranges by an S→N acyl transfer to form a native amide bond between the peptides with no foreign organic structure remaining (Figure 17.29). The reaction proceeds at physiological pH using fully unprotected (i.e., unblocked) amino acid functional groups, which is unusual in peptide synthetic strategies.

Peptides typically are prepared for this ligation process using alpha-alkyl thioesters, because they are simple to make at the time of peptide synthesis. However, due to the relatively slow reaction kinetics of alkyl thioesters, most native chemical ligation processes have been catalyzed through the use of thiol compound additives, such as benzyl mercaptan or thiophenol (Dawson *et al.*, 1997). These compounds react with the initial alpha-alkyl thioester to form another intermediate, an aryl thioester, which is more reactive toward the N-terminal cysteine on the other peptide to be coupled. A study of the rate of reaction for different thiol catalysts indicated that (4-carboxymethyl)thiophenol performed the best. The addition of this compound to a native chemical ligation reaction resulted in at least a 10-fold improvement in reaction rates (Johnson and Kent, 2006).

Another advantage to the use of a thiol additive is that the abundance of free thiol groups in the reaction environment will prevent the oxidation of the cysteine thiol at the N-terminal of the other peptide. Without added thiol transesterification catalysts, disulfide formation resulting in dimerization of the Cys peptide would be a dominant side reaction in aqueous, oxygenated buffer conditions.

Native chemical ligation has been used successfully to couple two unprotected peptides together during solid phase synthesis, wherein one of the peptides is attached to the resin using a thioester linkage and the other peptide is introduced containing a cysteine at its

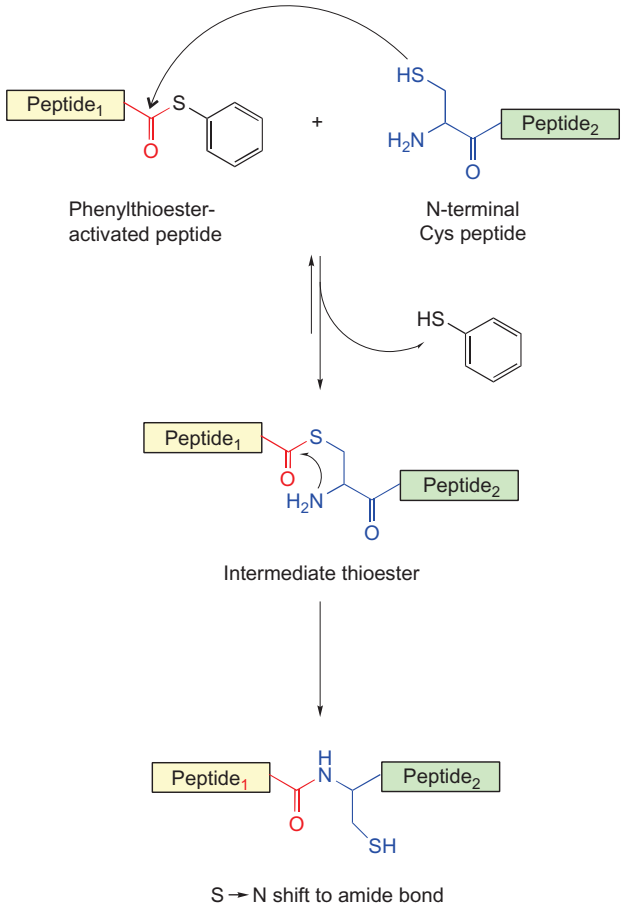

FIGURE 17.29 The native chemical ligation reaction can be used to form larger peptides from smaller peptides, if one contains a cysteine residue at its N-terminal and the other one contains a thioester on its C-terminal. Reaction of the peptide derivatives gives a native peptide (amide) bond.

N-terminal (Camarero *et al.*, 1998). The ligation process could also form cyclic peptides, although the efficiency of the reaction was less than the conjugation of two separate peptides.

So efficient is this method to link peptide sequences together in a native amide bonded state that complete proteins of various sizes have been synthetically made (Hackeng *et al.*, 1999), such as the preparation of a serine protease (Pal *et al.*, 2003), bovine pancreatic trypsin inhibitor (Lu *et al.*, 1998), cytochrome b562 (Low *et al.*, 2001), and the triple zinc finger protein Zif268 (Beligere and Dawson, 1999). Many other examples of full or partial protein synthesis can be found in the published literature (for reviews, see Dawson and Kent, 2000, and David *et al.*, 2004).

Native chemical ligation can also be extended to the conjugation of peptides or proteins to other molecules or surfaces. For instance, Reulen *et al.* (2007) prepared liposomes that contained cysteine–PEG–phospholipid derivatives and then coupled thioester-modified peptides or

proteins to form a protein–liposome conjugate. Using this procedure, approximately 100 molecules of a collagen binding protein could be coupled to the cysteine-containing liposomes.

In addition, Dose and Seitz (2005) employed native chemical ligation to synthesize peptide nucleic acids (PNAs) by linking shorter segments of PNAs to make long contiguous strands, which could not be made through typical oligo synthesis procedures.

7.1. Expressed Protein Ligation and Inteins

Although there are a limited number of reports indicating that N-terminal cysteine-containing proteins can be expressed recombinantly, the *in vivo* production of a protein having a C-terminal thioester is considerably more difficult. That's why the initial development of native chemical ligation techniques was restricted to the use of peptide synthesis to generate the two peptide derivatives for ligation. However, the recombinant generation of C-terminal thioesters and N-terminal cysteine residues in peptides for native chemical ligation can now be achieved using intein technology. In the same frame that native chemical ligation reactions were being discovered and explored, intein technology was being investigated as a new *in vivo* native protein splicing and ligation mechanism.

Inteins are certain sequences of amino acids in precursor proteins that can catalyze a cleavage of their own internal peptide structure, resulting in the excision of the intein peptide segment and ligation together of the two peptide segments flanking the excised region (exteins). The exteins are thus ligated together with a native peptide (amide) bond. The immediate C-terminal side flanking the intein usually contains either a serine/threonine residue or a cysteine amino acid group at the splice junction. The N-terminal extein side next to the intein can also contain either a serine/threonine group or a cysteine residue, which are able to form an ester or thioester functionality, respectively. If a cysteine group is present at the N-terminal splice junction side of the intein, then the thioester intermediate that forms is very similar to the reaction intermediate of native chemical ligation.

The intein segment is excised through a number of steps that first involves an N→S shift at the C-terminal cysteine residue at the extein junction to create a thioester intermediate. Then nucleophilic attack of either the serine/threonine hydroxyl or the cysteine thiol of the extein on the N-terminal side of the intein proceeds to cleave the C-terminal extein and ligate it to the N-terminal extein thiol (or hydroxyl) through another (thio)ester bond. Therefore, the cleavage and ligation reaction proceeds through a second ester or thioester intermediate that involves either an O→N shift or an S→N shift, which cleaves off the intein segment entirely. The complete thioester reaction route is shown in Figure 17.30, which can be seen to be very similar to that of a native chemical ligation reaction, illustrated previously.

Muir *et al.* (1998) realized that the intein reaction could be used to facilitate a native chemical ligation with a synthetic N-terminal cysteine-containing peptide or cysteine-containing molecule. With the discovery of a mutant intein that could form an intermediate thioester but not go on to complete the splice and ligation reaction (Xu and Perler, 1996; Chong *et al.*, 1997), this expression technology now could be combined with the native chemical ligation reaction to facilitate a new expressed protein ligation (EPL) method.

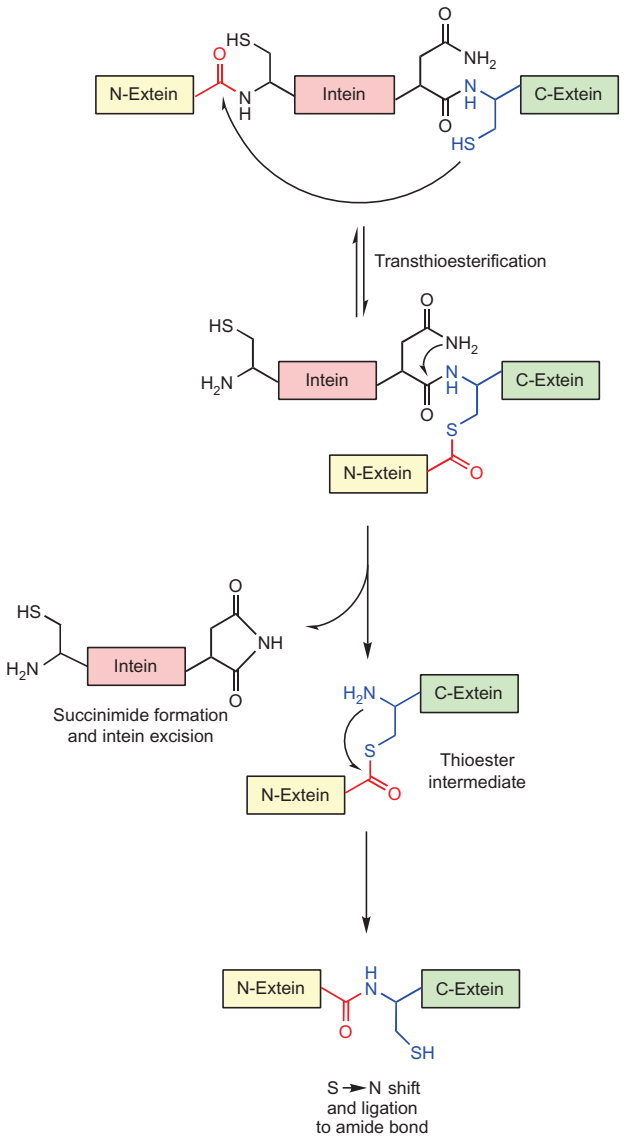

FIGURE 17.30 The native process leading to intein excision and ligation of extein fragments involves a sequence of reactions involving transthioesterification, cleavage of the intein fragment, and an S→N shift, which ligates the two extein peptides together via an amide bond.

Fusion vectors are available that combine a recombinant protein with a mutant mini-intein segment (not containing an endonuclease domain) and followed by a chitin binding domain (CBD) (Zhang *et al.*, 2001). These mutants typically also have an alanine substitution that replaces the cysteine or serine/threonine usually found on the C-extein splice junction. Alanine cannot facilitate attack on the thioester on the N-extein side and thus the intein is not cleaved. Using the CBD portion, the entire expressed fusion protein can be purified on a chitin column through specific affinity binding and then the N-extein segment induced to cleave using DTT, which results in release of the desired recombinant protein having a C-terminal thioester.

However, if the expressed protein is treated on the affinity support using thiophenol, this also will release the protein and result in a phenylthioester at its C-terminal, which is the reactive intermediate imminently suitable for native chemical ligation. Treatment of this activated thioester protein with a N-terminal cysteine peptide induces the native chemical ligation reaction and couples the peptide to the expressed protein through an amide bond (Severinov and Muir, 1998) (Figure 17.31).

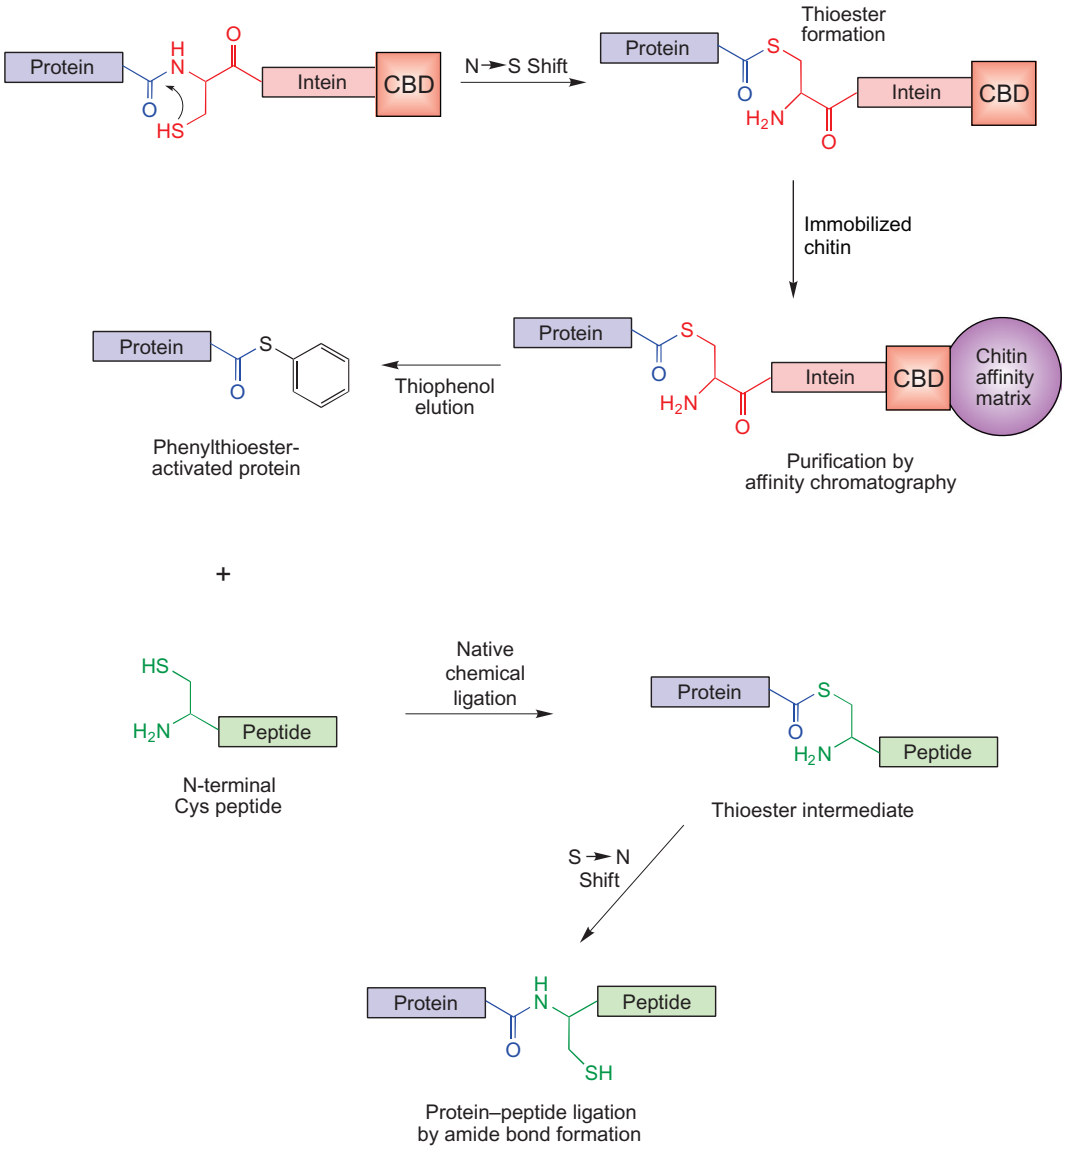

FIGURE 17.31 The expressed protein ligation process involves a fusion protein containing an intein tag plus a chitin binding domain. The fusion protein is captured on an immobilized chitin resin and after removal of contaminating proteins is eluted using thiophenol, which cleaves at the thioester bond between the intein and the desired expressed protein. This releases a phenylthioester-activated protein that can be used in the native chemical ligation reaction with another peptide containing an N-terminal cysteine residue. Conjugation results in a native amide (peptide) bond formed between them.

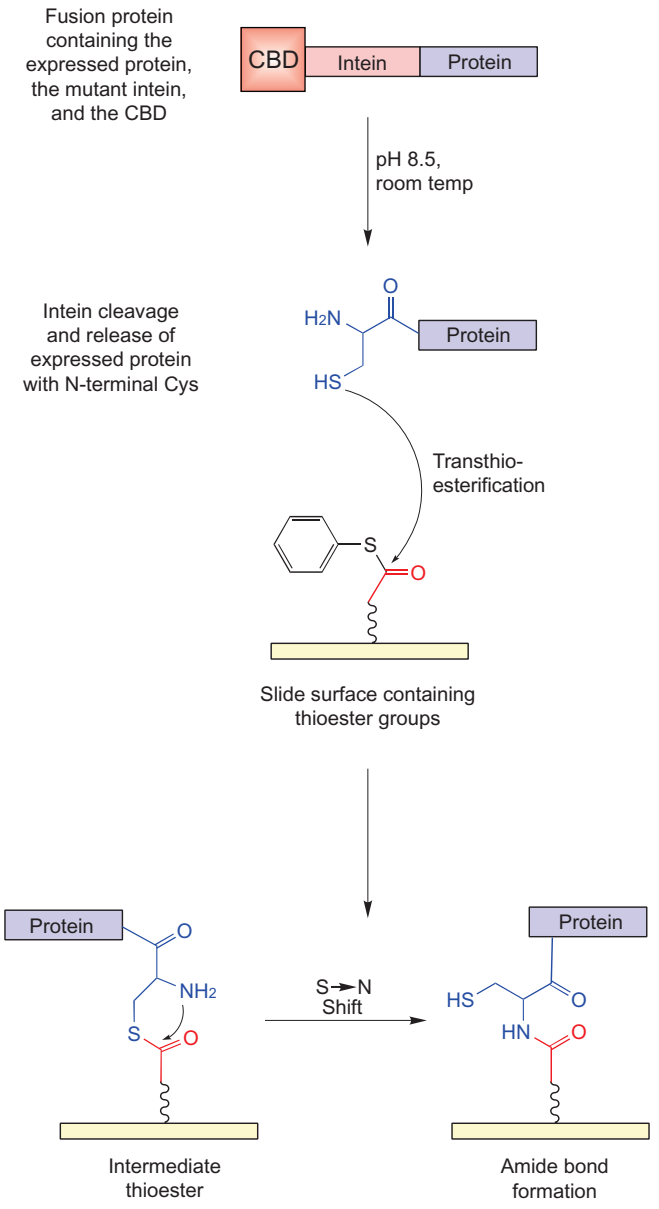

FIGURE 17.32 Expressed protein ligation reactions can be used to couple a fusion protein to a surface containing a thioester derivative. After cells are grown and the fusion protein expressed, a pH and temperature shift causes intein cleavage with release of the expressed protein with an N-terminal cysteine residue. Reaction with the thioester surface results in a native chemical ligation reaction that forms an amide bond linkage with the expressed protein.

Expressed protein ligation extends the applicability of native chemical ligation to recombinantly produced proteins using the mutant mini-intein vector system. Proteins being expressed using this method will contain a C-terminal thioester and therefore can be conjugated to any reagent or probe molecule containing a cysteine group with an available alpha-amine and thiol group. Expressed proteins can also be immobilized onto solid surfaces by coupling them solely at their C-terminal ends.

Girish *et al.* (2005) coupled proteins onto surfaces using this approach, but in this case expressing a protein containing an N-terminal Cys residue and then reacting it with a thioester group on a glass slide (Figure 17.32). A similar strategy has also been used with success to label specifically expressed proteins in live cells using thioester-containing probes (Nilsson *et al.*, 2003). Using the pTWIN vector (New England Biolabs), a recombinant system was developed to express proteins having an N-terminal Cys using the Ssp DnaB mini-intein segment (Yeo *et al.*, 2003). This intein contains a C-terminal asparagine residue that undergoes a self-cleaving reaction after a shift in pH and temperature. Growing cells in physiological pH conditions does not cleave the intein. However, after cell lysis, an increase to pH 8.5 under room temperature conditions will initiate the cleavage reaction. Thioester-containing probes, including thioester–fluorescent molecules or thioester–biotin, can be added directly to live cells to label these expressed proteins via native chemical ligation (Figure 17.33).

The following protocol for EPL, including purification using a CBD fusion tag followed by native chemical ligation, is based on the methods of Muir *et al.* (1998), Chong *et al.* (1997), Chong *et al.* (1998), Evans *et al.* (1998), Severinov and Muir (1998), and the NEB instruction manual for the IMPACT-TWIN system. The recombinant protein is recovered from the affinity column as the thioester derivative ready for reaction with a N-terminal Cys peptide or another tag containing a Cys residue.

Protocol

1. A gene encoding a recombinant protein of interest is cloned into a cleavable mutant intein–CBD plasmid vector and transfected into cells (e.g., using the IMPACT-TWIN system from New England Biolabs). The cells are grown in LB media with 200-µg/ml ampicillin at 37°C to an OD_{600} nm of about 0.5 to 0.8, induced to express the fusion protein complex by the addition of 1-m*M* IPTG, and incubated overnight.
2. Prepare a chitin affinity column by washing with at least 10 bed volumes of 25-m*M* HEPES, 250-m*M* NaCl, 1-m*M* EDTA, 0.1% Triton X-100, pH 7.0 (wash buffer).
3. Recover the cells by centrifugation, lyse them in wash buffer containing protease inhibitors (e.g., 20-µ*M* PMSF), and clarify the supernatant by centrifugation.
4. Apply the lysate onto the affinity column and wash with at least 10 column volumes of wash buffer to

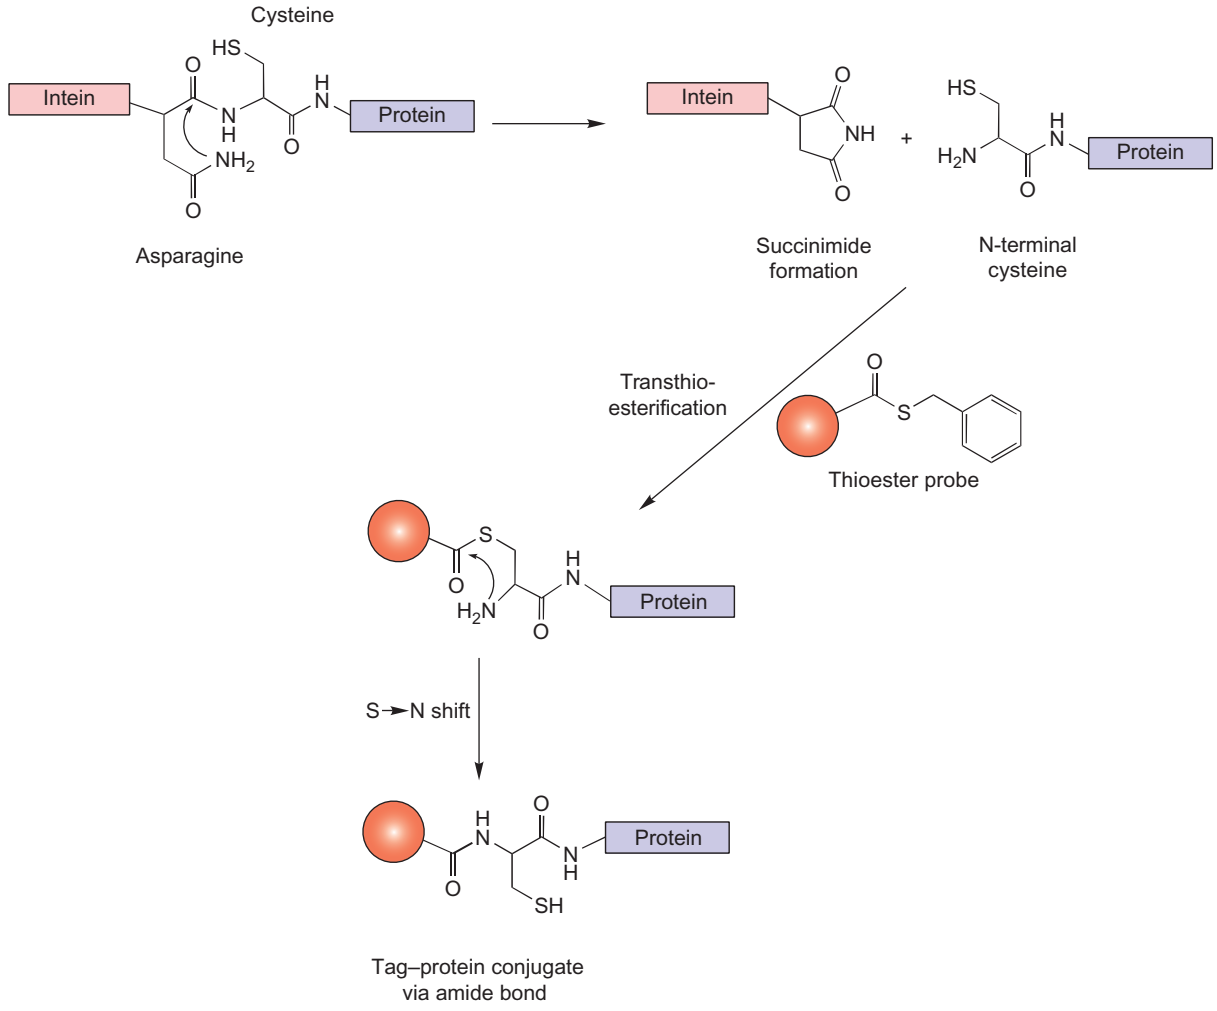

FIGURE 17.33 An expressed protein containing a mutant intein segment can undergo self cleavage to form an N-terminal cysteine residue, which can then be reacted with a thioester probe to specifically label the protein via an amide bond.

remove not-bound protein. Monitor the eluate by absorbance at 280 nm to ensure that baseline has been reached.

5. Wash the column with 2 to 3 column volumes of elution buffer (25-m*M* HEPES or Tris-HCl containing 500-m*M* NaCl, 1-m*M* EDTA, and 2% (v/v) thiophenol (or 50-m*M* 2-mercaptoethansulfonic acid), pH 8.5. Next, add 2 column volumes of elution buffer containing 1 to 2-m*M* of an N-terminal Cys peptide or Cys-containing tag. Stop the flow and incubate the column at room temperature for 24 h. The thiophenol will cleave the recombinant protein at the intein splice junction, while the cysteine-containing peptide will react with the intermediate ester through transthioesterification and an S→N shift to ligate the molecules via an amide bond.
6. Elute the conjugated molecules using wash buffer and purify using dialysis or gel filtration.

CHAPTER

18

PEGylation and Synthetic Polymer Modification

1. DISCRETE PEG REAGENTS

Poly(ethylene glycol) (PEG) has been used for many years as a modification and conjugation reagent for biological molecules (Roberts *et al.*, 2002; Veronese, 2009; Ikeda and Nagasaki, 2012). Part of the rationale for using PEG polymers in bioconjugation applications includes a dramatic increase in the water solubility of modified molecules, a decrease in immunogenicity due to the shielding of modified molecules from the immune system, protection of modified protein and peptides from digestion by proteolytic enzymes, and effectively increasing their hydrodynamic volume and decreasing clearance rates by renal filtration, all of which results in an increase in the serum half-life of modified molecules *in vivo*. Thus, hydrophobic drugs modified with PEG polymers become much more water soluble, foreign proteins and other immunogenic molecules are hidden from the circulating antibodies and cells of the immune system, labile peptides or proteins cannot be degraded by enzymes, and the reticuloendothelial system and kidneys cannot remove labeled drugs as quickly as their unlabeled counterparts. For these reasons, many drug candidates using PEG modification are currently in clinical trials and several are already on the market.

The majority of PEG applications involve the use of long-chain linear or branched PEG polymers having molecular masses of at least 2.5 kDa to over 50 kDa (see Section 2, this chapter, for selected applications of these long PEG polymers). PEG is typically made from ethylene oxide by an anionic ring-opening reaction, which results in long polymer molecules consisting of the general structure $HO(CH_2CH_2O)_nH$. The number of repeat units (n) in standard commercial PEG polymers created through this process can typically be anything from less than 50 to over 1100. However, in these conventional PEG polymers of any given size, there actually exists a distribution of chain lengths, as is typical for any polymer-based substance. The range of chain lengths for a given PEG size is approximately Gaussian in distribution, which means that most PEG reagents prepared by standard polymerization processes are fairly disperse. The level of polydispersity is usually indicated by Mw/Mn, which is called the polydispersity index (PDI) and is equal to the weight average molecular weight (Mw) divided by the number average molecular weight (Mn). If the PDI is equal to 1, the polymer is said to be monodisperse. For PEG polymers, the PDI is typically less than 1.2, which is quite good for polymeric materials, but this value probably reflects the concern over the use of polydisperse PEG for therapeutic applications. Even at this low level of PDI, the chain distribution often can be quite high. Kenworthy *et al.* (1995) reported that the mean number of repeat units and variance for PEG-2000 averages 53 units with a variance of 11, while a PEG-5000 polymer has an average 130 units with a variance of 20. Shorter chain PEG polymers have a tendency to have greater polydispersity than the larger polymers. For example, the commercially available PEG-1500 can have between 19 and 48 repeat units in a typical preparation, which correspond to a molecular weight distribution of 800 to 2100 Daltons (Davis and Crapps, 2006). Thus, most commercial sources of crude PEG polymers are highly disperse and they probably should be avoided entirely for critical bioconjugation work, unless they have been carefully purified to isolate a single chain length. This isolation process typically is done using size exclusion chromatography, which is a time-consuming and expensive procedure and still may not yield an entirely homogeneous PEG preparation.

However, true monodisperse PEG reagents have become available, which are made not by polymerizing small monomers, but by linking short, discrete PEG segments together to create pure polymers of known structure and purity. These discrete PEG molecules can be made in chain lengths from as little as 2 to over 24

repeating ethylene oxide units, and theoretically, virtually any chain length can be produced by building up from smaller precursors (Davis and Crapps, 2006).

In the synthesis process, a short PEG segment containing a hydroxyl protecting group on one side and a free hydroxyl on the other end is reacted with another PEG segment containing a reactive group on one end and a protecting group on the other end. The reactive group must also be a good leaving group, so that once it reacts with the hydroxyl on the other PEG unit, a conjugation reaction occurs to form an ether bond. This results in the covalent linking of the two PEG molecules together to form a longer PEG compound equal to the combined length of the reactants. Deprotection of the ends can then be done to add additional functionality, such as a reactive group, functional group, or to form a hydroxyl or methoxy end (mPEG).

Prior to this synthetic method being developed, small PEG-containing compounds were limited to very short ethylene oxide segments, such as the commonly used reagents ethylene glycol and tetraethylene glycol. Now, using new discrete PEG reagents, the advantages that PEG compounds have provided for use in the modification and crosslinking of biomolecules can be incorporated at known polymer lengths into any bioconjugation reagent to enhance its properties.

Discrete PEG reagents have been reported that incorporate reactive groups, fluorescent probes, metal chelates, drug molecules, affinity ligands, biotin, and a host of other constituents. For instance, Wei *et al.* (2006) developed a PEG-functionalized texaphyrin derivative, which was shown to have enhanced solubility and anti-cancer activity *in vivo*. Four $mPEG_4$ chains decorating the central gadolinium(III) texaphyrin were found to convey dramatic anti-proliferative effects compared to the parent chelate without PEGs present. In another application using the chelator DOTA, Shi *et al.* (2011) created several ^{111}In-labeled cyclic RGD peptides with PEG_4 linkers to target integrin receptors on human gliomas cells. For the creation of real-time fluorescence imaging probes for MMP enzymes, Zhu *et al.* (2011) used amine derivatives of $mPEG_4$, $mPEG_{12}$, $mPEG_{24}$, and $mPEG_{67}$ attached to the C-terminus of the peptide sequence to improve water solubility and *in vivo* activity. The $mPEG_{12}$ probe provided the best specific MMP targeting ability toward SCC7 tumor cells in mice.

In another application of a PEG_4 spacer, Clevenger *et al.* (2004) prepared a biotinylated derivative of the antibiotic geldanamycin (GDA) to use as an inhibitor of the 90-kDa heat shock protein Hsp90. Use of the PEG linker in building such an organic drug complex has the advantage of adding a hydrophilic arm to an otherwise very hydrophobic probe. The biotin–PEG_4–GDA conjugate could be used to bind the active site of Hsp90 proteins and then affinity-purify them on a (strept)avidin-containing resin.

Similarly, Kruszynski *et al.* (2005) used the reagent NHS–PEG_4–biotin to make biotinylated analogs of human MCP-1. This compound, described later in this section, provides a long-chain biotin handle that has better solubility properties than the corresponding aliphatic reagent NHS–LC–biotin, which has been used in many applications (Chapter 11, Section 6.2). Kornilova *et al.* (2005) used the same PEG reagent to biotinylate various γ-secretase peptide inhibitors to create probes of this multi-protein complex.

Hydrophilic short biotin–PEG tags have also found their way into the design of multifunctional crosslinkers to study protein structures by mass spectrometry. Fujii *et al.* (2004) developed a homobifunctional NHS ester crosslinker that, in addition, has a PEG–biotin handle (Figure 18.1). The reagent is actually a trifunctional compound similar to the biotinylated PIR compound described in Chapter 24, Section 1.4. The NHS ester arms are of identical length to provide linkages of the same molecular distance in each direction, while the PEG group on the biotin arm avoids the hydrophobic collapse of alkyl chain spacers by providing an extremely hydrophilic linker with high freedom of motion in aqueous environments. Due to the increased water solubility provided by the PEG linker arm, the sensitivity of mass spectrometry analysis was enhanced over the use of more traditional aliphatic spacers. In particular, this discrete PEG compound was found to be optimal for performing mass spectrometry analysis in three dimensions (MS^3).

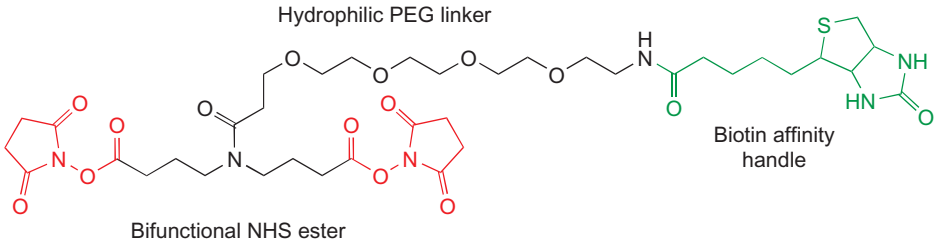

FIGURE 18.1 A trifunctional reagent for studying protein interactions by mass spectrometry. The *bis*-NHS ester arms crosslink interacting proteins, while the discrete PEG-containing biotin arm can be used to isolate or detect the conjugates using (strept)avidin reagents.

Coupling of affinity molecules to surfaces can also be enhanced by the use of discrete PEG linkers. Nishimura *et al.* (2005) modified an amino surface with a NHS–PEG_{12}–maleimide crosslinker to create a hydrophilic self-assembled monolayer (SAM) surface that was thiol reactive for the conjugation of sulfhydryl-modified RNAs. This array was then used to investigate the binding specificity of synthetic kanamycins with selected RNA sequences to prove the specific interaction of ribosomal RNA with this molecule. The PEG linkers on surfaces provide lower nonspecific binding character than alkyl linkers, when preparing SAM surfaces for affinity interactions.

The low nonspecificity of PEG layers was also used to eliminate biomolecule binding to certain areas of an array. Kidambi *et al.* (2004) patterned an mPEG–carboxylate molecule onto polyelectrolyte multilayers to mask portions of the surface. The extremely low binding character of PEG provides advantages for creating patterned surfaces that other modifiers using aliphatic alkyl linkers do not provide.

SAM surfaces on metals, such as gold particles or planar arrays, have been enhanced in their performance and properties through the use of PEG-containing modifications. Prime and Whitesides (1991) used an mPEG–thiol combined with a slightly longer thiol–PEG–carboxylate compound to create monolayers on gold through dative bonding with the thiol groups. The thiol–PEG–carboxylate compound is typically used at about 10% of the concentration of the thiol–mPEG compound to form a lawn of low-binding mPEG molecules which is interspersed with enough carboxylates to provide sites for covalent attachment of affinity ligands or antibodies. Spangler *et al.* (2004) improved upon this strategy by creating a dendritic structure branching off from a central phenyl ring core and containing two thiol arms and a single PEG arm containing either an mPEG group or a PEG–carboxylate (Figure 18.2). The presence of two thiol groups increases the strength of the linkage with the gold surface, thus providing resistance to oxidative cleavage of the SAM surface.

In another application involving a study of biotin compounds for potential use *in vivo*, it was found that the preferred structures included molecules that contained PEG spacers to provide increased water solubility and *in vivo* activity (Wilbur *et al.*, 2000). Fifteen biotin derivatives were conjugated to cyanocobalamin, which is a binder of cobalt that may be used in radiotherapy for cancer. Structures with enhanced activity were formed with PEG spacers of varying length between the cyanocobalamin and the biotin handle, which provided maximal hydrophilicity to the entire complex.

Biotinylation reagents have historically used aliphatic chains to provide a spacer between a modified molecule and the bicyclic ring of biotin. This allows for enough molecular distance for (strept)avidin to easily bind during detection or targeting applications. Even long spacers on biotin reagents have typically been constructed of hydrophobic alkyl chains for the biotinylation of proteins. This can be detrimental to protein solubility, because biotin itself is sparingly soluble in aqueous solution and adding an alkyl spacer to this group only decreases its water solubility further. In particular, antibodies modified with long hydrophobic biotin compounds often aggregate and lose activity, especially at high modification levels. Replacing the alkyl chain with a discrete PEG spacer, however, can dramatically increase water solubility and prevent antibody aggregation as well as significantly boost long-term stability.

Discrete PEG reagents can provide benefit for nearly any crosslinking compound or modification reagent designed for use in aqueous environments. Frequently, PEG chain lengths between 4 and 24 repeating ethylene oxide units create increasingly hydrophilic character for modified biomolecules or surfaces. The following sections describe a number of these PEG compounds, including crosslinkers, biotinylation compounds, and multi-armed PEG modification agents designed to block molecules and surfaces. In addition, PEG-based compounds are available that have functional groups on both ends for use as building blocks to create other PEG compounds or as spacers to build unique surface functionality. Most of these reagents are available commercially through Quanta BioDesign or Thermo Fisher Scientific.

Modification or crosslinking agents containing a discrete PEG spacer are often not powders or crystalline substances, but frequently they are thick, sticky, viscous liquids. Such materials are difficult to dispense by weighing out a small portion from a vial. For this reason, it may be best to dissolve an entire vial in a dry organic solvent prior to use or try to weigh out a much larger quantity than may be initially required. Stock solutions may be stored for weeks at <0°C, but long-term stability of active groups is dependent on the quality of the solvent used. For this reason, it is best to prepare solutions fresh.

Organic solvents that can be used with discrete PEG compounds include DMSO, DMF, DMAC (*N*,*N*′-dimethylacetamide), and methylene chloride. The compounds are also very soluble in many other commonly used organic solvents, which provide flexibility for doing reactions. DMAC is particularly convenient, because it is easily dried of contaminating water (using molecular sieves), it does not decompose like DMF (producing amines), and it does not have the odors of some of the other solvents. Methylene chloride can be used for water-insoluble molecules that are to be reacted with the PEG compounds, but do not require subsequent water miscibility.

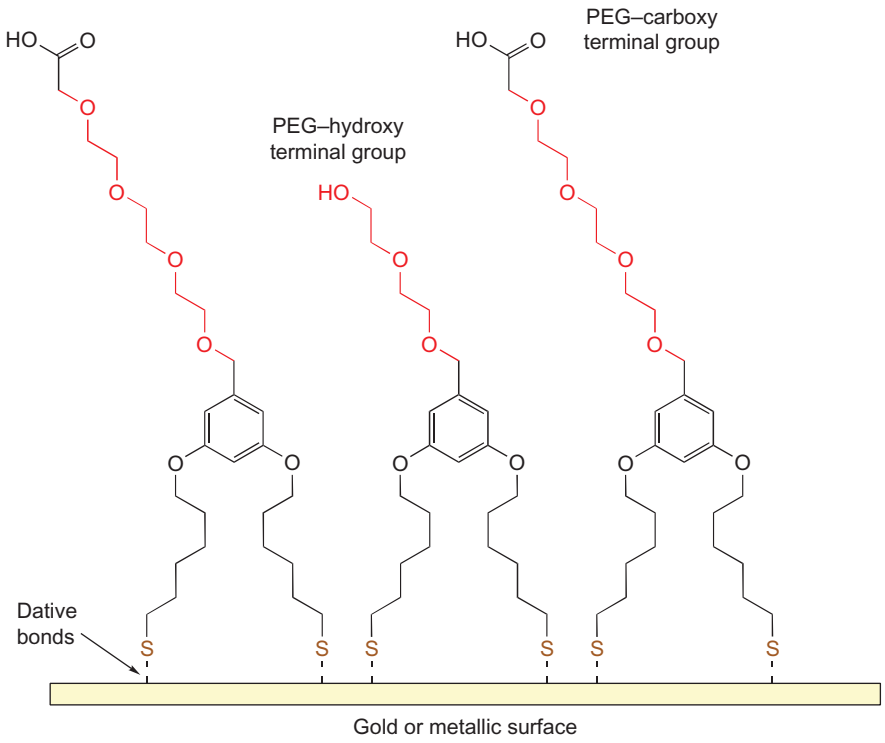

FIGURE 18.2 Dithiol linkers containing discrete PEG arms can be used to stably modify metallic surfaces for coupling biomolecules.

1.1. Homobifunctional PEG Crosslinkers

Compounds having the same functionality on both ends are homobifunctional in nature and can be conjugated with the same target functionality on biomolecules, surfaces, or other molecules. Chapter 5 describes traditional homobifunctional compounds in detail, but the discrete PEG-based reagents are described here, because of their unique hydrophilic properties.

bis-NHS Ester–PEG Compounds

Bifunctional NHS esters can be used to conjugate two amine-containing molecules together. The NHS ester groups react with amines to form amide linkages with loss of NHS. Two different PEG spacer lengths are available in this type of reagent, a PEG_5 compound and a PEG_9 derivative (Figure 18.3). Unlike the popular BS^3 reagent (Chapter 5, Section 1.2), which is initially hydrophilic and water soluble due to the presence of negatively charged sulfo-NHS esters on both ends but after reacting leaves behind a 6-carbon hydrophobic spacer, these PEG compounds attach two molecules together using a long and very hydrophilic bridge.

The *bis*-NHS–PEG_5 reagent provides a 21.7-Å spacer after attaching both ends to amines on two molecules, which is nearly twice the spacer distance provided by BS^3. The longer chain *bis*-NHS–PEG_9 reagent has a very long 35.8-Å spacer. All of these distances are measured between the carbonyl groups of the two NHS esters, which would form the amide bonds and remain behind after crosslinking two molecules together. The distances represent the energy minimized, maximal molecular distance of a linear structure and may not reflect how such structures exist in solution. All such molecular distance measurements are approximations and only serve to provide comparable information relative to the sizes of different reagents.

The reaction of the NHS esters occurs at physiological pH or under slightly basic conditions to couple rapidly with amines and form amide bonds (Figure 18.4). The NHS ester groups are also subject to hydrolysis in aqueous solution, and the rate of hydrolysis increases with increasing pH. The more hydrophilic the molecule, the greater the potential for hydrolysis. Nectar reported that for long-chain polymeric PEGs containing NHS esters that the half-life of hydrolysis effectively triples upon lowering the pH one unit. In addition, the molecular constituents immediately adjacent to the NHS ester affect the half-life of hydrolysis of activated PEG compounds. For instance, the addition of a 4-carbon aliphatic chain between the PEG polymer and the NHS ester results in a half-life of hydrolysis of about 44 min at pH 8. Reducing this to only a 2-carbon unit decreases the half-life of the NHS ester to about 3 min. Therefore, to aid in NHS ester stability maintaining a reaction pH in the range of 7.0 to 7.5 is optimal for most applications.

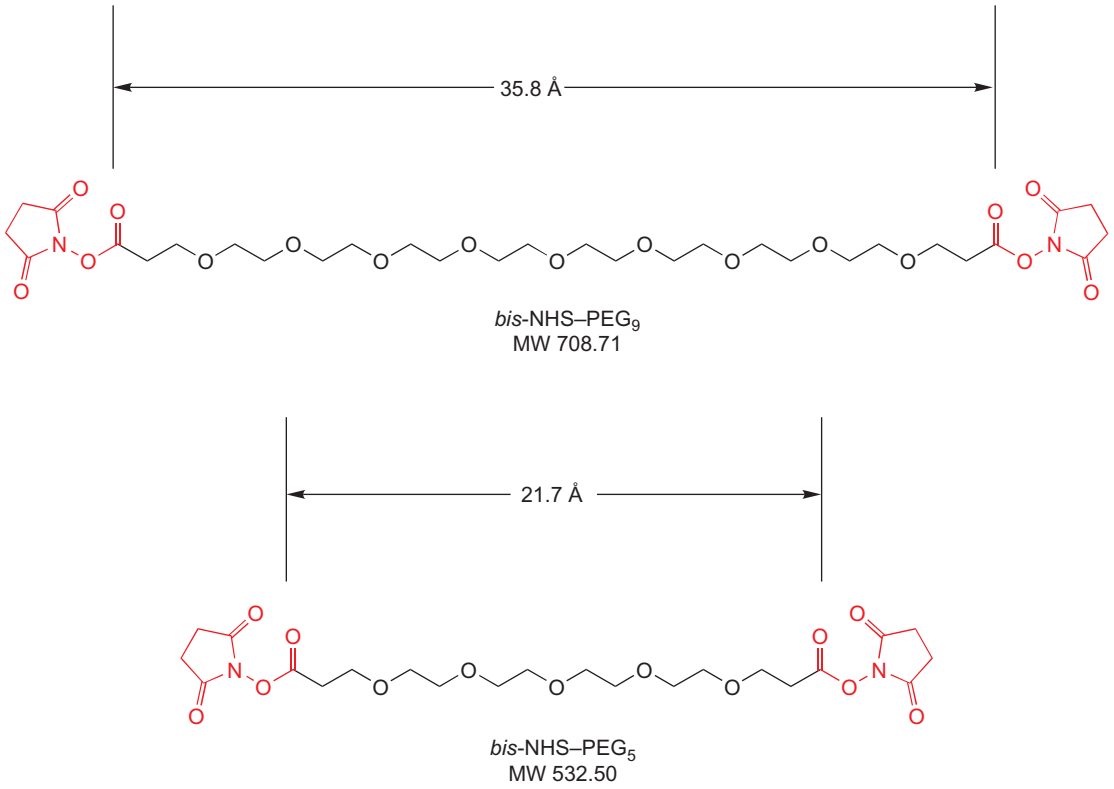

FIGURE 18.3 Homobifunctional NHS ester compounds containing PEG spacers for water solubility.

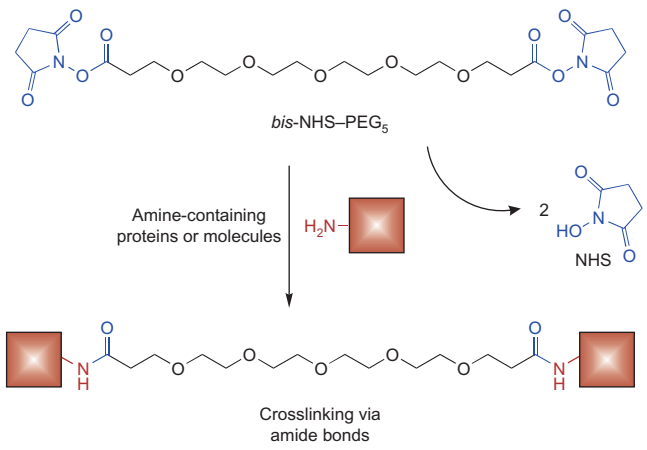

FIGURE 18.4 The reaction of *bis*-NHS–PEG_5 with amines on proteins yields amide bond linkages with amine-containing molecules.

The following protocol describes a general method for using *bis*-NHS ester–PEG compounds. Optimization of concentrations should be carried out for each application to ensure the best possible results. See also the protocol in Chapter 24, Section 1, which describes the use of homobifunctional NHS-ester compounds to study protein interactions. These *bis*-NHS–PEG compounds may provide a superior crosslinker for studying such interactions due to their water solubility and the fact that the PEG bridge will not get buried in hydrophobic pockets on proteins or within hydrophobic membrane structures.

Protocol

1. Dissolve the *bis*-NHS–PEG compound in a dry, water-miscible organic solvent to make a concentrated stock solution. To prepare a 10-m*M* solution of the *bis*-NHS–PEG_9 reagent, dissolve 7 mg per milliliter of DMAC; for the *bis*-NHS–PEG_5 reagent dissolve 5.3 mg/ml of DMAC.
2. Dissolve the molecules to be conjugated in 0.1-*M* sodium phosphate, pH 7.2 (for aqueous reactions), or in DMSO, DMAC, or methylene chloride (for organic reactions). If proteins are to be conjugated, a concentration of 1 to 10 mg/ml in buffer will work well in this protocol. For more dilute protein solutions, greater quantities of the *bis*-NHS–PEG compound may have to be added than recommended here to obtain similar levels of crosslinking.
3. Add a quantity of the crosslinker solution to the protein solution to provide a 1- to 10-fold molar excess of reagent over the concentration of protein. The use of lower molar ratios will limit the potential for oligomerization of proteins in solution. A series of reactions using different concentrations of crosslinker

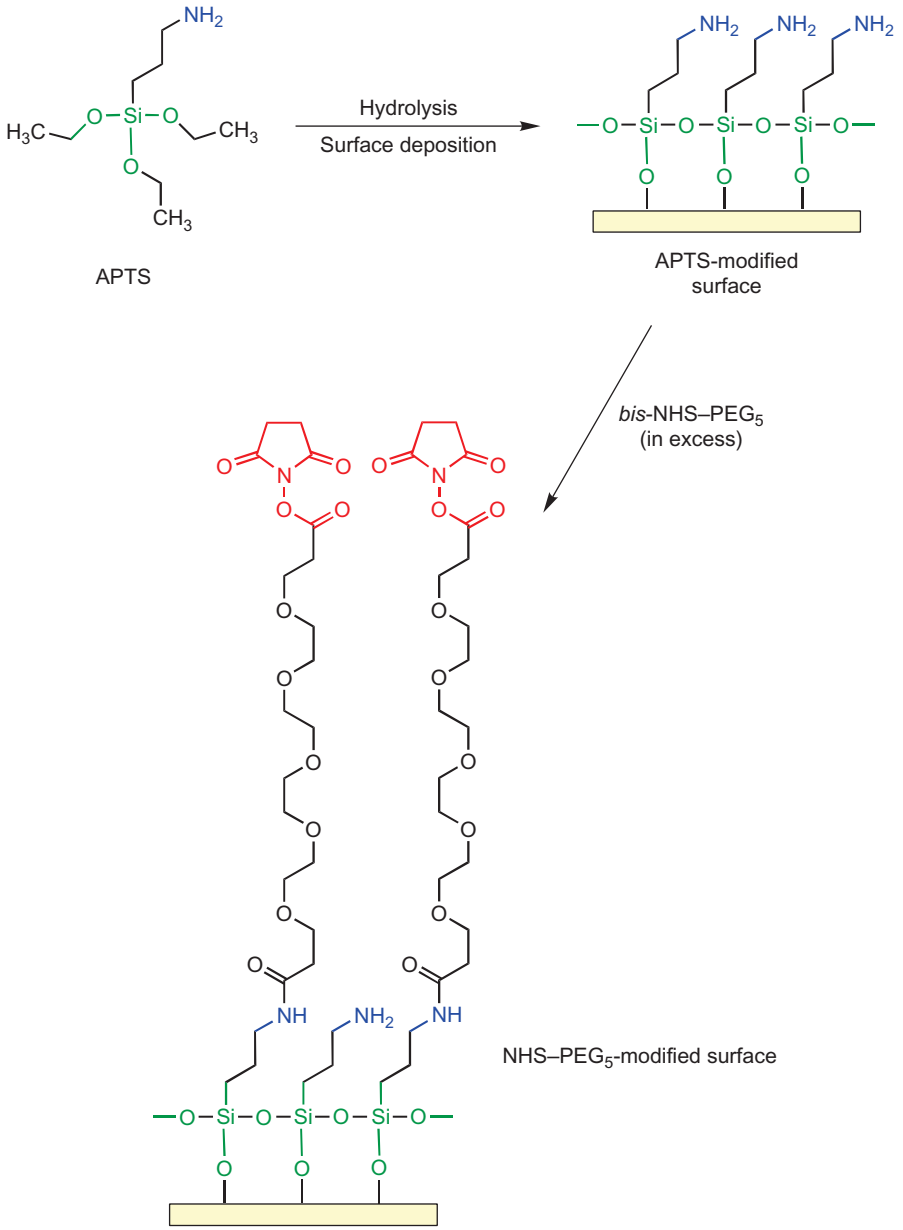

FIGURE 18.5 The modification of an APTS-modified surface containing amines with *bis*-NHS–PEG_5 yields hydrophilic spacers containing terminal NHS esters for coupling proteins.

may have to be performed to determine the optimal level to use for a particular application.

4. React for 30 to 60 min at room temperature.
5. Remove excess crosslinker by dialysis or gel filtration.

The *bis*-NHS–PEG compounds may also be used for modifying surfaces or particles that contain amine groups. If the *bis*-NHS–PEG reagent is reacted in large excess to the concentration of amines, then a single end of each crosslinker will couple to the amine groups on the surface and result in a PEG spacer terminating in a reactive NHS ester for further conjugation. Surfaces modified with an amino–silane group, such as 3-aminopropyltriethoxysilane (APTS), are particularly good for further modification with PEG-based reagents. For instance, APTS-modified glass slides or silica particles contain aminopropyl groups that can be modified with the *bis*-NHS–PEG compounds. This will create a hydrophilic monolayer having low nonspecific binding character and that can be used to covalently link to biomolecules *via* the terminal NHS ester group (Figure 18.5).

The following procedure can be used with planar or spherical surfaces containing amine groups. The reaction is performed in organic solvent to preserve the

activity of the terminal NHS ester after modification of the surface. For particle modification, care should be taken in choosing a solvent that will not damage the particle core structure, such as the potential for certain organic solvents to dissolve polymeric particles. Silica particles, however, are very robust to solvent conditions and can be used without damage. See also Chapters 10, 14, and 15 for other particle conjugation methods.

Protocol

1. In a fume hood, wash the amine-containing surface with organic solvent to remove any contaminants or water (especially when working with particles). Suggested solvents to use for this reaction are highly pure and dry DMAC, DMSO, or DMF. Particles can be washed by repeated centrifugation and resuspension.
2. Dissolve *bis*-NHS–PEG_5 into the solvent of choice at a concentration of 1 mg/ml also containing an equal molar concentration of triethylamine as base. Add the crosslinker solution to the surface or to the particles to coat them fully. When working with particles, centrifuge them to remove solvent prior to resuspending in the crosslinker solution.
3. React for 30 to 60 min at room temperature with mixing.
4. Wash the surface or particles with solvent at least 3 times to remove excess crosslinker.

Planar surfaces activated with the NHS–PEG groups may be sealed in a pouch and stored dry in the presence of a desiccant. Activated particles may be stored as a suspension in dry solvent under a head of nitrogen at 4°C until used for further conjugation (e.g., in DMAC). The addition of an amine-containing protein or another amine-molecule will cause covalent coupling to the surface NHS ester groups to form amide bonds.

bis-Maleimide PEG Compounds

Homobifunctional crosslinkers containing thiol-reactive maleimides on each end of a PEG spacer are available in several sizes. These compounds are hydrophilic and react with sulfhydryls to produce thioether linkages, which are stable under most conditions. The following compounds can be obtained from Thermo Fisher or Quanta BioDesign.

$BM(PEG)_2$, $BM(PEG)_3$, and bis-MAL–$dPEG_3$

$BM(PEG)_2$ is 1,8-*bis*-maleimidodithyleneglycol, a hydrophilic reagent containing a 14.7-Å spacer arm. This compound is also called $BM(PEO)_2$ by Thermo Fisher, wherein PEO is the acronym for poly(ethylene oxide), but to maintain a consistent nomenclature throughout this book, it is referred to under the PEG name. Another pair of crosslinkers, $BM(PEG)_3$ and *bis*-MAL–$dPEG_3$ have one additional PEG unit and

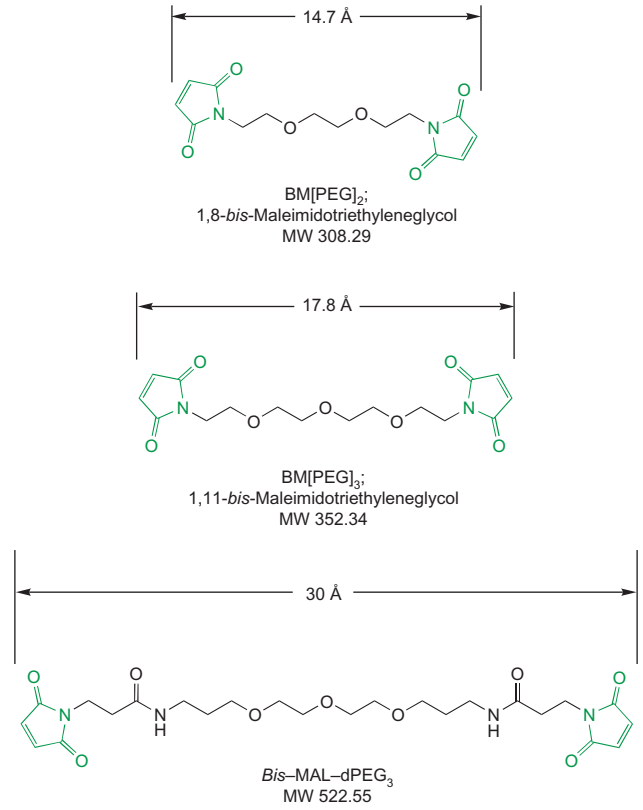

FIGURE 18.6 The structures of $BM(PEG)_2$, $BM(PEG)_3$, and *bis*-MAL–$dPEG_3$ contain thiol-reactive maleimide groups on the ends of a discrete PEG spacer arm.

provide similar bifunctional maleimides, but differ only in their structures leading from the PEG spacer to the maleimides (Figure 18.6). $BM(PEG)_5$, has a 17.8-Å spacer, while *bis*-MAL–$dPEG_3$ has a longer 30-Å length. These dimensions are measured between the outer hydrogens on the maleimide groups using linear three-dimensional structures after energy minimization. The actual structural configurations in aqueous solution almost certainly will not be linear and thus the molecular dimensions will differ from these values.

All of these bifunctional maleimides can be used to conjugate together two proteins containing available thiol groups (Figure 18.7). For instance, artificial bispecific antibodies have been created by coupling two disulfide-reduced antibodies together having different antigenic specificities using the thiol-reactive crosslinker SPDP (Chapter 6, Section 1.1). This was done by reducing the disulfides in the hinge region of antibodies to produce two heavy-/light-chain complexes containing one antigen binding site each and then conjugating the fragments from both antibodies together with SPDP (Foglesong *et al.*, 1989). Coupling one reduced antibody with another of a different specificity using a hydrophilic reagent such as $BM(PEG)_2$ will form a conjugate having two different antigen binding capabilities. The

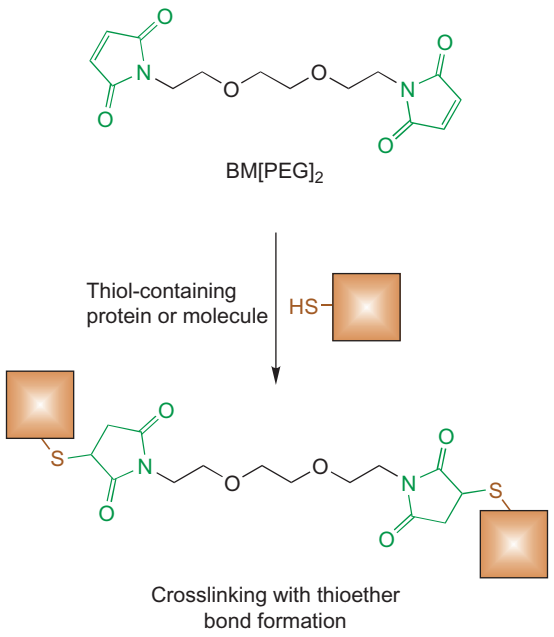

FIGURE 18.7 $BM(PEG)_2$ reaction with thiol-containing proteins forms crosslinks *via* thioether linkages.

advantage of using a PEG-based compound over SPDP is greater water-solubility of the resultant conjugate.

$BM(PEG)_2$ can also be used to determine protein–protein interactions or subunit interactions if there are free thiol groups available on each protein or subunit. The following protocol can be used to crosslink two thiol-containing proteins.

Protocol

1. Dissolve the thiol-containing proteins to be crosslinked in 50-m*M* sodium phosphate, pH 6.5–7.5, containing 10-m*M* EDTA to prevent metal-catalyzed sulfhydryl oxidation.
2. Dissolve $BM(PEG)_2$ in DMSO or DMF at a concentration of 10 to 20-m*M* (3.1 mg/ml to make a 10-m*M* solution).
3. Add a quantity of the crosslinker solution to the protein solution to provide a 1- to 10-fold molar excess of crosslinker to protein. Lower molar ratios will help prevent oligomerization of protein if the proteins contain more than one available thiol group. A series of different molar ratios may be studied to optimize the level of reagent addition.
4. React for 1 to 2 h at room temperature.
5. Purify the conjugate by dialysis or gel filtration.

1.2. Heterobifunctional PEG Reagents

Heterobifunctional crosslinkers contain different reactive groups or functionalities at each end of a spacer arm. Traditional reagents of this type are discussed in Chapter 6, but the PEG-based compounds are reviewed exclusively here, because of their unique water-soluble characteristics. The most popular aliphatic heterobifunctional compound is SMCC (or sulfo-SMCC), which contains an NHS ester on one end and a maleimide group on the other end. However, this compound suffers from a cross-bridge that is both water insoluble and immunogenic. Redesigning this crosslinker to have a PEG cross-bridge provides enhanced water solubility for modified proteins or other molecules as well as displaying very low immunogenicity. These benefits of discrete PEG spacers create a new generation of heterobifunctional compounds, which dramatically improve the performance of conjugates made from them. The following sections describe these reagents in more detail.

Maleimide–PEG_n–NHS Ester Compounds

One of the most useful types of crosslinkers ever invented is a heterobifunctional compound containing an NHS ester on one end and a maleimide group on the other end. The ability to link an amine-containing molecule to another molecule containing a thiol group provides control over the conjugation process, which avoids the potential for oligomerization that often occurs when using homobifunctional crosslinkers. Probably the most significant recent development in this type of reagent is the introduction of PEG spacers in their cross-bridge construction. Unlike the previous iteration of these compounds that all used hydrophobic spacers (Chapter 6, Section 1), the PEG-based reagents provide water-solubility both of the initial compound and of the crosslink itself after the reaction has taken place.

NHS–PEG_n–maleimide crosslinkers are available as a series of different chain lengths of PEG within the cross-bridge, including repeating ethylene oxide units of 2, 4, 6, 8, 12, and 24 (Quanta BioDesign and Thermo Fisher). This series provides a range of molecular lengths after conjugation from 17.6 Å to 95.2 Å, so that an optimal size can be determined for nearly any application (Figure 18.8). The longest crosslinker of the group, NHS–PEG_{24}–maleimide, has a total length that compares to almost the diameter of a typical immunoglobulin (IgG) antibody molecule. Longer-chain NHS–PEG–maleimide crosslinkers may be appropriate especially for the masking of surfaces to permit coupling of affinity ligands, while avoiding the potential for nonspecific interactions with the surface structure. In addition, these heterobifunctional PEG compounds are superior choices for linking haptens to carrier proteins to create immunogens. In this application, the PEG chain provides a high degree of freedom of motion and does not illicit an immune response itself, thus effectively generating antibodies *in vivo* with greater specificity toward the hapten, not the carrier or the crosslinker.

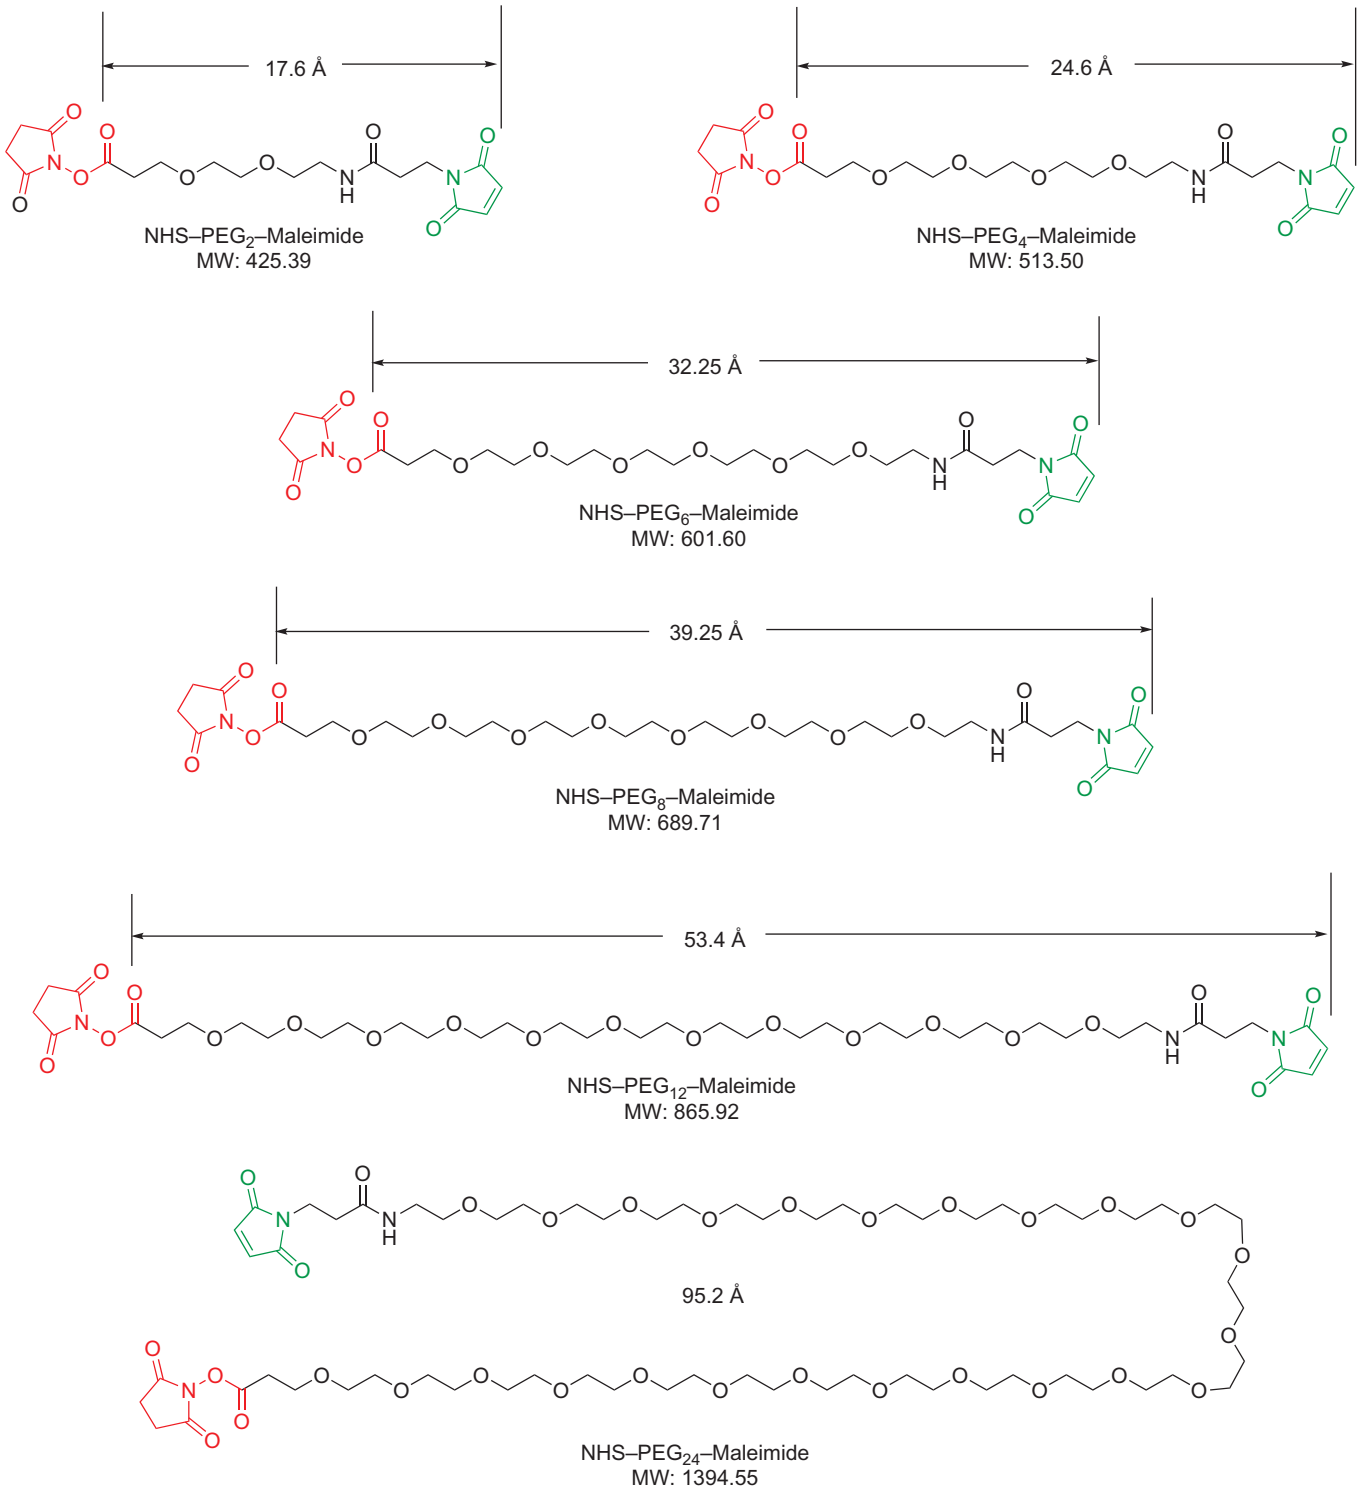

FIGURE 18.8 Series of NHS–PEG–maleimide crosslinkers.

In use, NHS–PEG–maleimides are first reacted in at least a 10-fold molar excess with an amine-containing molecule, such as a protein, to form an intermediate derivative with terminal maleimide groups. Depending on the number of maleimide modifications needed, the molar excess of crosslinker may be adjusted to provide the desired level of activation. The maleimide groups are more stable in aqueous solution than the NHS esters, so the modified protein can be purified from excess crosslinker before reacting it with

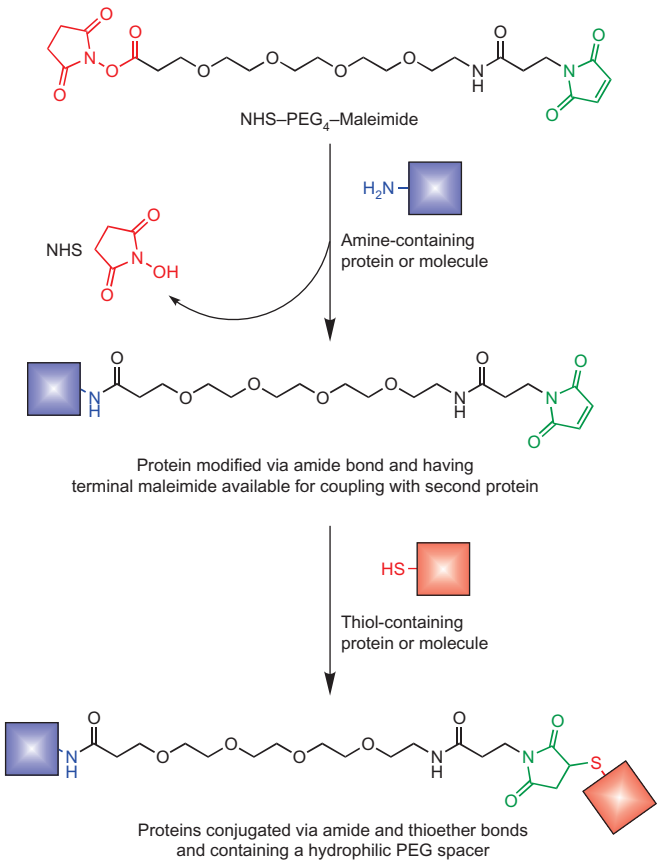

FIGURE 18.9 NHS–PEG_4–maleimide conjugation reactions are carried out in two steps involving modification of an amine-containing molecule with the NHS ester end with subsequent coupling of the maleimide end with a thiol-containing molecule.

a sulfhydryl-containing molecule or protein. After purification, the maleimide–PEG–protein derivative is reacted with a second protein containing sulfhydryls to form the final conjugate *via* a thioether bond (Figure 18.9). The higher the number of maleimide–PEG modifications on the first protein, the greater the number of potential sulfhydryl-containing proteins may be conjugated to it. The ratio of the reactants is often chosen to give at least several thiol-proteins conjugated to each of the maleimide–PEG–protein derivatives. Optimization of this ratio should be carried out to determine the best conjugate for a given application.

The intermediate maleimide–PEG–protein derivative maintains excellent solubility due to the presence of the PEG chains. Unlike a hydrophobic NHS–maleimide-type crosslinker made from an aliphatic cross-bridge, the PEG chains have a tendency to increase the solubility of modified proteins or other molecules. This effect is amplified when using PEG compounds of longer dimensions. The result is that modified proteins remain soluble, and even if not every maleimide group gets conjugated to a thiol-containing molecule, the presence of unreacted crosslinkers on the protein surface does not contribute to nonspecific interactions of the conjugates.

Most of these PEG crosslinkers come as thick, sticky, viscous liquids or low-melting solids (PEG_2). For this reason, weighing out a small sample of a compound can be difficult or impossible. It is usually best to dissolve an entire vial or a larger amount in organic solvent at a known concentration to permit accurate dispensing of a smaller amount into a reaction. Suitable solvents to prepare a stock solution include dry (molecular sieved) DMSO, DMF, DMAC, acetonitrile, or methylene chloride (for non-water-miscible reactions).

The following protocol is a general guide for using NHS–PEG_n–maleimide crosslinkers. This method may be used as a starting point for developing an optimized procedure for creating a unique conjugate.

Protocol

1. In a fume hood, dissolve the NHS–PEG_n–maleimide compound of choice in a dry, water-miscible organic solvent to make a concentrated stock solution. For instance, to prepare a 100-m*M* solution of the NHS–PEG_6–maleimide reagent (MW 601.6), dissolve an entire 100-mg vial of the crosslinker in 1.66 ml of DMAC (dry DMSO or DMF works well, too).
2. Dissolve the amine-containing protein to be activated in 0.1-*M* sodium phosphate, pH 7.2 (coupling buffer). A protein concentration of 1 to 10 mg/ml in buffer will work well in this protocol. For more dilute protein solutions, greater quantities of the NHS–PEG_n–maleimide compound may have to be added to obtain equivalent levels of modification.
3. Add a quantity of the crosslinker solution to the protein solution to provide at least a 10-fold molar excess of reagent over the amount of protein present. Higher levels of reagent to protein may be used, even up to a 50-fold molar excess, to obtain a large number of active groups for subsequent coupling to a thiol-containing protein. Conversely, the use of lower molar ratios will limit the number of maleimide–PEG modifications on each protein to just a few. A series of reactions using different concentrations of crosslinker may have to be done to determine the optimal level to use for a particular application.
4. React with gentle mixing for 30 min at room temperature or 60 min at 4°C.
5. Remove excess crosslinker by centrifugal dialysis or gel filtration using a molecular weight exclusion of 5000. This procedure should be carried out quickly due to the labile nature of the maleimide group in aqueous solution, which will hydrolyze to a ring-open maleamic acid that is ineffective at coupling to thiols.
6. Dissolve a sulfhydryl-containing protein in coupling buffer containing 10-m*M* EDTA at a concentration of at least 1 to 10 mg/ml. Thiols may be generated

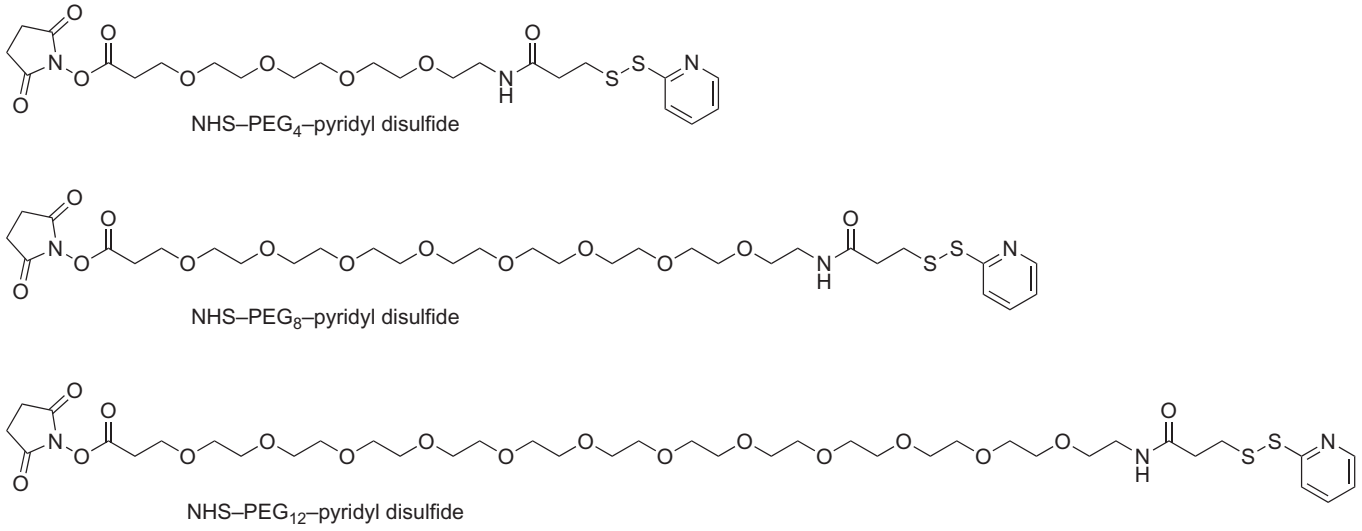

FIGURE 18.10 Examples of NHS–PEG$_n$–pyridyl disulfide compounds that can be used to crosslink amine-containing molecules with thiol-containing molecules.

in proteins by disulfide reduction or through use of a thiolation reagent (Chapter 2, Section 4.1). The amount of the thiol-containing protein needed is determined by the optimal molar ratio desired in the final conjugate of the thiol-containing protein to the maleimide-activated protein purified in step 5. Often, this means performing a reaction of the thiol-containing protein to the maleimide–PEG–protein in at least a 4-to-1 molar ratio, but higher ratios (e.g., 15 to 1) can also be used, depending on the application. Note that the number of thiol-containing protein molecules that can be conjugated with the maleimide–PEG–protein is limited by the number of reactive maleimide groups present and also by the molecular size of the two molecules being conjugated. Steric crowding will limit how many thiol-containing proteins can be attached to the maleimide-activated protein.

7. Add the thiol-containing protein to the maleimide–PEG–protein in the desired molar ratio to initiate the conjugation reaction.
8. React with gentle mixing for at least 2 h at room temperature or overnight at 4°C.
9. The conjugate may be purified to remove unconjugated protein using gel filtration on a column of resin having a molecular weight cut-off able to accommodate the proteins being separated.

NHS–PEG$_n$–Pyridyl Disulfide Compounds

One of the earliest heterobifunctional reagents that were introduced for bioconjugation applications is SPDP (Chapter 6, Section 1.1). This compound has an NHS ester on one end for coupling with amine groups, forming amide bonds, and a pyridyl disulfide on the other end to couple with thiols, which forms disulfide bonds. The reagent has been used extensively to design cleavable conjugates with all types of molecules, especially to create antibody–toxin complexes, which can release a toxin payload after binding to tumor cells *in vivo* (Chapter 20, Section 3.2.1). SPDP has an aliphatic spacer that is hydrophobic and is of limited molecular length (6.8 Å), which limits its usefulness for applications that might benefit from a longer cross-bridge. The longer analog to this reagent, NHS–LC–SPDP, contains an internal 6-aminocaproic acid spacer that provides greater length, but the increase in hydrophobicity due to the aliphatic portion can be problematic. A new alternative set of compounds built upon PEG cross-bridges now is available that solves the problems associated with hydrophobic heterobifunctionals (Thermo Fisher, Quanta BioDesign). These NHS–PEG$_n$–pyridyl disulfide compounds contain the same reactive groups on either end as SPDP, but the internal PEG spacer options provide water solubility and a dramatically decreased nonspecific binding characteristic in biological systems or samples. Quanta BioDesign calls these compounds by the name SPDP–dPEG®n–NHS ester and Thermo Fisher uses the general name PEGn–SPDP, where "n" in both names represents the number of repeating PEG units in the cross-bridge.

NHS–PEG$_n$–pyridyl disulfide reagents are available in options containing a PEG$_4$, PEG$_8$, PEG$_{12}$, PEG$_{16}$, PEG$_{20}$, PEG$_{24}$, or PEG$_{36}$ internal cross-bridge, which provides molecular lengths of approximately 26 Å, 37 Å, 54 Å, 64 Å, 79 Å, 97 Å, or 138 Å, respectively. Figure 18.10 shows the three shorter chain lengths in this series. The longest of these reagents provide chain lengths that equal or exceed the diameters of most biological macromolecules, such as proteins. These second-generation reagents are similar in reactivity to the original SPDP-type crosslinkers,

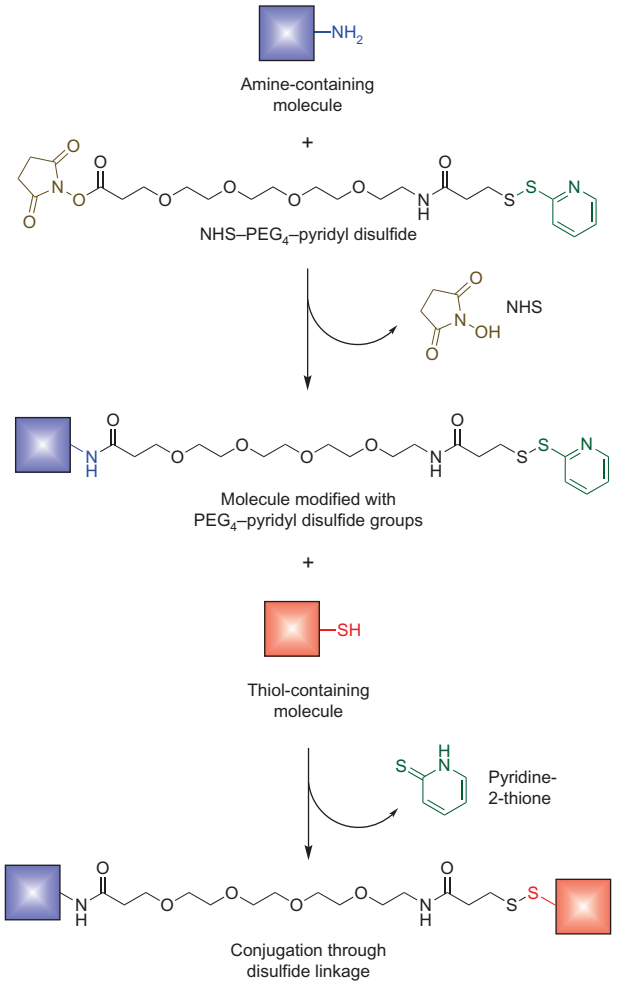

FIGURE 18.11 The reactions of NHS–PEG_4–pyridyl disulfide in conjugating an amine-containing molecule with a thiol-containing molecule. The disulfide bond formed in the final reaction is reversible using a disulfide reducing agent.

nevertheless they have superior properties related to hydrophilicity, spacer arm length, and decreased nonspecific binding.

Figure 18.11 illustrates the NHS–PEG_4–pyridyl disulfide compound and its reactions for conjugating an amine-containing molecule with a thiol-containing molecule. The NHS ester end is typically reacted first to form a stable amide bond with an amine-containing molecule. After purification of the modified molecule from excess reagent, the pyridyl disulfide end can next be coupled to a thiol-containing molecule to form a disulfide bond. The disulfide linkage is reversible by using reducing agents such as DTT, TCEP, or 2-mercaptoethylamine. The compounds can also be used as a thiolation agent to modify amines on molecules, particles, or surfaces to create terminal thiols for further modification or coupling of another molecule or affinity ligand. Thiolation reactions with SPDP-type reagents have been performed since their introduction and the similar PEG-based compounds may be used for this purpose using the same general protocols. For thiolation, the pyridyl disulfide end is simply reduced to create the free thiol on the modified component instead of immediately reacting it with another thiol-containing molecule. Thus, the same crosslinker can be used to create reactive pyridyl disulfide groups on one molecule and thiolate a second molecule to create SH groups. These two modified molecules then can be reacted together to form a bioconjugate containing the combination of two PEG internal cross-bridges linked by a central disulfide bond.

The following protocols for the conjugation of an antibody with a thiol-containing particle can be applied in a similar manner to the conjugation of a pyridyl disulfide-modified antibody with another protein that has been thiolated with this reagent. In this protocol, an antibody molecule is modified with NHS–PEG_4–pyridyl disulfide and a particle is thiolated to contain thiol groups using the same crosslinker. The two modified intermediates are then reacted to form the final conjugate, which is linked together by disulfide bonds. For modification of surfaces or particles, the reactions should be optimized to include enough of the reagent to thoroughly modify the surface amine groups and create the desired density of PEG–pyridyl disulfides for further conjugation. The use of long PEG cross-bridges in the coupling of proteins and other molecules to surfaces can have the added benefit of providing significant hydrophilicity to the substrate, thus increasing the freedom of motion in aqueous solution and decreasing the nonspecific binding potential of the final complex toward nonrelevant molecules in a sample.

Protocol for Activation of an Antibody with NHS–PEG_4–Pyridyl Disulfide

1. Dissolve 2 mg of an antibody (IgG) in 200 µl of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, containing 10-m*M* EDTA (coupling buffer). Note: This makes a 10-mg/ml solution of the antibody in coupling buffer. More dilute antibody solutions may require an increase in the amount of crosslinker added to the reaction to obtain the same level of modification as this protocol provides.
2. Dissolve 2 mg of NHS–PEG_4–pyridyl disulfide crosslinker in 200 µl of dry DMSO, DMF, or DMAC (makes a 17.9-m*M* solution).
3. Add 7.5 µl of the dissolved crosslinker to the antibody solution and immediately vortex mix to create a uniform solution. This amount of addition represents approximately a 10-fold mole excess of the crosslinker over the antibody in the solution. Note: Some optimization of the amount of NHS–PEG_4–pyridyl disulfide compound to add should be

performed to obtain the best possible final conjugate in the intended application. Experiments carried out using a range of different mole excesses of crosslinker over the antibody present can identify the best level of modification to use.

4. React for 30 min at room temperature with periodic mixing in a sealed container (e.g., microfuge tube).
5. Purify the modified antibody by dialysis or size exclusion chromatography using a 5-ml desalting column. Use coupling buffer as the dialysis or chromatography solution. Concentrate the antibody using centrifugal concentrators to approximately 200 µl, if necessary. The pyridyl disulfide-activated antibody may be used immediately to conjugate with a thiol-containing particle or protein.

Protocol for Thiolation of Amine-Containing Particles with NHS–PEG$_4$–Pyridyl Disulfide

1. Wash 10 mg of amine-containing particles with 50-m*M* sodium phosphate, pH 7.5, containing 10-m*M* EDTA, while using centrifugation to separate the particles or another appropriate method of exchanging them into coupling buffer. Finally, resuspend the particles in 1 ml of coupling buffer.
2. Dissolve 2 mg of NHS–PEG$_4$–pyridyl disulfide into 200 µl of dry DMSO, DMF, or DMAC (17.9-m*M* solution).
3. Add 55 µl of the NHS–PEG$_4$–pyridyl disulfide solution to the particle suspension with mixing.
4. React with mixing for 30 min at room temperature.
5. Wash the modified particles with coupling buffer at least 3 times using centrifugation and resuspend in 1 ml of the same buffer.
6. Reduce the pyridyl disulfide groups on the particles by the addition of DTT to a final concentration of 50-m*M* and incubate for 30 min with mixing at room temperature.
7. Thoroughly wash the thiolated particles with coupling buffer to remove excess reducing agent and the released pyridine-2-thione. After the final wash and centrifugation, resuspend the thiolated particles in 1 ml of coupling buffer and proceed to part (C).

Protocol for Conjugation of the Pyridyl Disulfide-Modified Antibody to the Thiolated Particles

1. Mix the thiolated particles prepared in part (B) with the activated antibody solution prepared in part (A) using vortex mixing.
2. React for 18 h at room temperature (or at 4°C) with constant mixing using an end-over-end rotator with the particle suspension contained in a sealed centrifuge tube.
3. Wash the particles using coupling buffer at least 3 to 5 times using centrifugation and resuspension.

The immobilized antibody may be stored until use at 4°C in water or buffer containing a preservative.

NHS–PEG$_n$–Azide/Alkyne Compounds for Chemoselective Ligation

Another family of heterobifunctional compounds containing an internal PEG spacer is represented by reagents with an NHS ester on one end and either an azide or alkyne group on the other end (Figure 18.12). These reagents react with amines on proteins or other molecules to create an amide bond derivative having a terminal functionality suitable for use in chemoselective ligation reactions, particularly click chemistry cycloaddition and Staudinger ligation (Chapter 17, Sections 5 and 6). Click chemistry is the reaction between an azide and an acetylene group in the presence of a catalytic amount of Cu(I) yielding a triazole ring linkage, which is a very efficient process for bioconjugation purposes. NHS ester heterobifunctional compounds containing these groups may be used to functionalize biomolecules, organic compounds, particles, or surfaces with azides or alkynes. Since both the azido and acetylene groups are highly stable in aqueous solution or in the presence of biomolecules, the modified substances or devices maintain nearly indefinitely the ability to conjugate molecules containing the opposite functionality.

The azide-containing PEG compounds can also be used in the Staudinger ligation process with a phosphine-containing group having an electrophilic trap. This reaction, like the click chemistry process, is chemoselective and highly bioorthogonal in that the functional groups will not react with typical functionalities present in biological solutions. The Staudinger ligation reaction with PEG–azide compounds proceeds to give an amide bond with either retention of the phosphine component or, in the traceless version of the reaction, with loss of the phosphine and formation of a zero-length crosslink between the two reacting molecules (Figure 18.13).

Click chemistry or Staudinger ligation-equipped heterobifunctional crosslinkers containing a hydrophilic PEG spacer provide a stable, yet highly efficient means to conjugate or immobilize biomolecules. The PEG spacer provides water solubility, low nonspecific binding character, and low immunogenicity.

Three PEG lengths are available in NHS–PEG$_n$–azide compounds, including n = 4, 8, or 12 ethylene oxide repeat units (Figure 18.12) (Quanta BioDesign and Thermo Fisher). The NHS–PEG$_4$–azide compound provides a 16-atom spacer, which is 17.7 Å long after reaction with an amine-containing molecule. The NHS–PEG$_8$–azide and the NHS–PEG$_{12}$–azide reagents provide longer spacer arms having molecular distances of 32.2 Å and 46.4 Å, respectively. All of these measurements are done using three-dimensional molecular models that

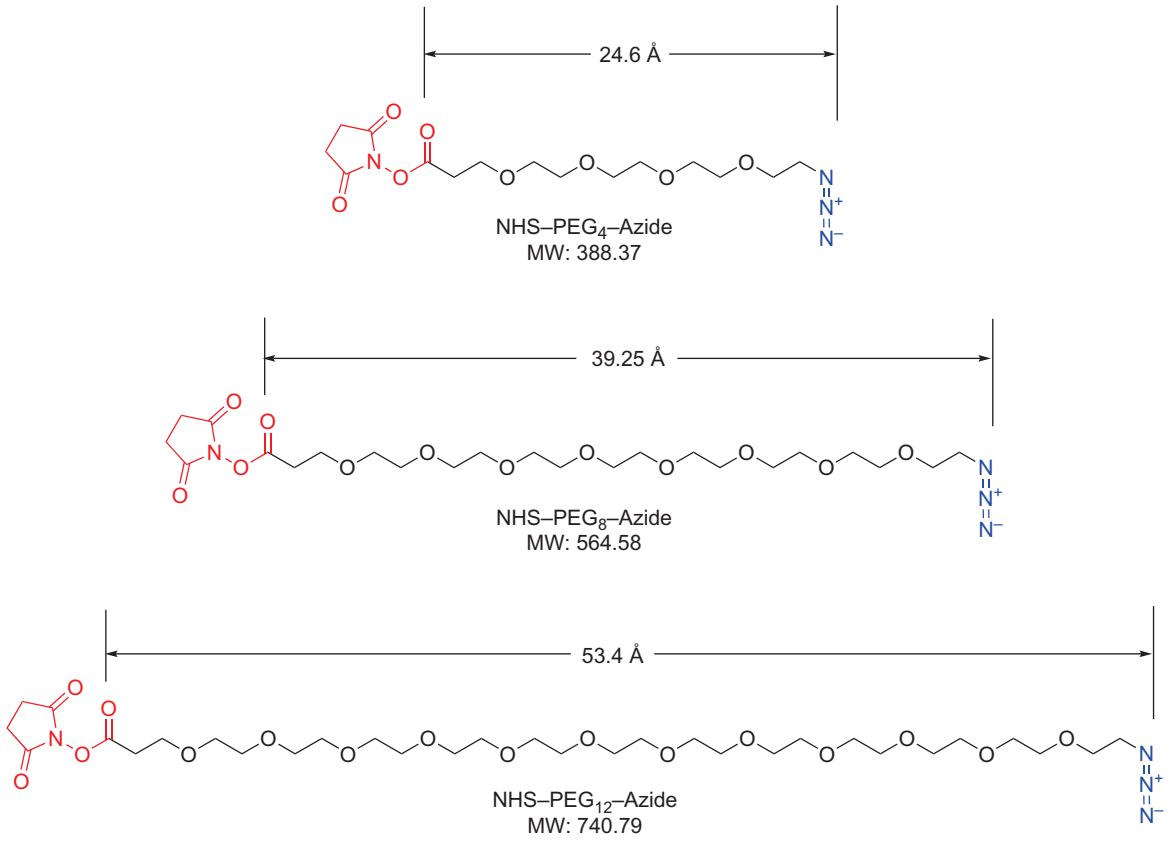

FIGURE 18.12 NHS–PEG–azide compounds can be used to modify amine-containing proteins or other molecules for subsequent conjugation using either the click chemistry reaction or Staudinger ligation.

are linearized structures with distances taken from the NHS ester carbonyl group to the first nitrogen atom of the azide. The actual molecular dimensions between crosslinked molecules will differ from these values due to the different conformations that the PEG chains can take in aqueous solution and due to the formation of the triazole ring after the click reaction has taken place.

Only one reactive compound is currently available for modifying amine-containing molecules with an acetylene group, which is the propargyl–PEG_1–NHS ester containing only a single ethylene oxide unit (Figure 18.14) (Quanta BioDesign, Thermo Fisher). Other simple alkyne-based raw materials are also commercially available with functional groups, such as propargylamine and various carboxylic acid derivatives (4-pentynoic acid, Aldrich), which can be used in a carbodiimide reaction to modify molecules or surfaces. Creative PEGWorks also offers longer $mPEG_n$–alkyne reagents and *bis*-alkyne–PEG compounds as well as tetra-alkynyl PEG dendrimers, but no heterobifunctional compounds of discrete PEG lengths.

The following protocol may be used to modify a protein for coupling to a surface using the NHS–PEG_n–azide and propargyl–PEG_1–NHS ester compounds. Similar procedures may be used to conjugate two molecules together, such as forming an antibody–enzyme conjugate.

Protocol for Modification of Protein 1 with NHS–PEG_n–Azide Groups

1. Dissolve a first protein to be modified with an azide group in 100-m*M* sodium phosphate, pH 7.2 (PBS), at a concentration of at least 1 to 10 mg/ml.
2. In a fume hood, prepare a stock solution of an NHS–PEG_n–azide by dissolving it at a concentration of 20-m*M* in DMAC, DMSO, or DMF (using highly pure and dry solvent).
3. Add a quantity of the crosslinker solution to the protein solution with mixing to provide at least a 10-fold molar excess of crosslinker over the amount of protein present.
4. React with mixing for 30 to 60 min at room temperature.
5. Purify the azido–PEG–protein by dialysis or gel filtration using PBS to remove excess reactants and solvent. The azide modifications are stable to aqueous conditions, so the protein derivative may be stored in this form until needed, provided the protein is stable.

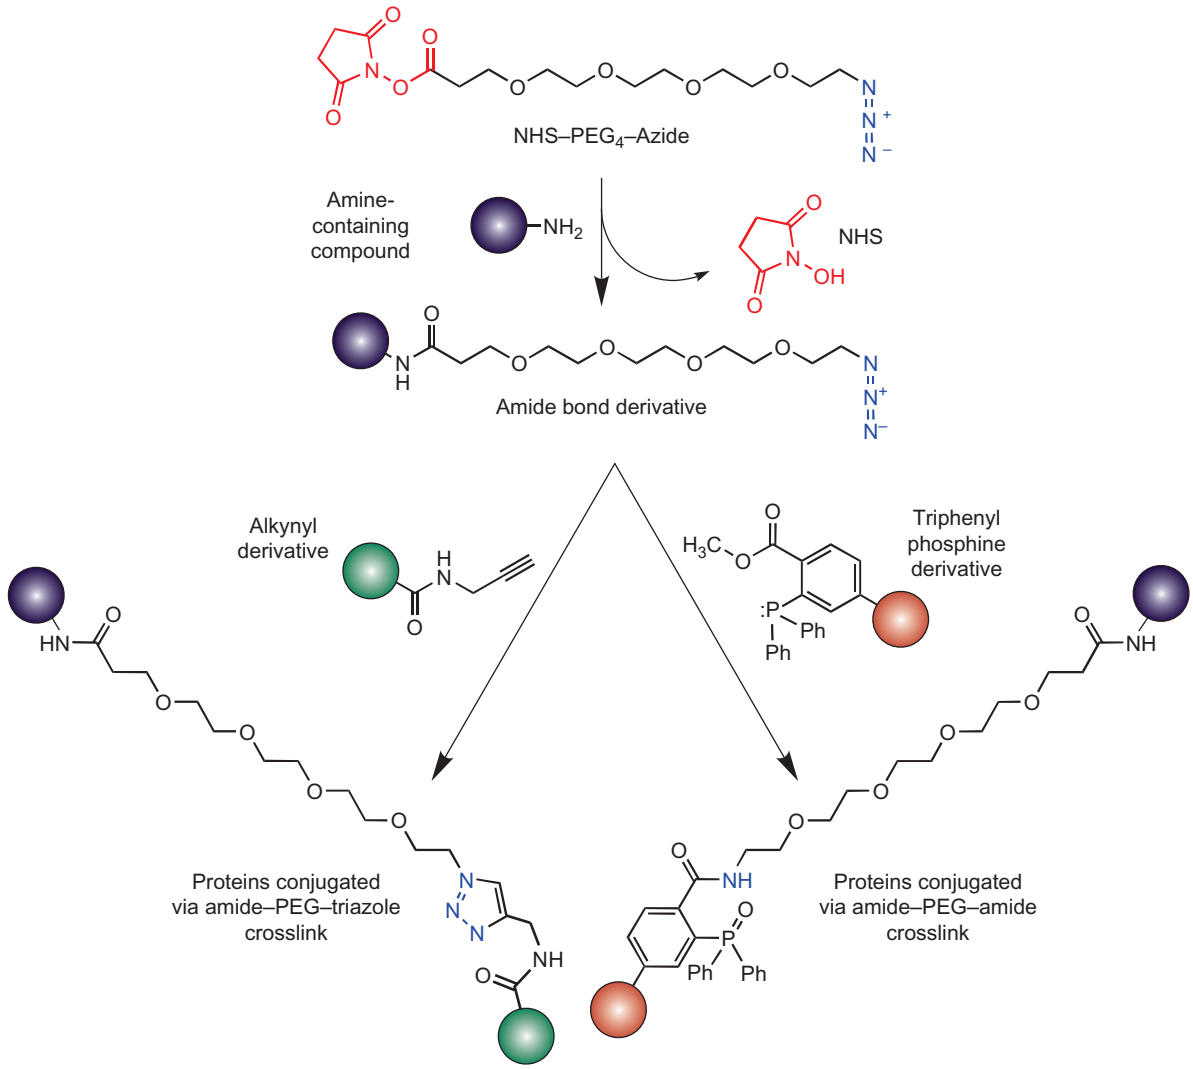

FIGURE 18.13 NHS–PEG_4–azide can be used to modify an amine-containing molecule to create an amide derivative terminating in azido groups. The azide modifications then can be used in a click chemistry reaction that forms a triazole linkage with an alkyne-containing molecule. Alternatively, the azide derivative can be used in a Staudinger ligation reaction with a phosphine derivative, which results in an amide bond linkage.

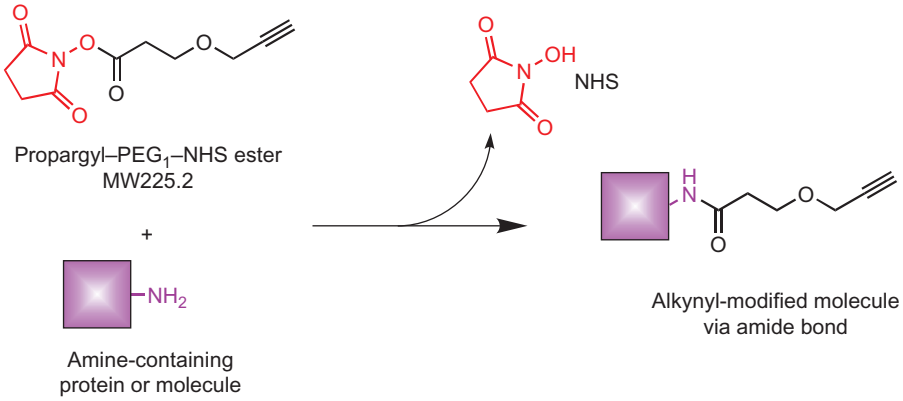

FIGURE 18.14 Progargyl–PEG_1–NHS ester can be used to react with amine-containing molecules to add short alkyne modification sites for subsequent click chemistry reactions with azide-containing molecules.

Protocol for Modification of Protein 2 with Propargyl–PEG$_1$–NHS Ester

1. Dissolve a second protein to be functionalized with alkyne groups at a concentration of 1 to 10 mg/ml in PBS.
2. In a fume hood, prepare a stock solution of propargyl–PEG$_1$–NHS ester in DMAC, DMSO, or DMF (highly pure and dry) at a concentration of 20-m*M* (4.5 mg/ml).
3. Add a quantity of the propargyl–PEG$_1$–NHS ester solution with stirring to the protein solution to obtain a 10-fold molar excess. Optimization of reactant ratios may be done to determine the best modification for a particular conjugation.
4. Gently mix for 30 to 60 min at room temperature.
5. Purify the alkyne-modified protein from excess linker by dialysis or gel filtration. The alkyne modification is stable in aqueous solution at this point.

Protocol for Coupling the Alkyne-Protein to the Azide-Modified Protein

1. With mixing, add a quantity of the azide-modified protein to the alkyne-modified protein to provide the desired molar excess over the quantity of protein and amount of alkyne groups present. Maintain the overall protein concentration at 1 to 10 mg/ml or greater to obtain the best reaction kinetics. Often, a one protein is reacted in 4-to 15-fold molar excess over a second protein to create a conjugate having several molecules of the first protein attached to the second protein. However, the appropriate molar excess may have to be determined by doing a series of reactions at different ratios and determining the best ratio for use in a particular application.
2. Add 2.5 µl of a solution containing 10-m*M* $CuSO_4.5H_2O$ and 50-m*M* ascorbic acid dissolved in water per ml of the protein mixture. Mix to dissolve.
3. React with mixing at room temperature for at least 4 h (or at 4°C overnight, if the protein is not stable at ambient temperature). The optimal time of reaction is dependent on the proteins being coupled together and the number of azide and alkyne reactive groups available on them. An alkynyl-modified protein added to the azide-modified protein at a high molar ratio probably would reach maximal coupling yield in a matter of hours.
4. Purify the protein conjugate by dialysis or gel filtration using a molecular weight cut-off appropriate for the sizes of the proteins being separated.

A similar protocol may be used to couple proteins or molecules modified with an azide or alkyne to a particle or surface modified with the other functionality.

Aminooxy- and Aryl Aldehyde PEG Reagents

Aminooxy groups, also called aminoxy or alkoxyamines, are compounds of the general formula R–ONH_2 that contain an oxygen-substituted hydroxylamine. This functional group contains a nucleophilic terminal amine that is able to undergo reactions with electrophilic reactive groups much the same as primary amines. However, the aminooxy group is relatively unreactive with the typical functional groups found on biological macromolecules. It even has a relatively low potential for interactions with negatively charged carboxylates or phosphate groups, because under physiological conditions it is not protonated and therefore does not carry a positive charge (pKa of aminooxy groups is 5–6, as opposed to amines, which is typically much higher (pKa~9)). Thus, aminooxy reagents largely are bioorthogonal with most macromolecules (Chapter 17) in that they have no inherent reactivity toward proteins, nucleic acids, or lipids typically found in biological samples. The exception to this statement is the potential reactivity to carbonyl sites on these molecules, if created by oxidative damage. This means that an aminooxy group is very reactive toward aldehydes and ketones, in which the formation of an oxime linkage occurs quite readily (see Chapter 15, Section 2.4, for additional details on this reaction).

In addition, aryl aldehyde groups are also particularly unreactive toward functional groups typically encountered in biological systems. Unlike aliphatic aldehydes, aryl aldehydes do not as readily form Schiff base interactions with amines in aqueous solution and thus do not spontaneously modify or crosslink proteins. The aryl aldehyde group may form weak Schiff base interactions, but these are quickly reversible under mild conditions, especially if another more reactive functional group is encountered. For instance, an aryl aldehyde rapidly reacts with an aminooxy group to form a stable oxime bond. This dehydration reaction occurs in mildly acidic aqueous buffers and is accelerated by the presence of an aniline catalyst, as described in Chapter 15, Section 2.4 (Cordes and Jencks, 1962; Dirksen *et al.*, 2006a,b; Dirksen and Dawson, 2008; Byeon *et al.*, 2010). Therefore, aminooxy reagents and aryl aldehyde reagents may be used in conjunction for bioconjugation strategies involving chemoselective and bioorthogonal reaction schemes, which can be used to crosslink, modify, or immobilize molecules in the presence of complex sample mixtures containing many other functional groups.

PEG-based aminooxy and aryl aldehyde crosslinking reagents now are available that combine the chemoselective nature of the two bioorthogonal reactive groups along with the hydrophilicity of discrete polyether spacer arms. These compounds contain one of these bioorthogonal groups at one end of a crosslinker

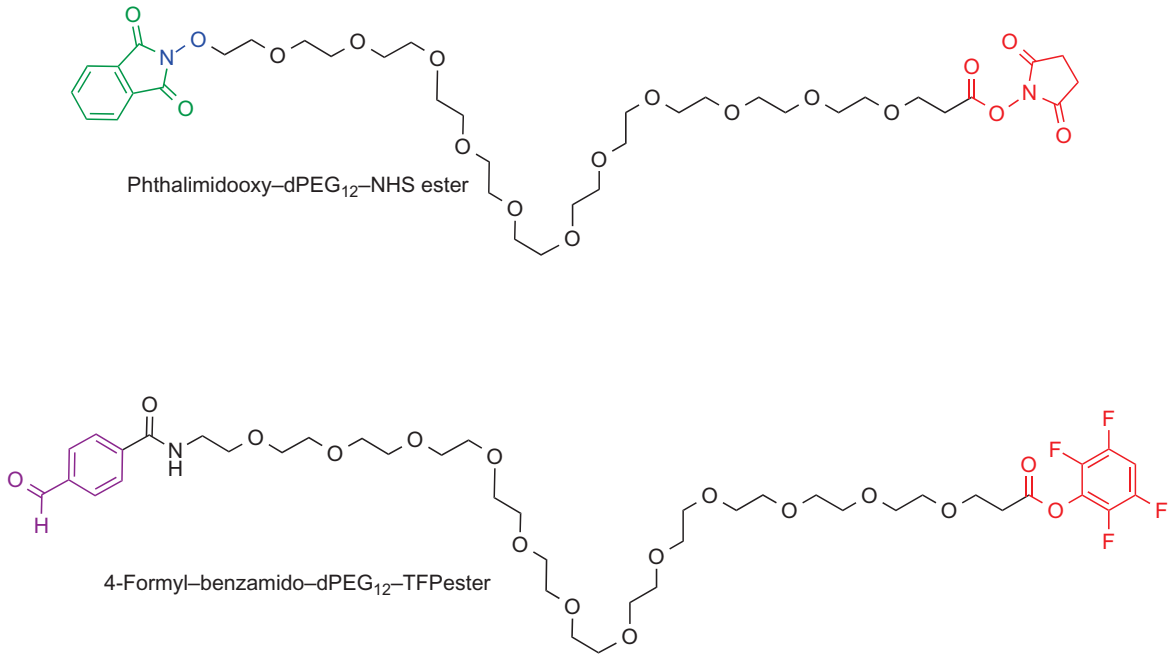

FIGURE 18.15 Aminooxy and aryl aldehyde crosslinking agents containing PEG_{12} spacer arms. The aminooxy compound has an amine-reactive NHS ester, while the aryl aldehyde compound has an amine-reactive TFP ester group.

and another type of reactive group or functional group at the other end—combined with a variety of different length PEG spacers as options for the central cross-bridge. Figure 18.15 illustrates two of these reagents, which may contain the aminooxy group as a protected phthalimide derivative to prevent its premature reaction with an electrophilic group at the opposite end. For instance, the phthalimidooxy–$dPEG_{12}$–NHS ester (Quanta BioDesign) has an amine-reactive group on one end for the initial modification of an amine-containing molecule or surface, while the aminooxy group is protected from reacting with the ester by use of the phthalimide protecting group.

Once an amine-containing molecule is modified with the PEG–phthalimidooxy group, the phthalimide can be removed using an aqueous solution of hydrazine to reveal the aminooxy group. The companion crosslinking reagents to the aminooxy compounds contain an aryl aldehyde group at one end, a PEG_{12} or PEG_{24} spacer group in the middle, and an amine-reactive tetrafluorophenyl (TFP) ester at the other end. Thus, two different molecules containing amines can be separately labeled with these reagents and later mixed to form a bioconjugate, which will get linked together by oxime bonds. Particles or surfaces may also be modified with one of these reagents to immobilize another molecule modified with the complementary bioorthogonal reagent. In this manner, a wide variety of bioconjugates may be prepared through the initial modification with these hydrophilic PEG-based reagents. The resultant oxime linkages are very stable and have no need to be reduced as is common with reactions between aldehydes and amines or aldehydes and hydrazides. Figure 18.16 shows the reactions that take place in the modification of two separate amine-containing molecules with the aminooxy and aryl aldehyde compounds and Figure 18.17 illustrates their subsequent conjugation to form a covalent complex.

The following protocols describe the reaction of the amine-reactive aminooxy and aryl aldehyde compounds with two separate amine-containing molecules (such as proteins) and their subsequent conjugation to form a complex linked together by oxime bonds. This general procedure can also be used with particles or surfaces containing amines to immobilize affinity ligands. Refer to Chapter 15, Section 2.4, for an alternative protocol using the phthalimidooxy–$dPEG_{12}$–NHS ester to immobilize aldehyde-containing affinity ligands on insoluble chromatography supports.

(A) Protocol for Modification of a Protein with PhthalimidooxyddPEG$_{12}$–NHS Ester

1. Dissolve an amine-containing protein, such as an antibody, at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5 (coupling buffer). For instance, 2 mg of an antibody may be dissolved in 200 µl of the buffer.
2. Dissolve 2 mg of phthalimidooxy–$dPEG_{12}$–NHS ester in 200-µl DMSO, DMF, or DMAC.

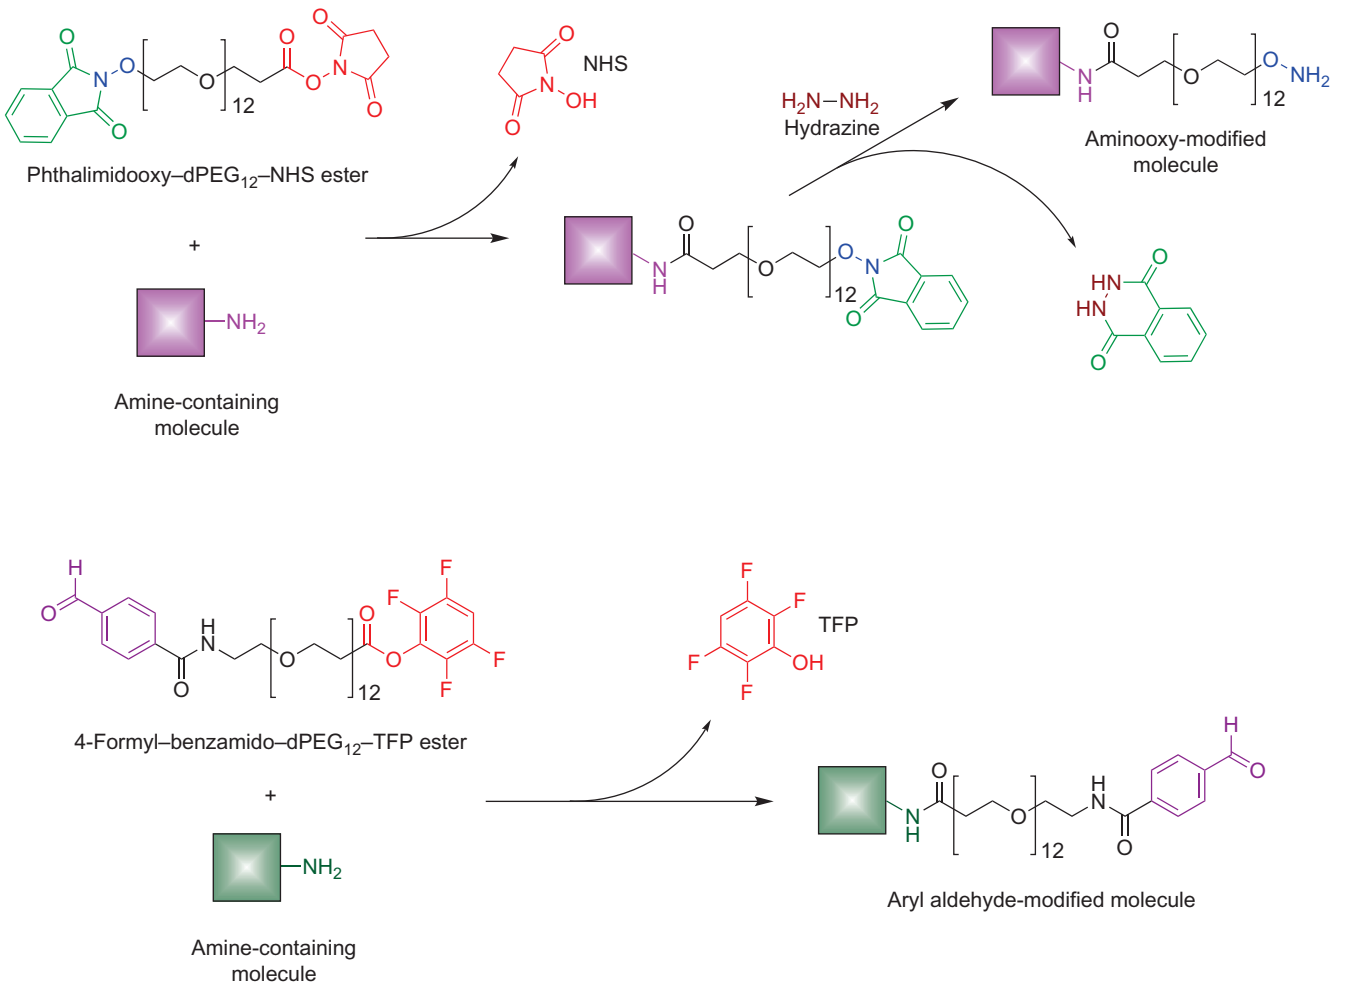

FIGURE 18.16 The reactions of the aminooxy and aryl aldehyde PEG-based crosslinkers in the modification of amine-containing molecules. The aminooxy group can be deprotected by the addition of hydrazine.

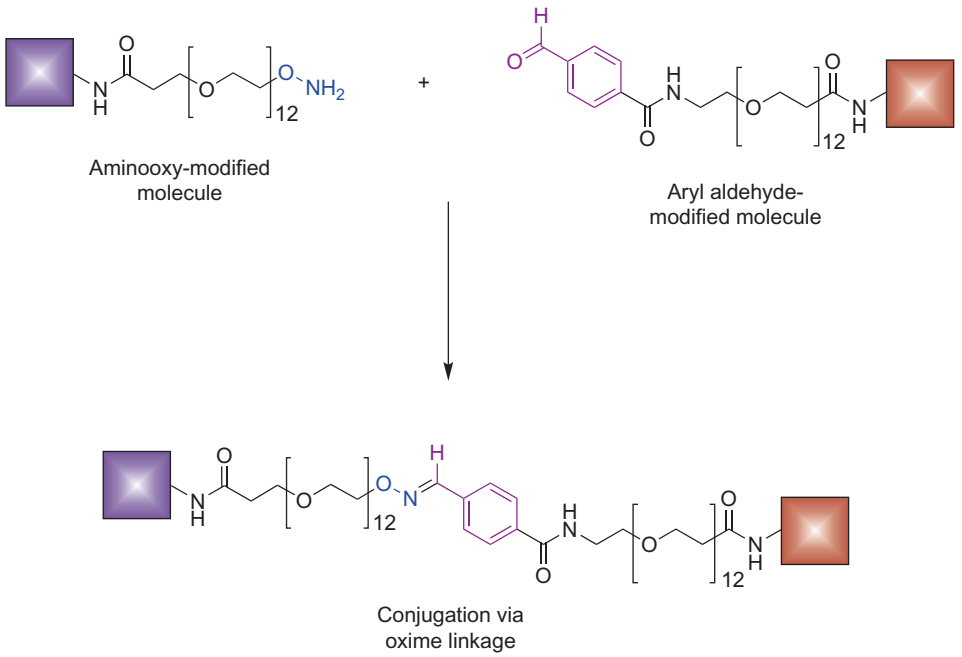

FIGURE 18.17 Molecules modified with the aminooxy and aryl aldehyde PEG-based crosslinkers can be conjugated through formation of a stable oxime linkage, which can be accelerated in aqueous solution by the addition of aniline as catalyst.

3. Add 17.5 µl of the crosslinker solution prepared in (2) to the antibody solution prepared in (1). This level of addition provides a 10-fold mole excess of the crosslinker over the quantity of antibody present. Note: Optimization of the amount to add of phthalimidooxy–dPEG$_{12}$–NHS ester compound should be carried out to obtain the best possible final conjugate in the intended application. Experiments performed using a range of different mole excesses of crosslinker over the antibody present can identify the best level of modification to use.
4. React for 30 min at room temperature with periodic mixing in a sealed container (e.g., microfuge tube).
5. Purify the modified antibody by dialysis or size exclusion chromatography using a 5-ml desalting column. Use 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5 (conjugation buffer) as the dialysis or chromatography solution. Concentrate the antibody using centrifugal concentrators to approximately 200 µl, if necessary. The protected aminooxy-modified antibody may be stored until use at 4°C in buffer containing a preservative.

(B) Protocol for Deprotection of the Phthalimidooxy-Modified Antibody

1. In a fume hood and while wearing the appropriate personal protective equipment, add 3.1 µl of hydrazine (3.2 mg) to the phthalimidooxy-modified antibody solution to make a final solution that is 0.5-*M* hydrazine. Mix well to dissolve. Note: At much higher concentrations of hydrazine (> 20%) and at elevated temperatures (60°C or 95°C), protein structural reactions may occur, including deglycosylation, deamidation, cleavage of ester bonds to form hydrazides, and deguanidination (de la Burde *et al.*, 1963; Takasaki and Kobata, 1978; Patel *et al.*, 1992). At the recommended concentration of 0.5-*M* hydrazine needed to deprotect the phthalimidooxy groups, no such chemical modifications on proteins should occur. However, to be certain that a particular protein or antibody is not sensitive to hydrazine at this concentration, a separate test of the protein dissolved in 0.5-*M* hydrazine should be carried out to check stability.
2. Incubate at room temperature overnight with periodic mixing to remove the phthalimide group from the aminooxy end of the crosslinker modification sites.
3. Purify the aminooxy-modified antibody by dialysis or size exclusion chromatography using a 5-ml desalting column. Use 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5 (conjugation buffer), as the dialysis or chromatography solution. Concentrate the antibody using centrifugal concentrators to approximately 200 µl, if necessary. Dispose of all hydrazine-containing solutions according to your facility's guidelines concerning hazardous waste disposal.

(C) Protocol for Modification of a Protein with 4-Formyl-Benzamido–dPEG$_{12}$–TFP Ester

1. Dissolve 2 mg of an amine-containing protein, at a concentration of 10 mg/ml in 200 µl of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5 (coupling buffer).
2. Dissolve 2 mg of 4-formyl–benzamido-dPEG$_{12}$–TFP ester in 200 µl DMSO, DMF, or DMAC.
3. Add a quantity of the crosslinker solution prepared in step 2 to the protein solution prepared in step 1 to result in a 10-fold mole excess of crosslinker over the amount of protein present (the amount to add is dependent upon the MW of the protein being modified). Note: Optimization of the amount of the amount of crosslinker addition should be carried out to obtain the best possible final conjugate in the intended application. Experiments performed using a range of different mole excesses of crosslinker over the protein present can identify the best level of modification to use.
4. React for 30 min at room temperature with periodic mixing in a sealed container (e.g., microfuge tube).
5. Purify the modified protein by dialysis or size exclusion chromatography using a 5-ml desalting column. Use 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5 (conjugation buffer) as the dialysis or chromatography solution. Concentrate the protein, if necessary, using centrifugal concentrators to approximately 200 µl. The aryl aldehyde-modified protein may be stored until use at 4°C in buffer containing a preservative.

Protocol for Conjugation of the Aminooxy-Modified Antibody with the Aryl Aldehyde-Modified Protein

1. Mix the deprotected aminooxy-modified antibody prepared in (B) with the aryl aldehyde-modified protein prepared in (C), with both proteins dissolved in conjugation buffer (0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5). Note: The conjugation reaction may be performed using an equal mole quantity of the modified proteins or it may be performed with one of the proteins in excess. Optimization of the reaction ratio of the two proteins may have to be carried out to determine the best resultant conjugate for the intended application. For instance, if the aryl aldehyde-modified protein happens to be an enzyme that can be used for detection purposes, it is typical to react the enzyme in excess over the amount of antibody present. Refer to Chapters 20 and 22 for suggested ratios of enzyme to antibody to use in particular conjugation strategies.

2. In a fume hood, add aniline to the conjugation reaction to obtain a final concentration of 0.1-*M*. Mix well to dissolve. Note: If the total solution volume is 400 µl, then add 7.2 µl of aniline to obtain the 0.1-*M* final concentration.
3. React for at least 2 to 4 h with periodic mixing at room temperature. Note: The blocking of excess aminooxy groups within the conjugate may be performed by the addition of 0.1-*M* glyceraldehyde and the blocking of excess aryl aldehyde groups may be performed using 0.1-*M* hydroxylamine, both blockers being dissolved in the conjugation buffer. However, these blocking steps should be carried out sequentially and with a purification step in between using dialysis or gel filtration to avoid the reaction of the blocking agents with each other.
4. Purify the conjugate with a buffer of choice using dialysis or size exclusion chromatography with a 10-ml desalting column. The final conjugate may be stored in buffer or water containing a preservative at 4°C.

1.3. Biotinylation Reagents Containing Discrete PEG Linkers

Biotin modification reagents are widely used to attach a biotin group to proteins or other molecules for subsequent use in avidin, streptavidin, or NeutrAvidin separations or assays. Traditional biotin compounds containing aliphatic or other hydrophobic linker arms are discussed in detail in Chapter 11, Section 6. In this chapter, the biotin–PEG compounds are exclusively discussed due to their unique hydrophilic properties, which include low nonspecific binding character and low immunogenicity.

Traditional biotinylation compounds include the very popular (sulfo)NHS–LC–biotin, which contains either an uncharged NHS ester or a negatively charged sulfo-NHS ester in addition to a C6 alkyl chain leading to the biotin group. Although the sulfo-NHS ester provides a degree of water solubility for the entire compound prior to using it to modify a protein, the resultant LC–biotin modification left on the protein is extremely hydrophobic. The result of adding such hydrophobic groups to a protein surface is often a balance between maintaining water solubility or tending toward protein aggregation and precipitation. Many antibodies that are biotinylated with NHS-LC–biotin undergo slow aggregation and loss of activity despite limiting the degree of biotinylation during production.

The use of discrete PEG spacers in the construction of biotinylation compounds not only increases the water solubility of the modification reagent itself, but significantly increases the hydrophilicity and stability of proteins modified with them. Even when high modification levels are used with PEG–biotin compounds, the resultant biotinylated protein is typically very water soluble and does not aggregate in solution.

The following compounds represent some of those that are commercially available for adding a PEG–biotin group to proteins and other molecules. Reactive group options include NHS esters for coupling to amines, maleimide groups for coupling to thiols, hydrazides for conjugation with carbonyl compounds, and a photoreactive benzophenone for nonselective insertion into molecular structures (Thermo Fisher, Quanta BioDesign, Solulink, and Molecular Biosciences). In addition, a chromogenic biotin compound containing a PEG spacer is available from Thermo Fisher and Solulink. This unique compound allows exact measurement of the amount of biotinylation by measuring the absorbance of the final purified conjugate.

NHS–PEG$_n$–Biotin Compounds

NHS ester biotinylation reagents are the most popular choice for adding a biotin group to another molecule that contains an available amine. The ester reacts with an amine at neutral or slightly alkaline pH values to form a stable amide bond with the amine-containing protein or molecule. Discrete PEG biotinylation compounds containing an NHS ester are available in chain lengths of 4 or 12 repeating poly(ethylene oxide) units and in one form that contains a cleavable disulfide in the cross-bridge.

The NHS ester compounds are sensitive to hydrolysis in aqueous solution, and they will likely hydrolyze faster than more hydrophobic biotinylation compounds due to their hydrophilicity. If a stock solution is made at a higher concentration to facilitate the addition of a small amount to a reaction solution, the initial solution should be made in a water-miscible organic solvent that is dried with a molecular sieve. Suitable solvents include DMAC, DMSO, or DMF. If using DMF, use only highly pure solvent, as it may contain amines that can react with the NHS ester groups (Figure 18.18).

Reactions performed with NHS–PEG$_n$–biotin compounds are typically done with the reagent in molar excess over the amount of protein being modified. The efficiency of the reaction is dependent upon the concentrations of reactants and the solvent exposed area of the amine groups on the protein. Reactions performed with a 10-fold molar excess of NHS–PEG$_n$–biotin usually will result in at least two to three biotin labels per protein, while doubling the molar excess should provide at least four to six biotin modifications; however, the yield of biotinylation varies depending on the protein being modified. The optimal number of biotin groups added to a particular protein should be determined experimentally to provide the best performance in the intended application. When using PEG-based biotinylation compounds, over-modifying an antibody

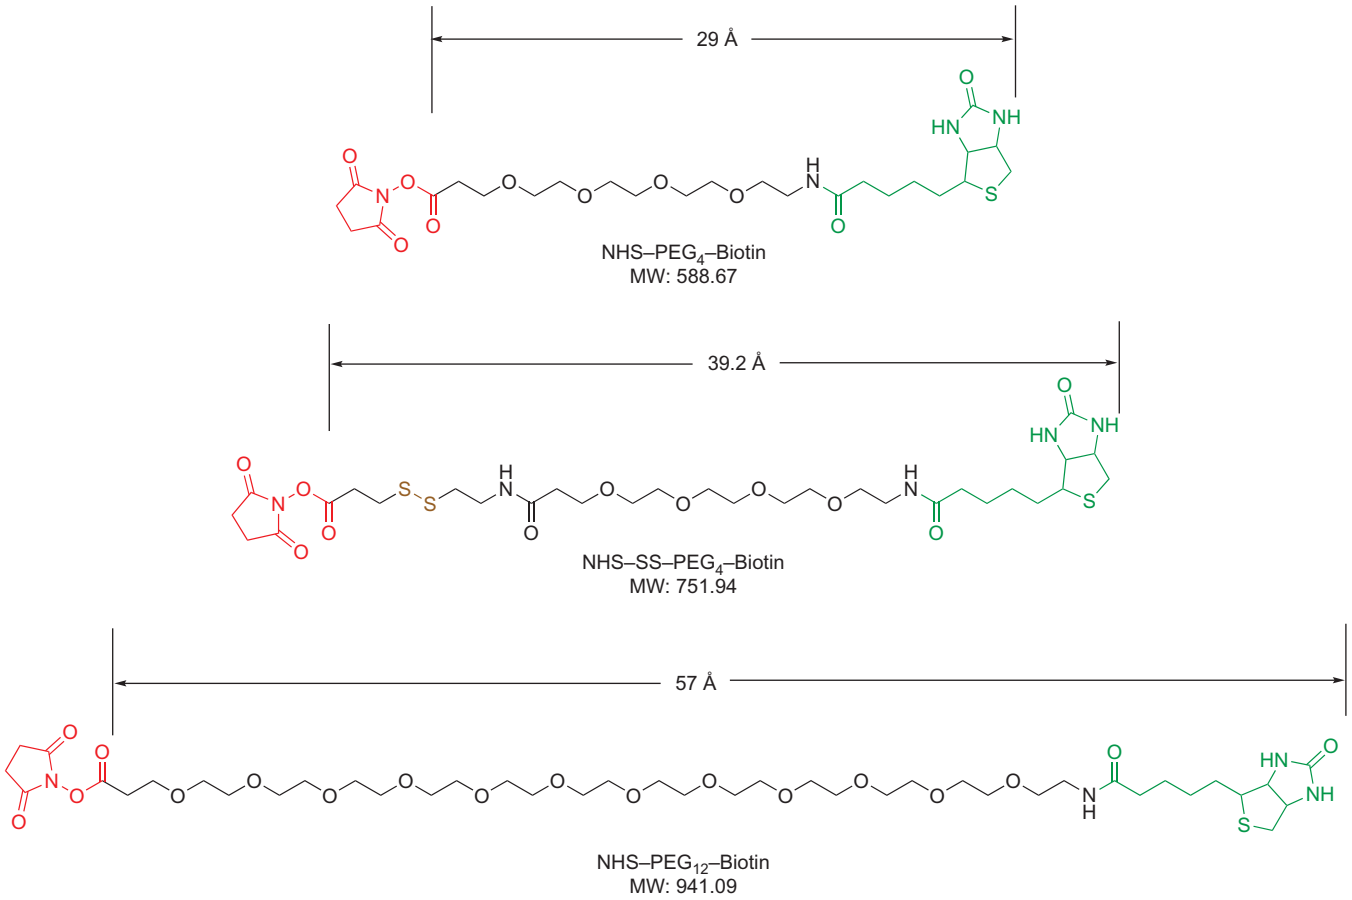

FIGURE 18.18 NHS–PEG$_n$–biotin compounds.

for example will not cause aggregation of the final conjugate as it would with aliphatic biotin reagents. Therefore, it is not as critical to maintain a low level of biotin modification to avoid this problem.

NHS–SS–PEG$_4$–biotin contains a cleavable disulfide bridge next to the PEG chain. This feature allows the biotin group to be released from the biotinylated molecule using a disulfide reducing agent, such as DTT or TCEP (Figure 18.19). This is useful for doing immunoprecipitation (IP) or co-immunoprecipitation (co-IP) assays, because a biotinylated antibody can be used to capture and affinity isolate a target protein on immobilized (strept)avidin and then elute the bound proteins by reduction (using 50-m*M* DTT for 2 h at room temperature or for 30 min at 50°C). This eliminates the severe denaturing conditions usually required to break the (strept)avidin–biotin bond, thus better preserving the native structure and activity of the captured proteins. Compounds of this type may also be used successfully in cell surface biotinylation, as described in Chapter 11, Section 6.2, under Sulfo-NHS–SS–Biotin.

The following protocol is based on the applications done at Thermo Fisher (formerly Pierce). The use of higher pH values for the NHS ester reaction than those recommended may result in lower biotinylation yields due to increased hydrolysis, especially when using an extremely hydrophilic PEG compound.

Protocol

1. Dissolve an antibody or protein to be modified at a concentration of 1 to 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2–7.5. Lower concentrations of protein may result in decreased reaction yields and require increased quantities of reagent to obtain acceptable levels of biotinylation. Avoid amine-containing buffers or components, such as Tris or imidazole, which will react with the NHS ester and interfere with the biotinylation process.
2. Dissolve the NHS–PEG$_n$–biotin compound in DMAC, DMSO, or DMF (pure and dry) at a concentration of 10 to 20 m*M*. Prepare fresh in a fume hood.
3. With mixing, add an aliquot of the biotinylation stock solution to the protein solution to provide at least a 10-fold molar excess over the concentration of protein present. A series of reactions with different

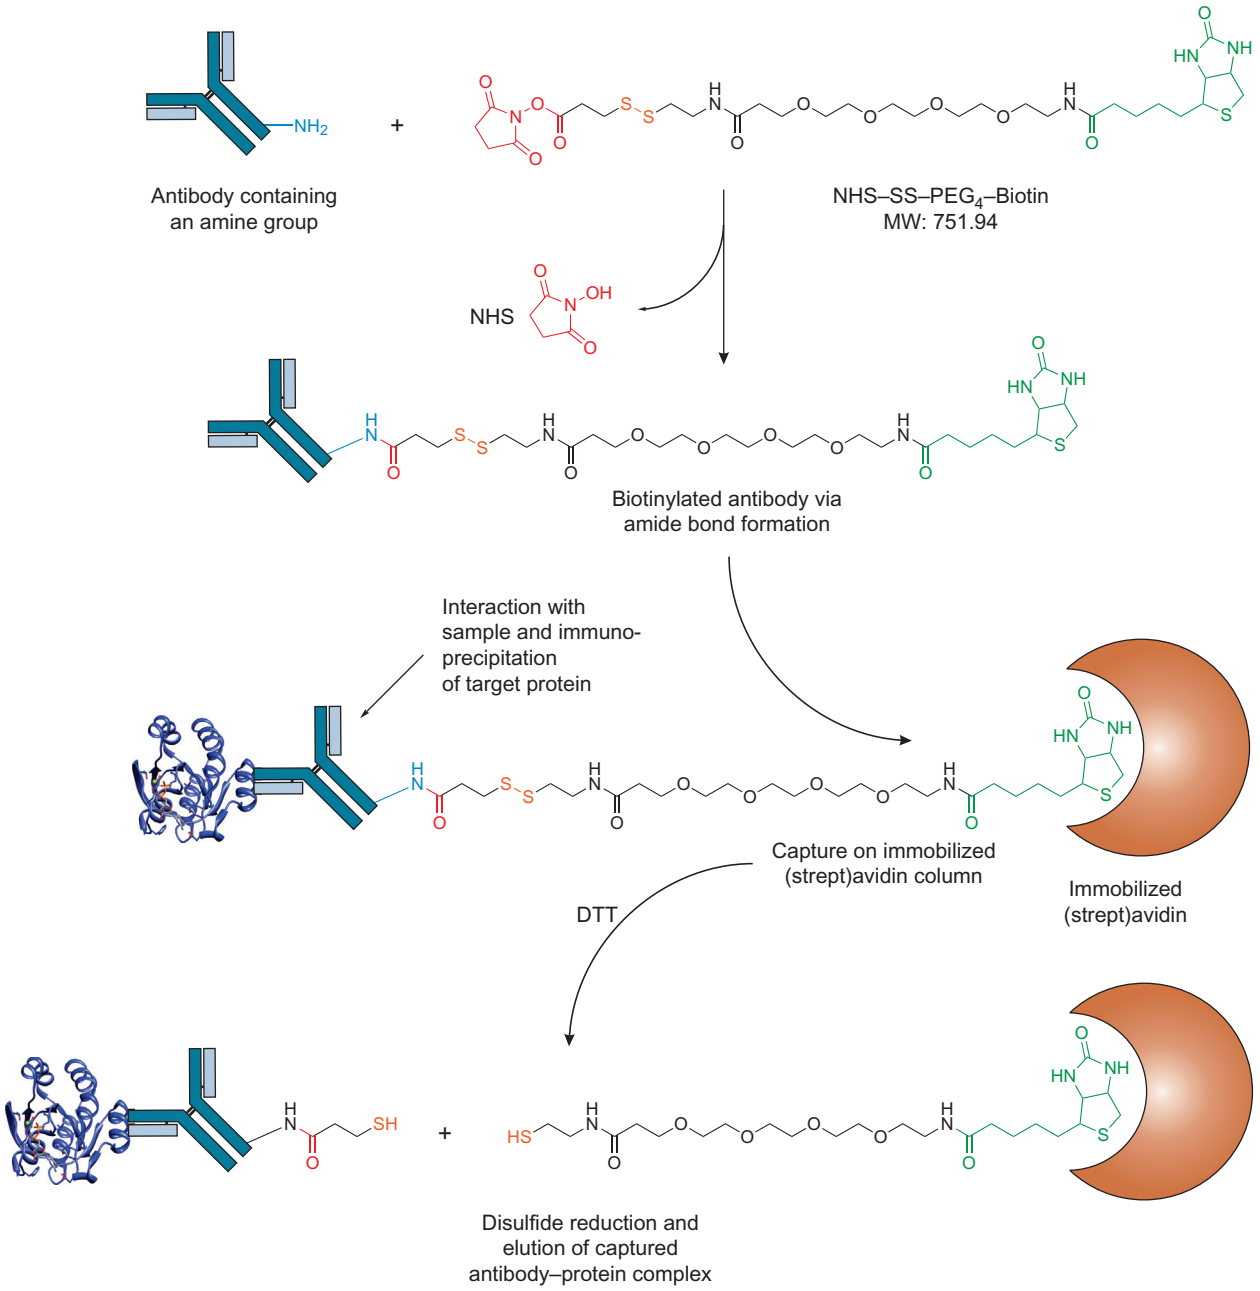

FIGURE 18.19 NHS–SS–PEG_4–biotin can be used to label a primary antibody molecule that has specificity for a protein of interest. Incubation of the biotinylated antibody with a sample, such as a cell lysate, allows the antibody to bind to its target. Capture of the antibody–antigen complex on an immobilized streptavidin reagent effectively isolates the targeted protein from the other proteins in the sample. The disulfide linkage in the spacer arm of the biotin tag permits elution of the immune complex from the streptavidin support using DTT and without using the strong denaturing condition typically required to break the streptavidin–biotin interaction.

molar amounts of the NHS–PEG_n–biotin compound may be performed to optimize the modification level.

4. React with gentle mixing for 30–60 min at room temperature or 2 h at 4°C.
5. Purify the biotinylated protein from excess reagent and reaction byproducts using dialysis or gel filtration (desalting resin).

NHS–Chromogenic–PEG_3–Biotin

A novel detectable biotinylation reagent containing a hydrophilic PEG spacer is NHS–chromogenic–PEG_3–biotin (also called chromogenic biotin; Solulink) (Figure 18.20). Next to the terminal NHS ester of this compound is a *bis*-aryl hydrazone group created from the reaction of a 6-hydrazinium nicotinate derivative and a benzaldehyde

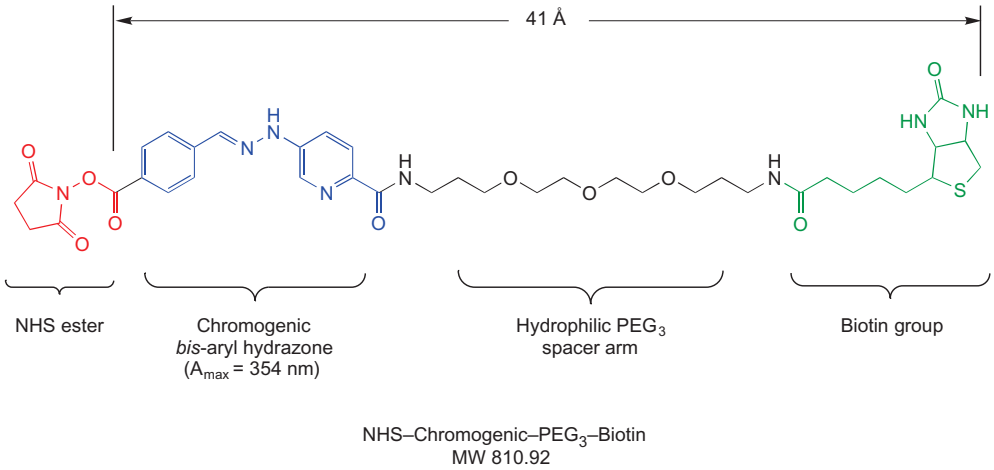

FIGURE 18.20 NHS–chromogenic–PEG_3–biotin contains an amine-reactive NHS ester that can be used to label biomolecules through an amide linkage. The chromogenic *bis*-aryl hydrazone group within the spacer arm of the reagent allows the degree of biotinylation to be quantified by measuring its absorbance at 354 nm. The compound also contains a hydrophilic PEG spacer, which provides greater water solubility.

group to form the chromogen having an absorbance at 354 nm ($\varepsilon = 29{,}000\,M^{-1}cm^{-1}$). The NHS ester end can be used to modify amine-containing molecules and form a stable amide linkage (Figure 18.21). The spacer arm contains a hydrophilic spacer made from three ethylene oxide units, which provide water solubility for the compound.

Proteins biotinylated with this reagent will have a characteristic absorbance band at 354 nm, which can be used to determine accurately the number of biotin groups per molecule. No other biotinylation compound has such built-in quantification capability. This feature eliminates the need to consume conjugate by doing a HABA assay to test for the level of biotin incorporation (Chapter 11, Section 6.1).

The following protocol is adapted from the manufacturers' recommendations.

Protocol

1. Dissolve a protein or other amine-containing molecule to be biotinylated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 to 7.5, at a concentration of 1 to 10 mg/ml. Note that protein solutions that are more dilute than this may require higher levels of biotinylation reagent addition to achieve the same yield of modification.
2. In a fume hood, dissolve NHS–chromogenic–PEG_3–biotin in DMF at a concentration of 12.33-m*M* (2 mg/200 µl DMF). With mixing, add a quantity of the reagent to the protein solution to provide the desired molar excess (i.e., 10- to 20-fold excess).
3. React for 30 to 60 min at room temperature or 2 h at 4°C.
4. Purify the modified protein from unreacted biotinylation reagent and reaction byproducts using dialysis or gel filtration. Complete removal of the excess reagent is necessary to provide accurate measurement of the biotin incorporation level by absorptivity.

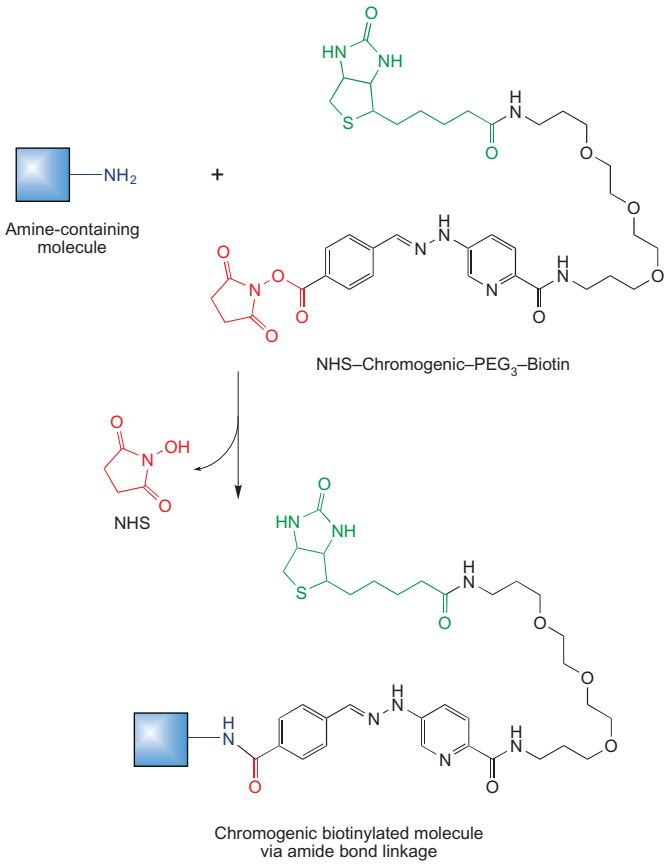

FIGURE 18.21 NHS–chromogenic–PEG_3–biotin reacts with amine groups in proteins or other molecules to form amide bond derivatives.

5. Measure the absorbance of the biotinylated protein solution at 354 nm. Use the molar extinction coefficient for the chromogenic group ($\varepsilon = 29{,}000\,M^{-1}cm^{-1}$) to determine the concentration of biotin present. To determine the molar ratio of

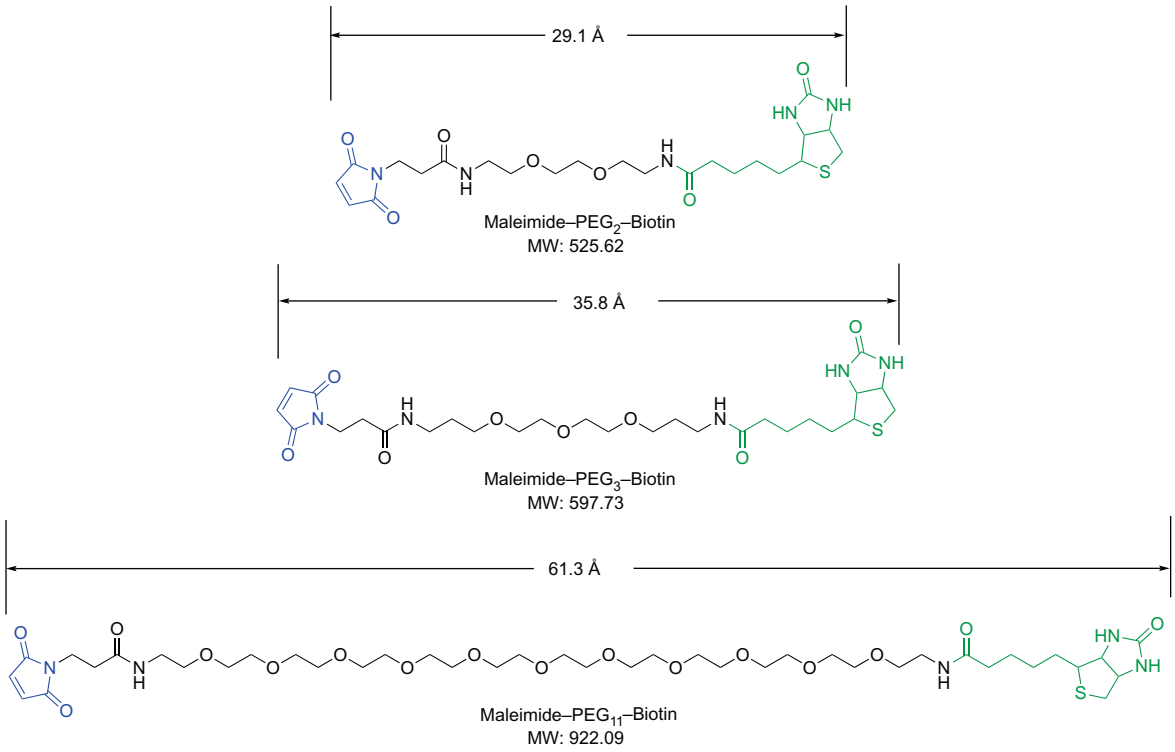

FIGURE 18.22 Maleimde–PEG$_n$–biotin compounds of three different discrete PEG sizes are available, including a PEG$_{11}$ chain that provides a molecular length of over 60 Å.

biotin to protein, divide the molar concentration of biotin by the molar concentration of protein present (which may be determined by using the Coomassie assay or the BCA assay methods).

Maleimide–PEG$_n$–Biotin Compounds

Discrete PEG–biotin compounds containing a terminal maleimide group may be used to label sulfhydryl-containing proteins and other molecules through thioether bond formation (Figure 18.22). The targeting of thiol groups in proteins is often used to direct the modification reaction away from binding sites or active centers in proteins, thus preserving activity. Maleimide reagents in general are the second most-popular reactive group used for bioconjugation purposes, second only to NHS esters. Unlike biotinylation compounds containing a hydrophobic hydrocarbon chain (Chapter 11), the discrete maleimide–PEG-based reagents provide increased hydrophilicity for modified molecules and maintain solution stability even at high substitution levels.

The maleimide group reacts with thiols in the pH range of 6.5 to 7.5 to form a stable thioether linkage with very little cross-reactivity with amines at this pH (Figure 18.23). However, the maleimide ring is subject to hydrolysis in aqueous solution, and since it is next to an extremely hydrophilic PEG chain in these reagents, this factor may increase the hydrolysis rate beyond that typically observed with hydrocarbon-based spacers (Chapter 3, Section 2.2). For this reason, stock solutions of a maleimide–PEG$_n$–biotin compound should be made in highly pure and dry organic solvent, which then can be added to an aqueous reaction medium to commence the biotinylation process.

The three maleimide–PEG$_n$–biotin compounds illustrated in this section provide short-, medium-, and very-long-chain spacer options, with the longer chains resulting in the greatest degree of hydrophilicity of modified molecules. The following protocol is adapted from general maleimide-based biotinylation methods, as discussed in Chapter 11, Section 6.3.

Protocol

1. Dissolve a sulfhydryl-containing protein or other thiol-molecule in a thiol-free buffer within a pH range of 6.5 to 7.5. The use of 20-m*M* sodium phosphate, 150-m*M* NaCl, pH 7.2, works well for this reaction. The concentration of protein should be in the range of 1 to 10 mg/ml. Lower concentrations of protein may result in the need to increase the molar excess of biotinylation reagent to obtain an acceptable level of modification. If a thiol is not present on the molecule to be biotinylated, one may be created by disulfide reduction or through the use of a thiolation reagent (Chapter 2, Section 4.1).
2. Prepare a stock solution of the maleimide–PEG$_n$–biotin compound in DMAC, DMSO, or DMF (pure and dry solvents only) at a concentration of 10 to 20 m*M*.

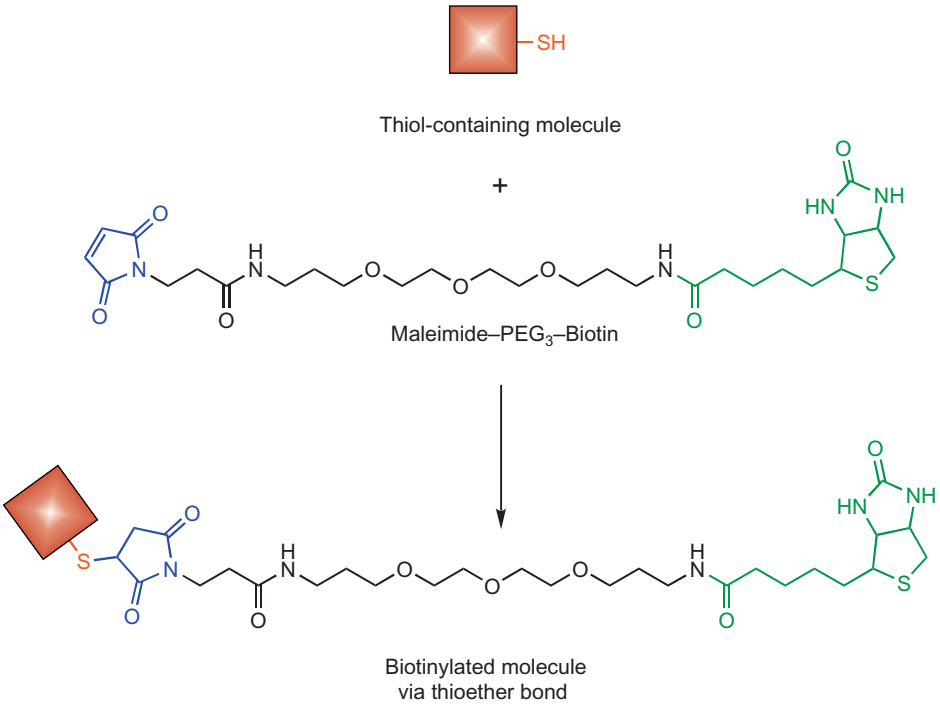

FIGURE 18.23 Maleimide–PEG_n–biotin compounds react with thiol-containing molecules to form thioether linkages.

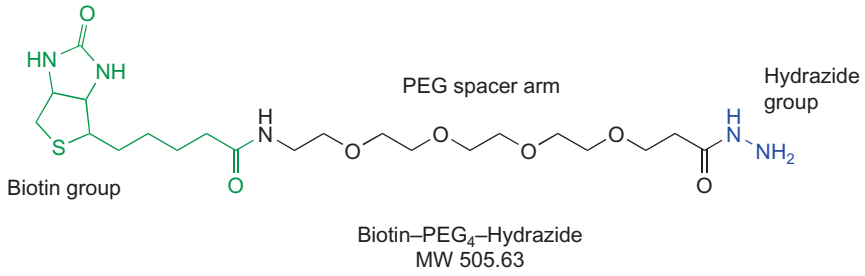

FIGURE 18.24 Biotin–PEG_4–hydrazide is a hydrophilic biotinylation reagent that can be used to modify glycans or carbohydrates at their reducing end or after periodate oxidation to create aldehydes.

3. With mixing, add an aliquot of the biotin solution to the protein solution to obtain at least a 10-fold molar excess over the quantity of protein present. As thiols are typically present in limiting amounts on proteins, the use of a high molar reagent ratio is not required to achieve acceptable yields of biotinylation.
4. React with gentle mixing for 2 h at room temperature or 4 h at 4°C.
5. Purify the biotinylated protein by dialysis or gel filtration using a desalting resin.

Hydrazide–PEG_4–Biotin

Hydrazide-containing PEG–biotinylation reagents provide reactivity with carbonyl groups (e.g., aldehydes) to label carbohydrates or glycoproteins via hydrazone bond formation (Figures 18.24 and 18.25). The hydrazide group may also be coupled with carboxylate-containing molecules using a carbodiimide reaction with EDC (Chapter 4, Section 1.1) or an active ester derivative (Chapter 3, Section 1.4). Like the other discrete PEG reagents, the hydrazide–PEG_4–biotin compound is very hydrophilic and will not promote aggregation or precipitation of labeled proteins. Aldehyde functionalities may be created on glycoproteins or other carbohydrates by oxidation using sodium periodate (Chapter 2, Sections 2.2, 4.4–4.6) or by modification with SFB (Chapter 17, Section 2). The reducing end of sugars or glycans may also be labeled with these hydrazide reagents to produce a biotin–carbohydrate that is modified at only a single site.

Hydrazide–PEG_4–biotin can be used to specifically label glycoproteins on cell surfaces after mild periodate oxidation of the glycan structures (Wilchek and Bayer, 1987). The hydrophilic nature of the PEG spacer will prevent the biotinylation reagent from easily penetrating

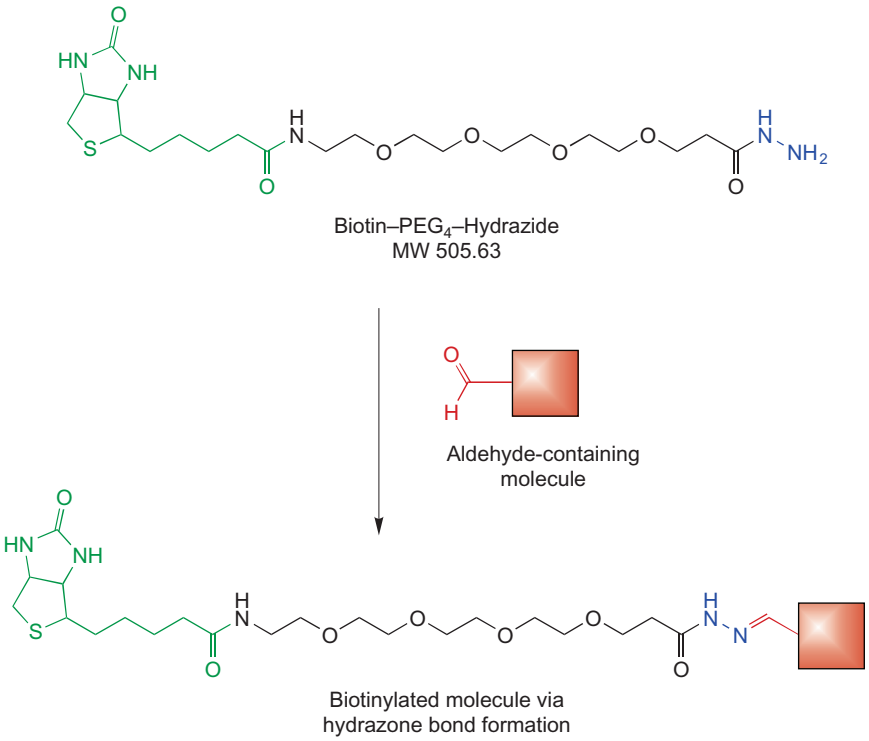

FIGURE 18.25 Biotin–PEG_4–hydrazide reacts with aldehyde-containing molecules to form a hydrazone linkage.

cell membranes, thus the labeling reaction is restricted to outer membrane glycoproteins. After biotinylation and cell lysis, the labeled proteins may be detected or isolated using (strept)avidin reagents (Jang and Hanash, 2003; Ding *et al.*, 2005; Handlogten *et al.*, 2005).

Hydrazide–PEG_4–biotin contains a 31.5-Å spacer consisting of 4 ethylene oxide units, which effectively imparts water solubility to the reagent. Other hydrazide biotinylation reagents that contain no spacer or a hydrocarbon spacer, such as biotin–hydrazide and biotin–LC–hydrazide, are water insoluble and actually will lower the solubility of modified molecules. Hydrazide–PEG_4–biotin can be used to modify molecules without the tendency for aggregation or precipitation. In addition, the compound is stable in aqueous environments, as it contains no groups that are easily hydrolysable. A stock solution may be prepared in a water-miscible organic solvent such as DMAC, DMSO, or DMF to facilitate transfer of a small amount to an aqueous reaction.

The following protocol describes a method for the periodate oxidation of a glycoprotein followed by biotinylation of the resultant aldehydes using hydrazide–PEG_4–biotin. Chapter 2, Section 4.6 describes an alternative protocol for the modification of glycans at their reducing ends with hydrazide compounds.

Protocol

1. Dissolve a glycoprotein to be oxidized in 0.1-*M* sodium acetate, pH 5.5 (oxidation buffer), at a concentration of 2 to 10 mg/ml. PBS at physiological pH may also be used for this reaction. The use of cold buffers for the oxidation step will limit the extent of carbohydrate oxidation and the potential for protein oxidation.
2. Dissolve sodium *meta*-periodate in oxidation buffer at a concentration of 20-m*M*. Protect from light.
3. Add an equal volume of the glycoprotein solution to the periodate solution with mixing.
4. React for 10 to 20 min with gentle mixing and protected from light.
5. Quench the oxidation reaction by the addition of at least a 4-fold molar excess of *N*-acetylmethionine or sodium sulfite over the concentration of periodate in the reaction mixture (e.g., 40-m*M*). Pre-dissolve the quencher in buffer at a higher concentration prior to adding an aliquot of it to the reaction solution. React for 10 min. Alternatively, the oxidation reaction may be stopped by the removal of excess periodate by gel filtration using a desalting column.
6. Prepare a 50-m*M* solution of hydrazide–PEG_4–biotin in DMAC, DMSO, or DMF. Add a quantity of this solution to the purified, oxidized protein to provide at least a 10-fold molar excess of biotinylation reagent over the concentration of protein present.
7. React with mixing for 2 h at room temperature.
8. The hydrazone bond can be reduced to stabilize the linkage by the addition of sodium cyanoborohydride to a final concentration of 50-m*M*. React for 30 min at room temperature with mixing. All operations with cyanoborohydride should be carried out in a fume

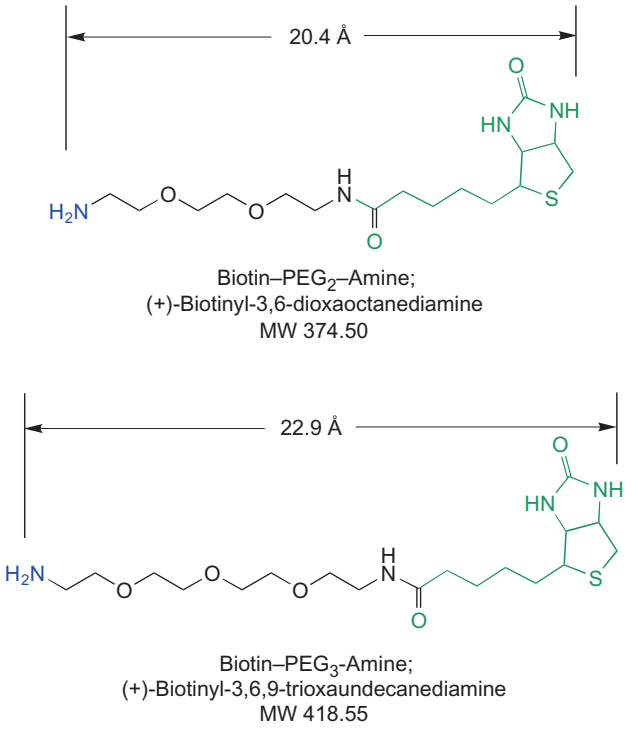

FIGURE 18.26 Biotin–PEG$_n$–amine compounds can be used to modify carboxylate- or aldehyde-containing compounds using a carbodiimide reaction.

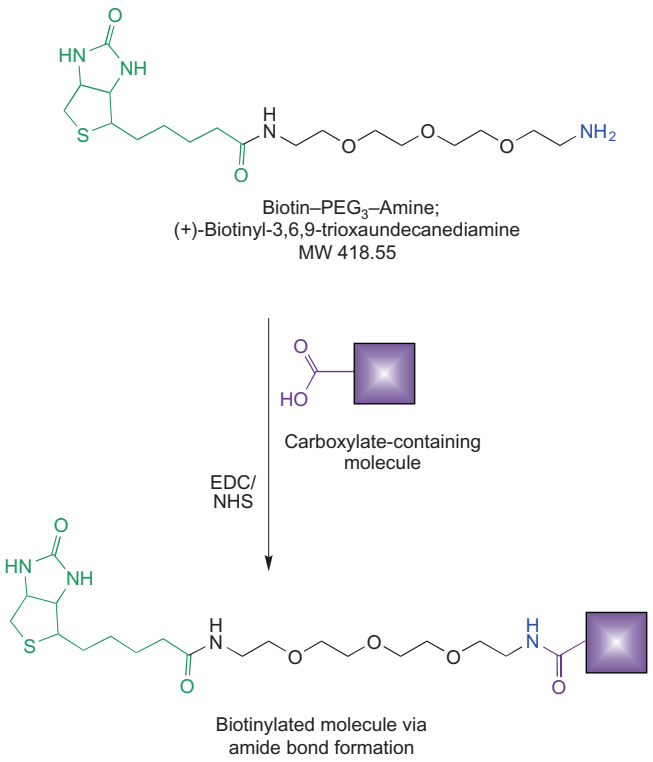

FIGURE 18.27 Biotin–PEG$_n$–amine can be used to add a biotin label to carboxylate-containing molecules using the EDC/(sulfo)NHS reaction, which forms a stable amide linkage.

hood. If the glycoprotein being modified is sensitive to disulfide reduction and potential denaturation, then this step should be avoided.

9. Purify the biotinylated glycoprotein by gel filtration or dialysis.

Biotin–PEG$_n$–Amine Compounds

Biotin compounds containing a PEG spacer that terminates in a primary amine can be used for the labeling of carboxylate molecules (Figure 18.26). Activated carboxylates, such as those containing an NHS ester, spontaneously react with the amines to give amide bond linkages. An active ester may also be formed *in situ* by the activation of carboxylates with EDC in the presence of NHS or sulfo-NHS (Chapter 4, Section 1.2) (Figure 18.27).

Biotin–PEG$_2$–amine contains a short, two-unit ethylene oxide cross-bridge that provides a 20.4-Å hydrophilic spacer, which has an amine on its end. Biotin–PEG$_3$–amine is identical except for one additional ethylene oxide unit. Both compounds are extremely water soluble and can be used to label organic molecules or biomolecules containing carboxylates. Bronfman *et al.* (2003) used the biotin–PEG$_n$–amine compounds to label nerve growth factor (NGF) peptide on its carboxylates using EDC-mediated amide bond formation. The biotinylated growth factor was then used to study receptor internalization in live cells by probing with fluorescent streptavidin conjugates.

The following protocol can be used to biotinylate carboxylate-containing molecules in aqueous solution using the EDC/sulfo-NHS reaction.

Protocol

1. Dissolve a carboxylate-containing peptide or other molecule in 0.1-*M* MES, pH 5.0 (reaction buffer). Ideally, this molecule should contain only one carboxylate with no amines to direct biotinylation to a single site and prevent polymerization of it during the conjugation process. However, if a peptide is to be biotinylated that also has amine groups, then the use of a very high molar excess of the biotin–PEG$_n$–amine reagent during the reaction will limit the potential for peptide–peptide linking. The concentration of the carboxylate molecule should be low if it also has amines present, but if it only has one or more carboxylates, then it can be prepared at higher concentration. For example, to use the biotin–PEG$_n$–amine compounds to biotinylate a protein, the concentration should be on the order of 1 to 2 mg/ml so that a large excess of biotinylation agent can be added. For molecules that are sparingly soluble in aqueous solution, they may be dissolved first in

ethanol and then added to the reaction buffer with mixing to make a final ethanol concentration of not more than 50%.
2. Dissolve the biotin–PEG$_n$–amine reagent in reaction buffer at a concentration of 25-m*M*.
3. Add a quantity of the biotin–PEG$_n$–amine solution to the solution containing the carboxylate molecule to achieve the desired molar excess. For molecules containing a single carboxylate to be modified, a 1.5- to 2-fold molar excess may be sufficient. However, for proteins or peptides that also contain competing amines, a much larger excess of biotin compound should be used (e.g., 100-fold excess). For instance, for protein biotinylation, add 120 µl of the biotin–PEG$_n$–amine solution per milliliter of the solution prepared in step 1.
4. Immediately before use, dissolve EDC in reaction buffer at a concentration of 25-m*M*. Add 12 µl of this solution per milliliter of the combined solution from step 2. Mix well.
5. React for 2 h at room temperature or 4 h at 4°C with gentle mixing.
6. Purify the biotinylated protein or molecule using dialysis or gel filtration. For small-molecule biotinylation where these separation methods may not be appropriate, other procedures may have to be developed, such as reverse-phase chromatography or organic precipitation techniques.

Aminooxy–PEG$_n$–Biotin Compounds

Aminooxy reagents are useful in forming covalent linkages with carbonyl compounds, such as aldehydes and ketones (see Section 1.2, this chapter, and Chapter 15, Section 2.4). Biotinylation reagents containing a PEG spacer with a terminal aminooxy group can be used to add a biotin affinity handle to molecules having these functionalities. For instance, glycoproteins and polysaccharides containing oxidizable diols can be reacted with sodium periodate to form aldehyde residues, which then can be biotinylated in a single step with an aminooxy–PEG$_n$–biotin reagent. In addition, carbohydrates and isolated glycans containing a reducing end may be specifically labeled with an aminooxy compound to form either cyclic or acyclic derivatives. The addition of a PEG spacer between the biotin end and the aminooxy end provides significant hydrophilicity and decreased nonspecific binding character to labeled molecules, thus increasing stability of biotinylated probes in solution and increasing the signal-to-noise of assays.

The reaction between an aminooxy compound and an aldehyde or ketone residue yields a stable oxime bond, which is a type of Schiff base but more stable than those formed between amines and carbonyls or hydrazides and carbonyls. This reaction is being used more often for bioconjugation purposes due to its chemoselectivity and its bioorthogonality (Chapter 17, Section 3) (Thumshirn *et al.*, 2003; Poethko *et al.*, 2004; Liu *et al.*, 2007; Colombo and Bianchi, 2010). The use of the aminooxy reactive group on biotinylation compounds is recent and includes various PEG-based cross-bridges, including a cleavable one containing an internal disulfide bond (Thermo Fisher and Quanta BioDesign).

Some of these aminooxy–PEG$_n$–biotin compounds are shown in Figure 18.28. They include different chain lengths of the internal PEG spacer, which provide options for spanning different molecular distances between the labeled molecule and the biotin end. With aliphatic biotinylation compounds, it has been shown to be beneficial to have an extended spacer arm to alleviate steric issues due to the docking of large streptavidin conjugates (see Chapter 11, Section 6.2). Aliphatic linker arms, however, create the potential for nonspecificity from hydrophobic interactions occurring with the cross-bridge. When using PEG-based spacers in biotin reagents, the increased length of a spacer can be more fully realized in aqueous solution due to the extreme hydrophilicity of the polyether arm. For this reason, glycoproteins and other molecules labeled with aminooxy-PEG$_n$–biotin compounds do not aggregate in solution like aliphatic biotin compounds typically do, especially at moderate to high biotinylation levels.

Aminooxy–PEG–biotin compounds can be used to biotinylate carbohydrates and glycoconjugates by an aniline-catalyzed reaction, which accelerates the formation of the oxime at slightly acid pH values (Cordes and Jencks, 1962; Dirksen *et al.*, 2006a,b; Dirksen and Dawson, 2008; Byeon *et al.*, 2010). The aniline first reacts with the aldehyde (or ketone) group to form an intermediate aryl imine, which then reacts more rapidly with the aminooxy group on the biotin reagent to form the oxime linkage (Kohler, 2009). Figure 18.29 illustrates this reaction in the biotinylation of an aldehyde-containing molecule with an aminooxy–PEG$_4$–biotin compound. The aldehyde-containing molecule may consist of a sugar, disaccharide, carbohydrate, or a glycan having an available reducing end or it may consist of a periodate-oxidized glycoprotein. For instance, polyclonal antibodies may be biotinylated at their associated carbohydrate after periodate oxidation (see Chapter 20, Section 1.3).

The following protocols describe the biotinylation of the reducing end of a carbohydrate using the aminooxy–PEG$_4$–biotin reagent or the biotinylation of a glycoprotein after periodate oxidation. Other aminooxy–PEG–biotin compounds may be substituted in these procedures with

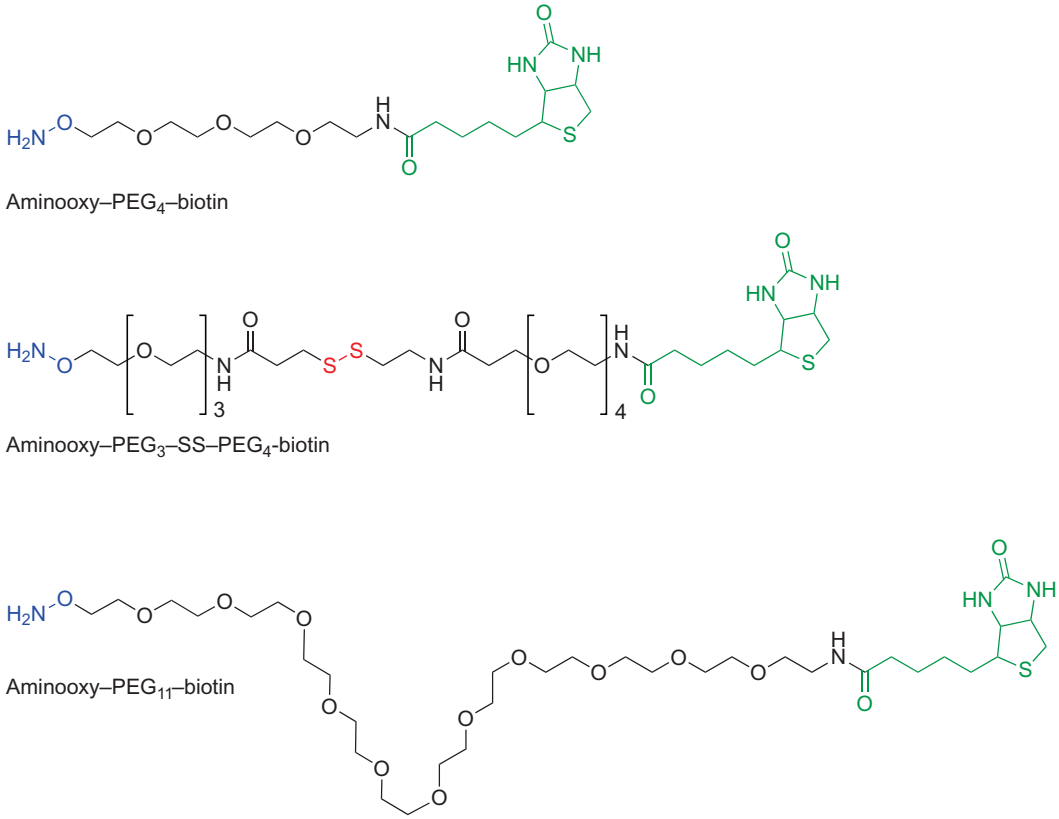

FIGURE 18.28 Aminooxy–PEG$_n$–biotin compounds.

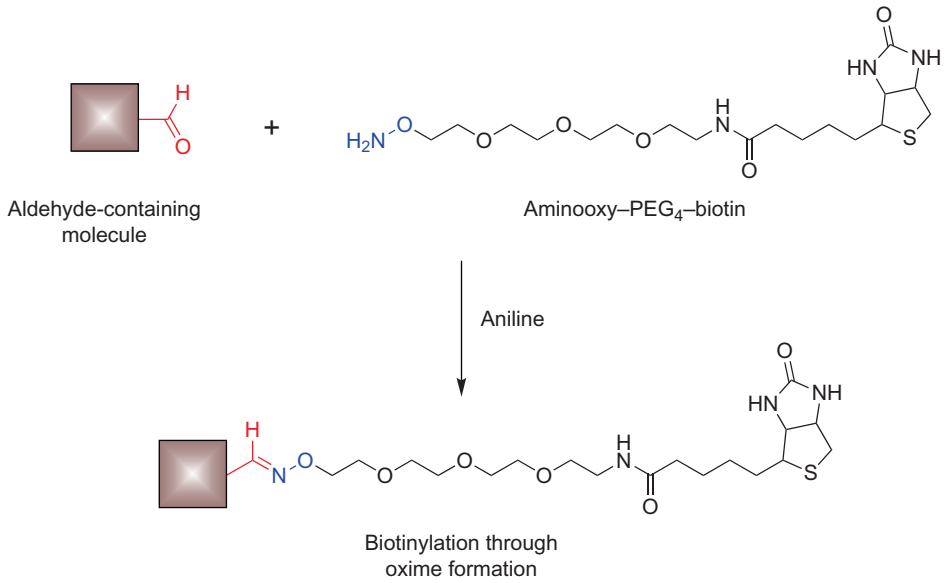

FIGURE 18.29 Biotinylation of an aldehyde-containing compound with aminooxy–PEG$_4$–biotin.

the appropriate changes in the amount of reagent added to a reaction due to differences in molecular weight. These protocols use the addition of aniline as catalyst to increase the reaction rates of oxime formation. For the biotinylation of a reducing carbohydrate, the protocol also results in a mixture of cyclic glycosyl bonds and acyclic oxime bonds to the reducing end of the carbohydrate (Peluso *et al.*, 2002).

(A) Protocol for Biotinylation of a Carbohydrate at its Reducing End

1. Dissolve a carbohydrate, polysaccharide, or glycan (having a reducing end available) at a concentration of at least 5–100 µ*M* in 1 ml of 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 4.5 (coupling buffer). Note: Higher concentrations of a reducing carbohydrate may be used, if soluble, as long as the total concentration does not exceed 0.1× the concentration of the biotinylation reagent used in the reaction (step 3). In addition, the buffer pH may be increased to the range of 5.5 to 6.5 and still obtain good yields of oxime bond formation.
2. In a fume hood, dissolve 50 mg of the aminooxy–PEG_4–biotin reagent (an entire vial; Thermo Fisher) in 460 µl of dry DMSO, DMF, or DMAC (makes a 250-m*M* solution). Note: PEG-based biotin reagents are often very hygroscopic and difficult to weigh out in small quantities. For this reason, it is typically easier to dissolve an entire vial of the reagent in a dry solvent rather than attempt to dispense it by weight.
3. Add 9.2 µl of the biotin solution from step 2 to the carbohydrate solution from step 1 with stirring to create approximately a 5-m*M* final concentration of aminooxy–PEG_4–biotin compound in the reaction medium.
4. In a fume hood, add 9 µl of aniline catalyst to the reaction mixture with stirring. This results in approximately a 0.1-*M* aniline solution in the reaction medium.
5. Seal the tube and continue the reaction for at least 4 h at room temperature and with constant mixing by end-over-end rocking.
6. Purify the biotinylated carbohydrate by dialysis or size exclusion chromatography using an exclusion limit for the membrane or for the chromatography support that excludes the molecular weight of the carbohydrate but allows the excess biotin compound and aniline catalyst to get into the pores and be removed. For the biotinylation of low-molecular-weight carbohydrates, this purification step may have to be altered to include separations such as HPLC chromatography on a reverse-phase column or differential precipitation steps to isolate the final biotinylated complex from excess reactants.

(B) Protocol for Biotinylation of a Glycoprotein after Periodate Oxidation

1. Dissolve a glycoprotein to be oxidized at a concentration of 2 mg/ml in 1 ml of 0.1-*M* sodium acetate, pH 5.5 (coupling buffer). Chill on ice.
2. Dissolve sodium periodate in 2 ml of coupling buffer at a concentration of 20-m*M*. Chill the solution on ice and protect from light.
3. To oxidize all the diols within the glycan portion of the glycoprotein to aldehydes, add 1 ml of the cold sodium periodate solution to the glycoprotein with mixing. To oxidize only the sialic acid groups within the carbohydrate add 50 µl of the sodium periodate solution to the glycoprotein solution with mixing.
4. Maintain the solution on ice and react for 30 min with periodic mixing and while protecting the solution from light.
5. Remove excess periodate from the oxidized glycoprotein by size exclusion chromatography on a column of Sephadex G-25 or the equivalent while using coupling buffer as the mobile phase. Concentrate the purified protein to approximately 1 ml using a centrifugal concentrator with a molecular weight exclusion limit of less than that of the glycoprotein (e.g., 10 kDa for most proteins).
6. In a fume hood, dissolve the aminooxy–PEG_4–biotin reagent at a concentration of 50-m*M* in DMSO, DMF, or DMAC. It may be simpler to dissolve an entire bottle of the biotin compound rather than weigh out a fraction of it, because of the hygroscopic or sticky nature of PEG-based substances.
7. Add 100 µl of the biotinylation reagent solution to the glycoprotein solution with mixing. This makes a final concentration of about 5-m*M* aminooxy–PEG_4–biotin in the reaction medium.
8. In a fume hood, add 9 µl of aniline to the reaction mixture and stir well. This makes approximately a 0.1-*M* solution with respect to the aniline catalyst.
9. React for 2 h at room temperature with periodic mixing.
10. Purify the biotinylated glycoprotein by dialysis or size exclusion chromatography to remove excess reactants and reaction by products.

Biotin–PEG_n–Azide and Biotin–PEG_3–Phosphine Compounds

Biotinylation reagents containing a PEG spacer arm and a chemoselective reacting group at the other end now are available to use in bioorthogonal reaction methods with alkyne-containing molecules or azide-containing molecules. The click chemistry reaction, which involves a copper-catalyzed cycloaddition of an azide group with an alkyne triple bond, has been used extensively to produce bioconjugates (Chapter 17, Section 5). In the presence of Cu–I, an alkyne will selectively couple with an azido group to give a triazole ring with very high yield and rapid reaction kinetics. This reaction is highly specific even in the presence of a wide variety of biomolecule functional groups within complex sample extracts. PEG-based biotinylation agents can label alkyne-modified substances within cells or homogenates to give biotin-modified targets that can be detected using streptavidin conjugates (Chapter 11).

In addition, PEG-based biotin reagents are also available that contain a reactive phosphine group on the other end, which can participate in the chemoselective

Staudinger ligation reaction (Chapter 17, Section 6). These compounds react in a bioorthogonal manner with azide-containing molecules to give an amide bonded conjugate. Much like the copper-catalyzed click reaction, biotinylation using biotin–PEG_3–phosphine is very specific for coupling to azido tags, even in the presence of other biomolecules; however, unlike the click reaction, the Staudinger ligation process occurs without the addition of a highly oxidizing substance (Cu–I). Thus, biotin–PEG_3–phosphine can be used to label live cells that have expressed azido-modified components, such as proteins, glycans, or lipids.

Figure 18.30 illustrates some of these biotinylation compounds that are useful in a broad range of chemoselective labeling processes. The central PEG spacer arms of these reagents aid in water solubility and decrease the tendency of the biotin tags to bind nonspecifically to hydrophobic pockets on biomolecules, which would definitely occur with the use of aliphatic cross-bridges. Even the properties of the phosphine biotin compounds are dramatically improved by the presence of the PEG spacer arms.

Figure 18.31 shows the reactions of the biotin–PEG_7–azide compound with an alkyne-labeled molecule Figure 18.32 shows the reaction of the biotin–PEG_3–phosphine compound with an azido-modified molecule. The reaction rate of the Staudinger ligation process is slower than the copper-catalyzed click reaction, but the advantage of being able to label and image in real time living cells is a major advantage of the phosphine/azide reaction.

The following protocol describes the use of biotin–PEG_3–phosphine to label azide-containing molecules by use of the Staudinger ligation reaction. The conjugation yields an amide bond to the carbonyl-containing phenyl ring on the triphenylphosphine group at the end of the biotin tag. This general reaction scheme can be used to label azido-proteins in solution or glycoproteins in cells that have been expressed with azido-sugar-containing glycans. Note that reducing agents should be avoided in the presence of azide-containing molecules, because the azido group might be degraded to form an amine with release of nitrogen gas, thus eliminating the activity of the azide to participate in the Staudinger ligation reaction.

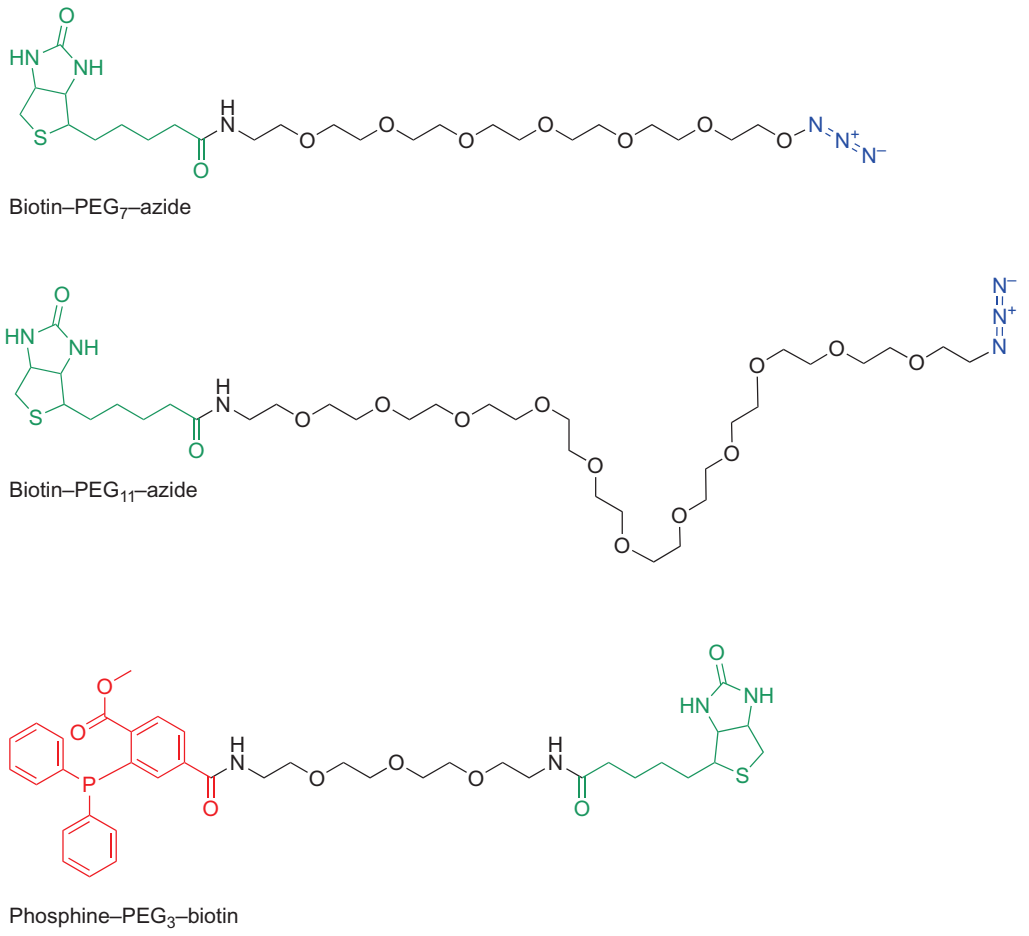

FIGURE 18.30 PEG-based biotin compounds that can be used in chemoselective ligation reactions. The first two azido compounds can be used in copper-catalyzed or copper-free click reactions with alkynes, while the third reagent contains a reactive phosphine group, which can be used in a Staudinger ligation reaction with an azido compound.

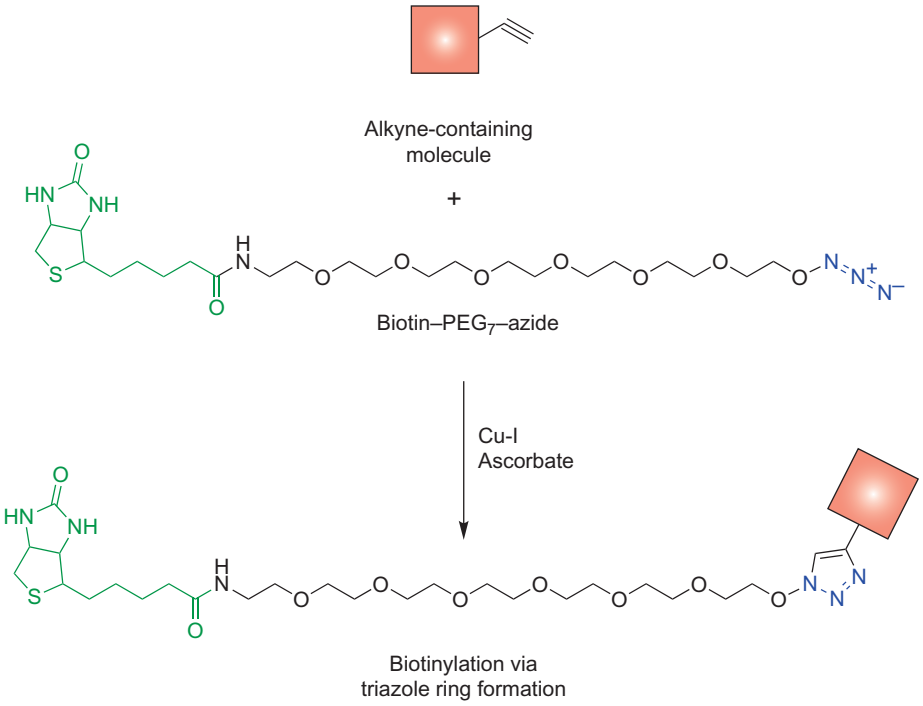

FIGURE 18.31 An alkyne-containing molecule can be biotinylated using an azide-containing PEG–biotin reagent to form a triazole bond.

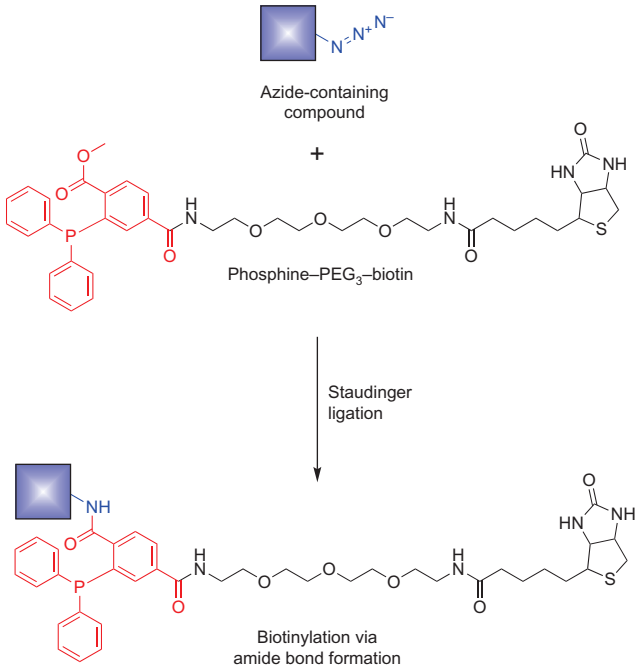

FIGURE 18.32 An azide-containing compound can be biotinylated with a phosphine-containing PEG–biotin reagent through amide bond formation.

For a suggested protocol on the use of the biotin–PEG_n–azide compounds to biotinylate alkyne-containing molecules, see the copper-catalyzed click chemistry reaction as described in the previous section entitled NHS–PEG_n–Azide/Alkyne Compounds for Chemoselective Ligation.

Protocol

1. Dissolve an azide-containing protein or other molecule in 50-m*M* sodium phosphate, pH 7.2, at a concentration of approximately 2–5 mg/ml. Notes: Higher protein concentrations may be used in this protocol provided the biotinylation reagent is adjusted in concentration as recommended in step 3. For probing living cells with the biotin–PEG_3–phosphine reagent, the use of physiological buffers compatible with cell viability may be used, provided that no reducing agents are present in the solution (e.g., 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2).
2. Dissolve biotin–PEG_3–phosphine in anhydrous DMSO, DMF, or DMAC to make a final concentration of 10-m*M*. The stock solution may be stored frozen at −20°C for 6 months with no loss of activity.
3. Add an aliquot of the biotin–PEG_3–phosphine solution to the azido–protein solution to obtain a 2-fold molar excess of the biotinylation agent over the concentration of protein. For use of higher protein concentrations, the amount of biotin compound added to the reaction may be reduced to a 10-fold excess without affecting the yield of biotinylation.
4. Incubate the reaction at 37°C for 2–4 h or at room temperature for overnight (at least 16 h).
5. Remove excess reactant by size exclusion chromatography using a desalting column or by dialysis. If cells are being labeled, wash the cells with buffer at least several times to remove unreacted biotin compound.

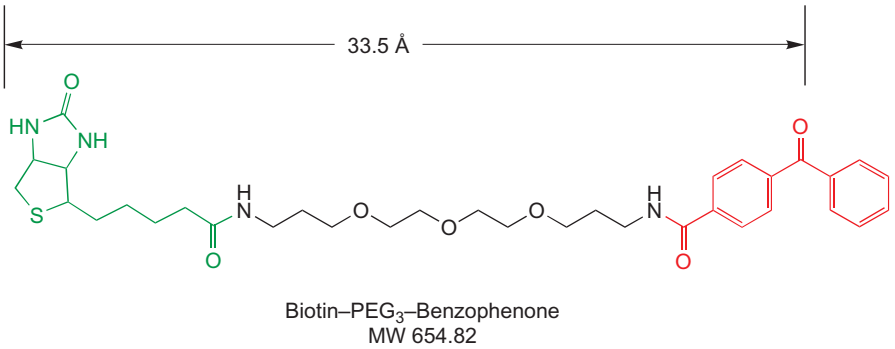

FIGURE 18.33 Biotin–PEG_3–benzophenone is a water soluble photoreactive biotinylation reagent that can be used to add a biotin group to surfaces or molecules containing no easily derivatized functional groups.

Biotin–PEG_3–Benzophenone

Biotin–PEG_3–benzophenone is a biotinylation reagent with a hydrophilic spacer containing three ethylene oxide units and a photoreactive group at its end (Quanta BioDesign) (Figure 18.33). The benzophenone is activated by UV light to an extremely reactive triplet-state ketone, which can insert into CH, NH, and other structures, resulting in a covalent bond (Chapter 3, Section 7.2). The reaction is one of the most efficient photoreactive conjugation mechanisms available (Campbell and Gioannini, 1979). Thus, this reagent provides a method of adding a biotin group to molecules that do not contain typical functionalities useful for bioconjugation. This may include polymeric surfaces or organic molecules lacking reactive targets.

The presence of the PEG_3 spacer in this compound provides water solubility to the biotin arm, whereas the benzophenone group should associate with more hydrophobic regions or surfaces, which may be ideal for the biotinylation photoreaction. The reagent can be used by dissolving it in an aqueous buffer suitable for use with whatever substance is to be biotinylated. After mixing this solution with the target molecule or surface, exposure to UV light will initiate the conjugation reaction. Unlike other photoreactive groups, a benzophenone does not undergo decomposition to an inactive form if it does not couple to target molecules. Instead, it degrades from the photo-excited state back to its initial state, so it can be once again photolyzed to an active state. This process increases the likelihood that the benzophenone will couple to a target molecule during the photoreaction. See Chapter 6, Section 4.3, for an illustration of the benzophenone-coupling reaction.

1.4. Discrete PEG Modification Reagents

Large-polymer PEG reagents having molecular weights > 2000 Daltons have been used for over 20 years as modification agents for biological molecules (Section 2.1). These compounds are often used with a reactive group on one end and a blocked hydroxyl group on the other end (e.g., as the methyl ether). In addition, large, branched PEG molecules have been created to add more bulk or exclusion volume at a modification site, thus increasing the protective effect of the PEG molecule toward the biological molecule.

Discrete PEG compounds have also been developed in various reactive forms with methyl ether blocking groups on the terminal end (Thermo Fisher, Quanta BioDesign). Unlike the original PEG polymer reagents that display polydispersity, these PEG compounds are pure and consist of only one chain length per reagent type. The chain lengths in discrete PEG modifiers include, for example, polyethylene oxide repeat units of 3, 4, 8, 12, and 24. NHS–$mPEG_n$ modification reagents can be used directly to couple with amine-containing molecules or proteins through amide bond formation. This reaction occurs in aqueous buffers at physiological pH or slightly alkaline pH conditions. Conversely, maleimide–$mPEG_n$ reagents are designed to conjugate with thiol-containing molecules, and these may be used to target reduced disulfide bonds in proteins or thiols created on molecules using a thiolation reagent.

In addition, branched-chain compounds have been developed consisting of a functional group or a reactive group followed by a PEG_4 chain, which then leads to three branches each having an $mPEG_{12}$ arm on them. Such compounds are expected to provide large exclusion volumes in aqueous solution to surround, protect, and solubilize modified molecules.

Another type of PEG modification reagent that has been developed contains a functional group on each end that can be used for conjugation purposes and which can be used to build structures on solid supports, surfaces, or on other molecules. Some of these reagents have been developed to contain an amine group on one end and a carboxylate on the other end. Such PEG-based amino acids can be used as spacer arms to mask surfaces or provide highly hydrophilic tethers for the attachment of affinity ligands. A thiol–PEG_n–carboxylate, for instance, can be used to modify metal particles or surfaces through dative binding of the thiol to the metal and then create PEG–carboxylic acids for further conjugation.

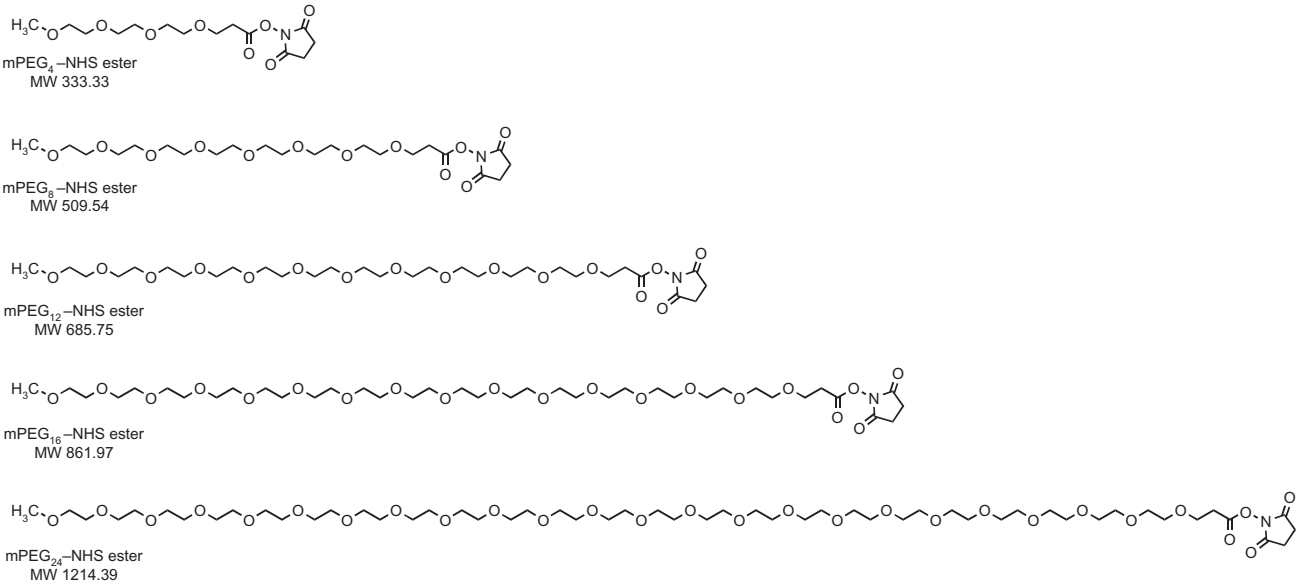

FIGURE 18.34 Discrete PEGylation reagents are available to provide a range of different chain lengths for adding mPEG modification arms to biomolecules. They can also be used to add water soluble mPEG groups to organic molecules that are normally not very soluble in aqueous solution. The NHS ester end of the mPEG compounds reacts with amine-containing molecules to form amide bonds, leaving the mPEG chain to interact with the aqueous environment.

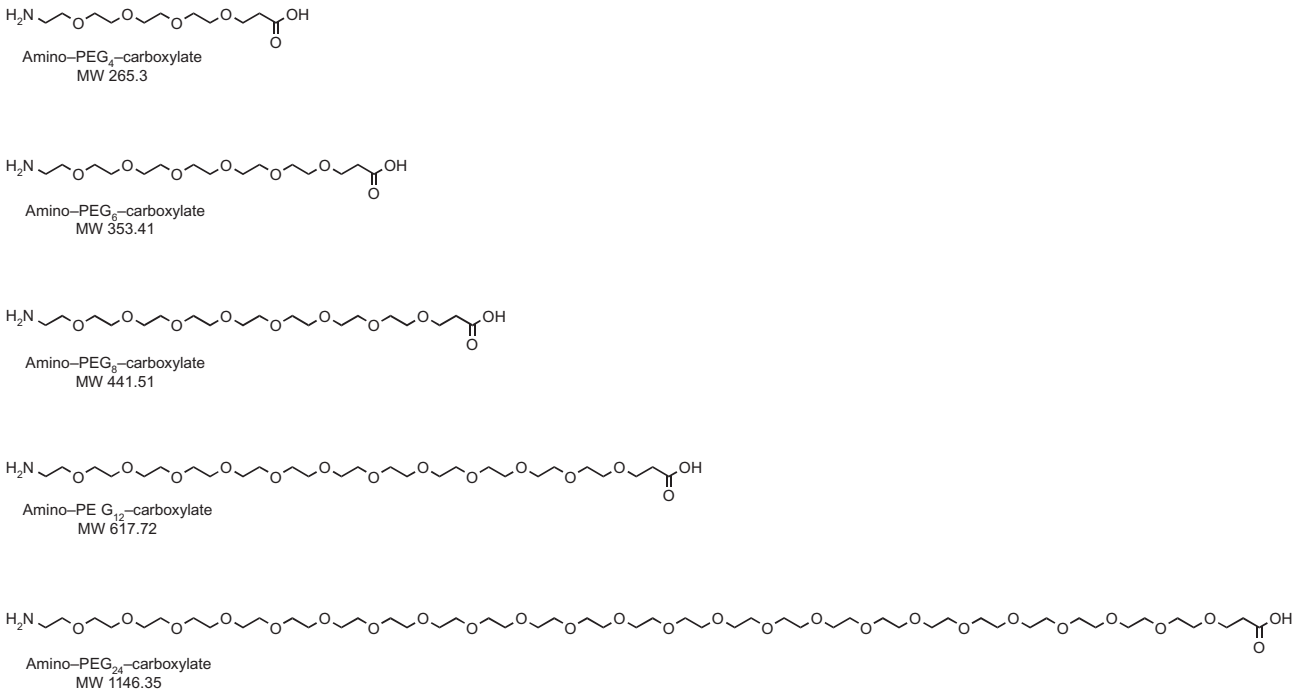

FIGURE 18.35 Amino–PEG$_n$–carboxylate compounds contain a primary amine on one end and a carboxylate group on the other end. They can be used to add water soluble spacer arms to molecules or surfaces. Using an amine-reactive group, the amino–PEG$_n$–carboxylate compound can be coupled *via* an amide bond, thus leaving the carboxylate end free for further conjugation reactions. Avoid the use of single-step EDC conjugation reactions, as this will polymerize the amino–PEG$_n$–carboxylate by reacting with both ends.

Figures 18.34, 18.35, and 18.36 illustrate these PEG-based modification reagents. The methods for their use follow the same general protocol guidelines as discussed in previous sections of this chapter for the corresponding reactive group or functional group. When modifying biomolecules with mPEG-based reagents, a series of modification levels should be investigated to determine the optimal performance in an intended application.

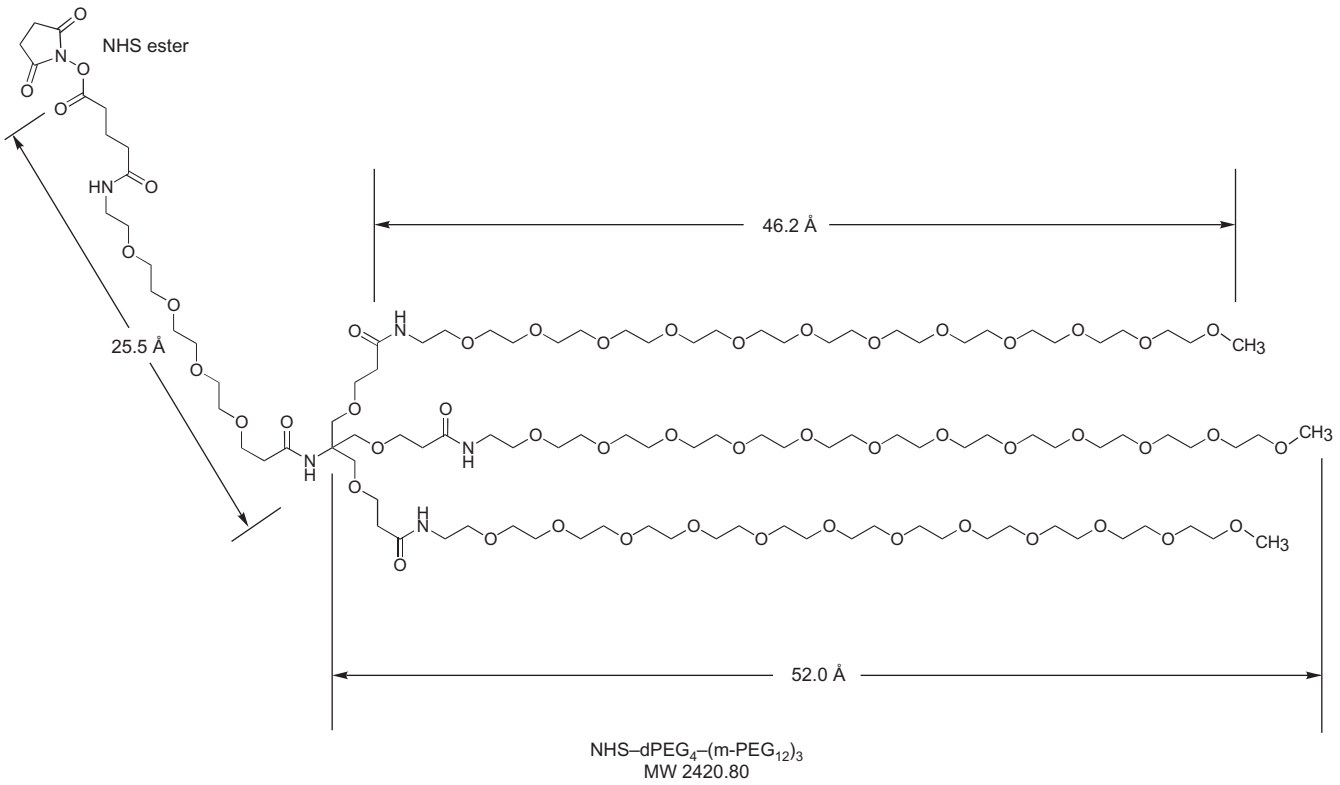

FIGURE 18.36 The branched PEGylation compound NHS–$dPEG_4$–$(mPEG_{12})_3$ contains three mPEG arms, which provide an increased sphere of hydration around modified molecules compared to straight-chain PEGylation compounds.

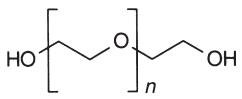
For surface or particle modification, reference should be made to Chapter 14, especially the section on covalent coupling to particles.

2. POLYMER MODIFICATION REAGENTS

Modification or attachment of proteins or other molecules with synthetic polymers can provide many benefits for both *in vivo* and *in vitro* applications. Covalent coupling of polymers to large macromolecules can alter their surface and solubility properties, creating increased water solubility or even organic solvent solubility for molecules normally sparingly miscible in such environments. Polymer modification of foreign molecules can provide increased biocompatibility, reducing the immune response, increasing *in vivo* stability, and delaying clearance by the reticuloendothelial system. Modification of enzymes with polymers can dramatically enhance their stability in solution. Polymer attachment can provide cryoprotection for proteins sensitive to freezing. Polymers with multivalent reactive sites can be used to couple numerous small molecules for creating pharmacologically active agents that possess long half-lives in biological systems. Similar complexes can be formed to create highly potent immunogens consisting of hapten–polymer conjugates for induction of an antibody response toward the hapten. Polymer modification of surfaces can effectively mask the intrinsic character of the surface and thus prevent nonspecific protein adsorption. Finally, multifunctional polymers can serve as extended crosslinking agents for the conjugation of more than one molecule of one protein to multiple numbers of a second molecule, creating large complexes with increased sensitivity or activity in detecting or acting upon target analytes.

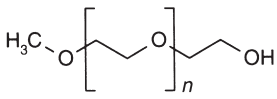
Many polymers have been studied for their usefulness in producing pharmacologically active complexes with proteins or drugs. Synthetic and natural polymers such as polysaccharides, poly(L-lysine) and other poly(amino acids), poly(vinyl alcohols), polyvinylpyrrolidinones, poly(acrylic acid) derivatives, various polyurethanes, and polyphosphazenes have been coupled with a diversity of substances to explore their properties (Duncan and Kopecek, 1984; Braatz *et al.*, 1993; Canal *et al.*, 2011; Gada *et al.*, 2012; Tong and Cheng, 2012). Copolymer preparations of two monomers have also been tried (Nathan *et al.*, 1993). See Chapter 1 for an in-depth discussion of polymeric scaffolds used in therapeutic bioconjugate applications.

The two polymers most often used in these applications are dextran and polyethylene glycol (PEG).



Both polymers consist of repeating units of a single monomer—glucose in the case of dextran and an ethylene oxide basic unit in the case of PEG. The polymers may be composed of linear strands or branched constructs. An additional similarity is that both types possess hydroxyl and ether linkages, lending significant hydrophilicity and water solubility to the molecules. Dextran and PEG can be activated through their hydroxyl groups by a number of chemical methods to allow efficient coupling of other molecules. Dextran can be activated at multiple sites throughout its chain, since each monomer contains hydroxyl residues. PEG, by contrast, only has hydroxyls at the termini of each polymer strand. Derivatives of both polymers are commercially available that incorporate other functional groups, including amines and carboxylates.

The following sections discuss the major properties and conjugation chemistries associated with the use of these polymers in modifying or conjugating proteins and other molecules.



2.1. Polymeric PEG Reagents

Since the first report by Abuchowski and co-workers in 1977 concerning the alteration of the immunological properties of bovine serum albumin (BSA) that had been modified with PEG, the interest in polymer modification of biological molecules has grown tremendously (Roberts *et al.*, 2012; Milla *et al.*, 2012). PEG coupled to other molecules can be used for altering solubility characteristics in aqueous or organic solvents (Inada *et al.*, 1986; Milla *et al.*, 2012 1986), for modulation of the immune response (Delgado *et al.*, 1992), to increase the stability of proteins and peptides in solution (Berger and Pizzo, 1988; Jain and Ashbaugh, 2011), to enhance the half-life of substances *in vivo* (Knauf *et al.*, 1988; Gunasekaran *et al.*, 2011), to aid in penetrating cell membranes, to alter pharmacological properties (Dunn and Ottenbrite, 1991; Liu, 2011), to increase biocompatibility, especially toward implanted foreign substances, and to prevent protein adsorption to surfaces (Chen *et al.*, 2009).

PEG consists of repeating units of ethylene oxide which terminate in hydroxyl groups on both ends of a linear chain. Some constructs have branches that have multiple linear strands emanating from the branch points. PEG is made from the anionic polymerization of ethylene oxide, resulting in the formation of polymer strands of various potential molecular weights, depending on the polymerization conditions. Thus, all polymeric PEGs are polydisperse and exist as distribution of multiple lengths and molecular weights. Most forms of PEG useful in bioconjugate applications have molecular weights less than about 20,000 and are soluble both in aqueous solution and in many organic solvents.

PEG
Poly(ethylene glycol)

mPEG
Monomethoxy-
Poly(ethylene glycol)

Unlike the PEG molecules formed from anionic polymerization techniques, highly discrete forms of the polymer also exist, made by controlled addition of small PEG units to create chains of exact molecular size. These discrete PEGs have a single molecular weight and do not display the polydispersity of the traditional PEG polymers. See Section 1 for a complete discussion of discrete PEG-based reagents and their applications.

Since the polymer backbone of PEG is not of biological origin, it is not readily degraded by mammalian enzymes (although some bacterial enzymes will break it down). This property results in only slow degradation of the polymer when used *in vivo*, and this characteristic also causes an extension of the half-life of modified substances. PEG modification serves to mask any molecule that it is coupled to—the "PEGylated" molecule often being protected from immediate breakdown or from being complexed and inactivated by immunoglobulins in the bloodstream.

PEG's properties in solution are especially unusual, frequently displaying amphiphilic tendencies, having the ability to both solubilize in aqueous layers and in hydrophobic membranes or organic phases. The partitioning quality of PEG across membranes is important in aiding the formation of hybridomas in the production monoclonal antibodies (Goding, 1986b). The partitioning characteristics of PEG also create the ability to use it in aqueous two-phase systems for the purification of biological molecules (Johansson, 1992).

PEG in solution is a highly mobile molecule that creates a large exclusion volume for its molecular weight, much larger in fact than proteins of comparable size. Whether in solution or attached to other insoluble supports or surfaces, PEG has a tendency to exclude other polymers. This property forms a protein-rejecting region that is effective in preventing nonspecific protein binding (Bergstrom *et al.*, 1992). Conjugation with PEG can create the same exclusion effects surrounding a macromolecule, even preventing interaction between a ligand and its target (Klibanov *et al.*, 1991), an enzyme and its substrate (Berger and Pizzo, 1988), or the immune system and a foreign substance (Davis *et al.*, 1979). Thus, PEG-modified molecules display low immunogenicity, have good resistance to proteolytic digestion, and survive in the bloodstream for extended periods (Abuchowski *et al.*, 1977a; Dreborg and Akerblom, 1990; Roberts *et al.*, 2012).

PEG can be conjugated to other molecules through its two hydroxyl groups at the ends of each linear chain. This process is typically done by the creation of a reactive electrophilic intermediate that is capable of spontaneously coupling to nucleophilic residues on a second molecule. To prevent the potential for crosslinking when using a bifunctional polymer, monofunctional PEG polymers can be used which contain one end of each chain blocked with a methyl ether group. Monomethoxypolyethylene glycol (mPEG) contains only one hydroxyl group per linear chain, thus limiting activation and coupling to one site and preventing the crosslinking and polymerization of modified molecules. The mPEG derivative also stabilizes the blocked end to oxidation or degradation in solution.

Trichloro-s-Triazine Activation and Coupling

The most common activation methods for PEG create amine-reactive derivatives that can form amide or secondary amine linkages with proteins and other amine-containing molecules. The oldest method of PEG activation is through the use of trichloro-*s*-triazine (TsT; cyanuric chloride) (Abuchowski *et al.*, 1977). TsT is a symmetrical heterocyclic compound containing three reactive chlorines. This reagent and its derivatives are extensively used in industrial applications to form strong covalent bonds between dye molecules and fabrics. The compound has also been used to activate affinity chromatography supports for the coupling of amine-containing ligands (Finlay *et al.*, 1978) (see Chapter 15, Section 2.1). Reaction of TsT with PEG results in the formation of an activated derivative with an ether bond to the hydroxyl group of the polymer. If mPEG is used, TsT activation will be restricted to the one free hydroxyl, thus forming a monovalent intermediate that can be coupled to proteins without polymerization (Figure 18.37).

The three reactive chlorines on TsT have dramatically different reactivities toward nucleophiles in aqueous solution. The first chlorine is reactive toward hydroxyls as well as primary and secondary amine groups at 4°C and a pH of 9.0 (Abuchowski, 1977a; Mumtaz and Bachhawat, 1991). Once the first chlorine is coupled, the second one requires at least room temperature conditions at the same pH to react efficiently. If two chlorines are conjugated to nucleophilic groups, the third is even more difficult to couple, requiring at least 80°C at alkaline pH. After activation of mPEG with TsT, it is therefore, for all practical purposes, only possible to couple one additional component to the triazine ring.

TsT activation provides a simple route to an amine-reactive PEG derivative and it has been used extensively as an activation method for modifying proteins (Wieder *et al.*, 1979; Zalipsky and Lee, 1992; Gotoh *et al.*, 1993). The modification of primary amine-containing molecules such as proteins is pH dependent. At physiological pH values, the reaction will proceed slower than in a more alkaline pH environment. Optimal derivatization efficiency is reached at conditions equal to or above pH 9.0. However, TsT reactivity is not exclusive toward amines. TsT–mPEG modification of proteins can result in modifying other nucleophilic groups such as sulfhydryls and the phenolate ring of tyrosine. In addition, there is potential for toxicity associated with TsT and its derivatives—an especially important consideration for *in vivo* use.

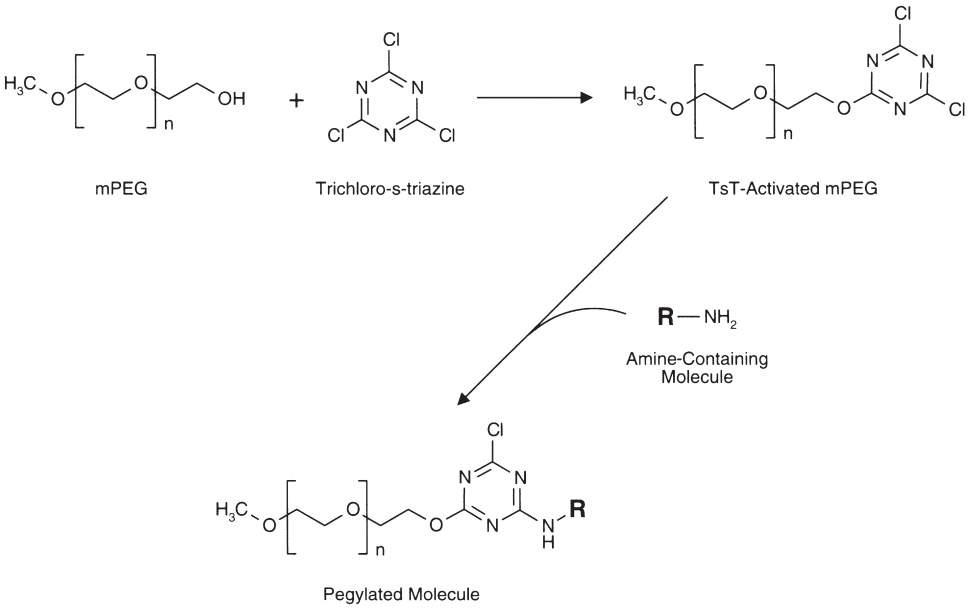


FIGURE 18.37 mPEG polymers may be activated by trichloro-*s*-triazine for the modification of amine-containing molecules.

The following protocol for mPEG activation using TsT and its coupling to proteins is based on the protocols of Abuchowski *et al.* (1977b) and Gotoh *et al.* (1993).

Protocol for the Activation of mPEG with TsT

Note: All operations should be carried out in a fume hood. Wear proper personal protective equipment and dispose of hazardous waste according to EPA guidelines.

1. Dissolve 5.5 g of TsT in 400 ml of anhydrous benzene which contains 10 g of anhydrous sodium carbonate.
2. Add to the TsT solution, 50 g of mPEG-5000 (monomethoxypolyethylene glycol having a molecular weight of 5000). Mix well to dissolve.
3. React overnight at room temperature with stirring.
4. Filter the solution through a glass-fiber filter pad and slowly add, with stirring, 600 ml of petroleum ether (bp 35–60°C).
5. Collect the precipitated product by filtration and redissolve it in 400 ml of benzene. Repeat steps 4 and 5 several times to ensure complete removal of unreacted TsT. The residual TsT may be detected by HPLC using a 250 × 3.2-mm LiChrosorb (5 µm particle size) column from E. Merck. The separation is performed using a mobile phase of hexane, and peaks are detected with a UV detector.
6. Remove excess solvents by rotary evaporation. The TsT–mPEG should be used immediately or stored in anhydrous conditions at 4°C.

Protocol for Coupling of TsT–mPEG to Proteins

1. Dissolve the protein to be modified with TsT–mPEG in ice-cold 0.1-*M* sodium borate, pH 9.4, at a concentration of 2 to 10 mg/ml. Other buffers at lower pH values (down to pH 7.2) can be used and still obtain modification, but the yield will be less. Avoid amine-containing buffers such as Tris or the presence of sulfhydryl-containing compounds, such as disulfide reductants.
2. Slowly add TsT–mPEG to the protein solution at a level of at least a 5-fold molar excess over the desired modification level. For example, Gotoh *et al.* (1993) added 100 mg of TsT–mPEG-5000 to 19 mg of protein dissolved in 6 ml of buffer. Add the polymer over a period of about 15 min with stirring at 4°C.
3. React for 1 h at 4°C.
4. Remove excess TsT–mPEG by dialysis or gel filtration using a column of Sephacryl S-300.

NHS Ester and NHS Carbonate Activation and Coupling

Carboxylate groups activated with *N*-hydroxysuccinimide (NHS) esters are highly reactive toward amine nucleophiles. In the mid-1970s, NHS esters were introduced as reactive ends of crosslinking reagents (Bragg and Hou, 1975; Lomant and Fairbanks, 1976). Their excellent reactivity at physiological pH quickly established NHS esters as the major amine-coupling chemistry in bioconjugate chemistry.

NHS ester-containing compounds react with nucleophiles to release the NHS leaving group and form an acylated product (Chapter 3, Section 1.4). The reaction of such esters with sulfhydryl or hydroxyl groups is possible, but does not yield stable conjugates, forming thioesters or ester linkages. Both of these bonds typically hydrolyze in aqueous environments or can undergo transesterification reactions. Histidine side chain nitrogens of the imidazolyl ring may also be acylated with an NHS ester reagent, but they too hydrolyze rapidly (Cuatrecasas and Parikh, 1972). Reaction with primary and secondary amines, however, creates stable amide and secondary amide linkages, respectively, that don't readily break down. In protein molecules, NHS ester groups primarily react with the α-amines at the N-terminals and the ε-amines of lysine side chains, due to their relative abundance.

PEG contains no carboxylate groups in its native state, but can be modified to possess them by reaction with anhydride compounds. Either PEG or mPEG may be acylated with anhydrides to yield ester derivatives terminating in free carboxylate groups. Modification of PEG with succinic anhydride or glutaric anhydride gives *bis*-modified products having carboxylates at both ends. Modification of mPEG yields the mono-substituted derivative containing a single carboxylate. Creation of the succinimidyl succinate and succinimidyl glutarate derivative of PEG was described by Abuchowski *et al.* (1984). A method for the succinylation of mPEG can be found later in Section 2.1. Subsequent formation of the NHS ester derivatives of these acylated PEG compounds produce highly reactive polymers that can be used to modify amine-containing molecules under mild conditions and with excellent yields (Figures 18.38 and 18.39). The main deficiency of the succinimidyl succinate or succinimidyl glutarate activation procedures is the potential for hydrolysis of the ester bond formed by acylation of the hydroxyl end groups of mPEG.

A modification of the anhydride-acylation route to obtaining reactive NHS ester–PEG compounds was introduced by Zalipsky *et al.* (1991, 1992). In this approach, the terminal hydroxyl group of mPEG is treated with phosgene to give a reactive intermediate, an mPEG–chloroformate compound. Next, the addition of *N*-hydroxysuccinimide (NHS) gives the succinimidyl carbonate derivative (Figure 18.40). Nucleophiles, such as the primary amino groups of proteins, can react with the succinimidyl carbonate to give stable carbamate (aliphatic urethane) bonds (Figure 18.41). The linkage is identical to that obtained through

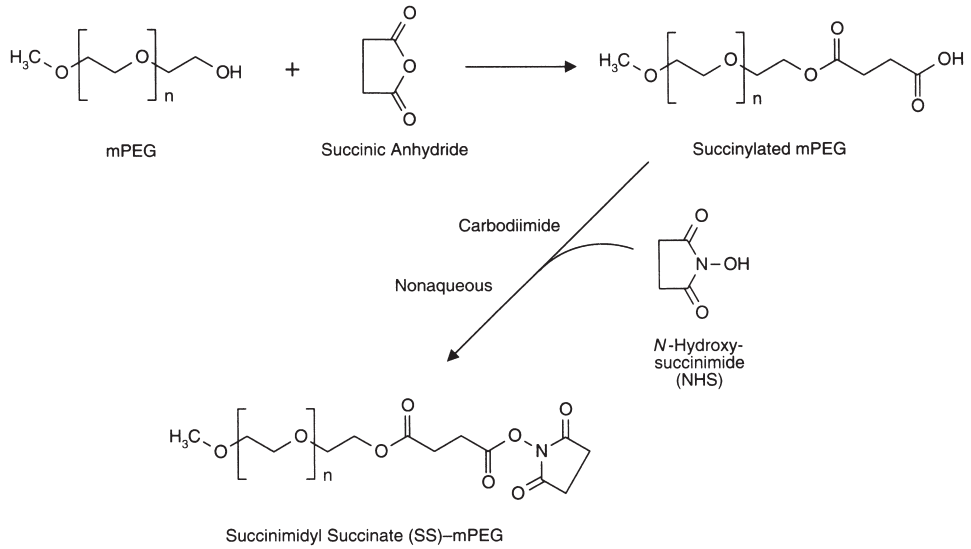

FIGURE 18.38 mPEG may be derivatized with succinic anhydride to produce a carboxylate end. A reactive NHS ester can be formed from this derivative by use of a carbodiimide-mediated reaction under nonaqueous conditions. The succinimidyl succinate–mPEG is highly reactive toward amine nucleophiles.

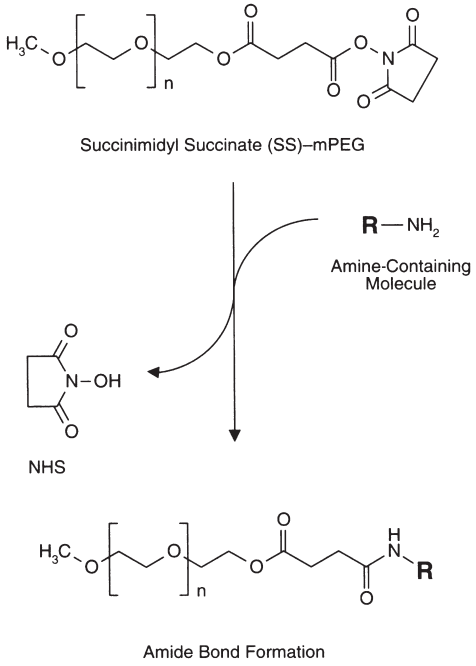

FIGURE 18.39 Succinimidyl succinate–mPEG may be used to modify amine-containing molecules to form amide bond derivatives. The ester bond of the succinylated mPEG, however, is subject to hydrolysis.

N,N′-carbonyldiimidazole (CDI) activation of hydroxyl groups with subsequent coupling of amines (Chapter 3, Section 3; Chapter 15, Section 2.1; and this chapter, Section 1.4). However, the reactivity of the succinimidyl carbonate is much greater than that of the imidazole carbamate formed as the active species in CDI activation.

Unlike the succinimidyl succinate or succinimidyl glutarate activation methods, succinimidyl carbonate chemistry does not suffer from the presence of a labile ester bond. The intermediate reactive NHS carbonate may hydrolyze in aqueous solution to release NHS and CO_2, essentially regenerating the underivatized PEG hydroxyl. After coupling to amine-containing molecules, however, the resultant carbamate linkage stabilizes the chemistry to the point that a modified molecule will not lose PEG by hydrolytic cleavage. For these reasons, the succinimidyl carbonate method of PEG activation and coupling has become the chemistry of choice for attaching the polymer to amine-containing proteins and other molecules.

A modification of Zalipsky's method by Miron and Wilchek (1993) simplifies the creation of the succinimidyl carbonate activated species. Instead of using highly toxic phosgene to form a chloroformate intermediate and then reacting with NHS, the new procedure utilizes either *N*-hydroxysuccinimidyl chloroformate or *N,N′*-disuccinimidyl carbonate (DSC; Chapter 5, Section 1.7) to produce the succinimidyl carbonate–PEG in one step (Figure 18.42). Since both activation reagents are commercially available, creating an amine-reactive PEG derivative has never been easier.

The following procedure is based on the Miron and Wilchek modification of Zalipsky's method.

Protocol for the Activation of PEG with N-Succinimidyl Chloroformate or N,N′-Disuccinimidyl Carbonate

Caution: The steps using flammable solvents, especially diethyl ether, should be done in a fume hood.

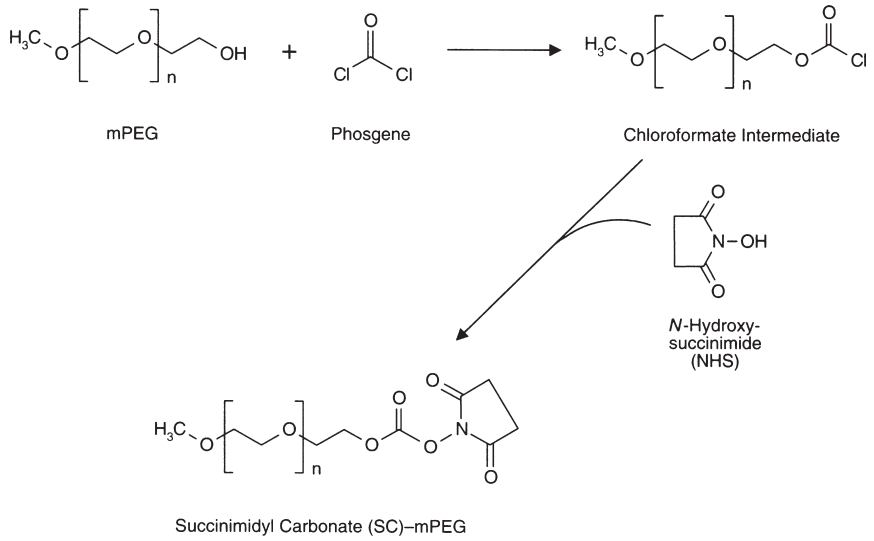

FIGURE 18.40 A succinimidyl carbonate derivative of mPEG was first prepared through the use of phosgene to form a chloroformate intermediate. Reaction with NHS gives the amine-reactive succinimidyl carbonate-mPEG.

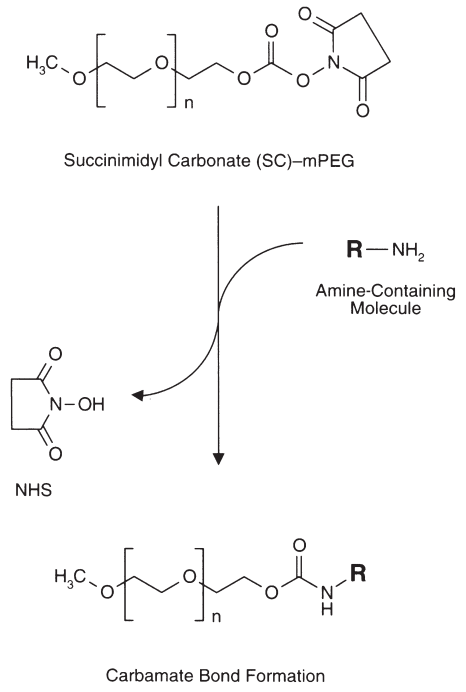

FIGURE 18.41 Succinimidyl carbonate-mPEG can be used to modify amine-containing molecules to form stable carbamate linkages.

1. Dissolve 5 g PEG or mPEG (MW 5000; 1 mmol) in 25 ml of dry dioxane. Heating in a water bath may be necessary to solubilize fully the polymer. Cool to room temperature.
2. Dissolve 6 mmol of either *N*-succinimidyl chloroformate or *N,N′*-disuccinimidyl carbonate (Aldrich) in 10 ml of dry acetone.
3. Dissolve 6 mmol of 4-(dimethylamino)pyridine (DMAP) in 10 ml of dry acetone (base).
4. With stirring, add the solution prepared in step 2 to the PEG solution prepared in step 1. Next, slowly add the solution prepared in step 3.
5. React for 2 h if activating with *N*-succinimidyl chloroformate or 6 h if using *N,N′*-disuccinimidyl carbonate (DSC). Maintain stirring with a magnetic stirring bar.
6. If *N*-succinimidyl chloroformate was used, filter out the white precipitate of 4-(dimethylamino)pyridine hydrochloride using a glass-fiber filter pad. Collect the supernatant.
7. For either activation chemistry, precipitate the succinimidyl carbonate (SC)–PEG formed by addition of diethyl ether until no further precipitation is observed (typically 3–4 volumes of solvent).
8. Redissolve the precipitated product in acetone and precipitate again using diethyl ether. Repeat at least once more to remove completely excess reactants.
9. Dry the SC–PEG and store at 4°C.

Protocol for the Coupling of SC–mPEG to Proteins

1. Dissolve the protein to be PEGylated in cold 0.1-*M* sodium phosphate, pH 7.5, at a concentration of 1–10 mg/ml.
2. With stirring, add a quantity of SC–mPEG to the protein solution at the molar ratio of polymer-to-protein desired. The ratio of activated polymer addition typically is expressed *versus* the molar quantity of primary amines present on the protein being modified. Ratios of SC–PEG to amines between

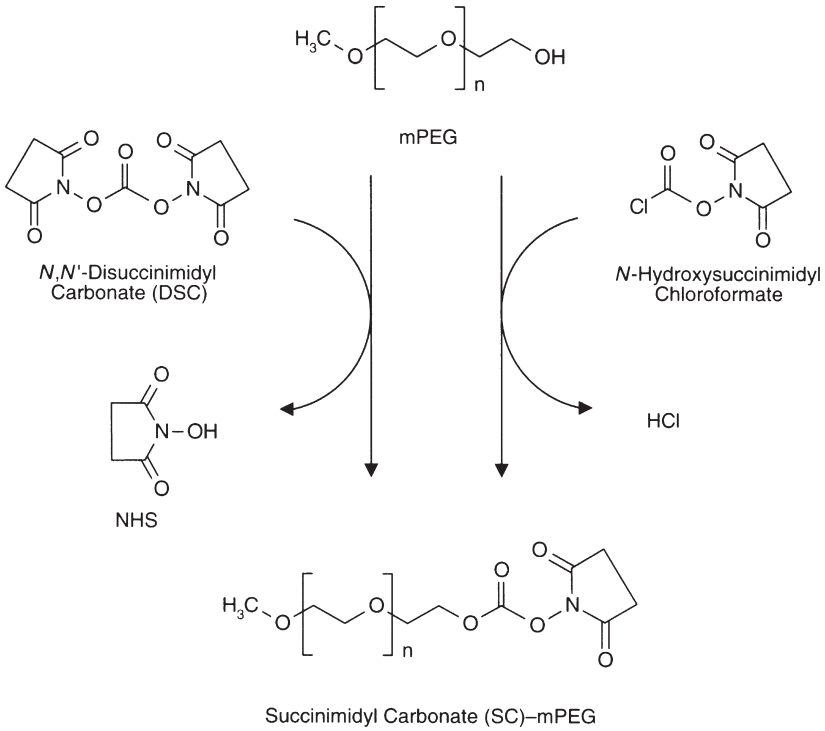

FIGURE 18.42 An alternative route to an succinimidyl carbonate derivative of mPEG can be accomplished by the reaction of the terminal hydroxyl group of the polymer with either *N,N′*-disuccinimidyl carbonate (DSC) or N-hydroxysuccinimidyl chloroformate.

0.3:1 and 8:1 were investigated by Miron and Wilchek (1993) for the derivatization of egg white lysozyme. The greater the ratio is of activated polymer to protein, the higher will be the molecular weight of the resultant complex. Experiments may have to be done using a number of different reaction ratios to determine the optimal PEGylation level for a particular protein.

3. React overnight at 4°C.
4. Remove excess SC–PEG by dialysis or gel filtration.

Carbodiimide Coupling of Carboxylate–PEG Derivatives

PEG contains only hydroxyl functional groups in its native state that need to be activated or modified in some manner to allow efficient conjugation to other molecules. These hydroxyls can be modified to possess carboxylates by reaction with anhydride compounds. Acylation of PEG with succinic anhydride or glutaric anhydride gives *bis*-modified products having carboxylates at both ends. Modification of mPEG yields the monosubstituted derivative containing a single carboxylate. Creation of these derivatives was first described by Abuchowski *et al.* (1984). Once the carboxylate–PEG modification is formed, it can be used to couple directly with amine-containing molecules by use of the carbodiimide reaction (Chapter 4, Section 1).

A carbodiimide may be used to activate the carboxylates to highly reactive *o*-acylisourea intermediates. When generated in the presence of an amine-containing protein or other molecule, these active esters will react with the nucleophiles to give amide bond derivatives (Figure 18.43). Atassi and Manshouri (1991) used this technique to PEGylate various peptides. In this instance, the reaction was carried out in dimethylformamide (DMF) due to the solubility of the peptides in this solvent. The organic-soluble carbodiimides dicyclohexyl carbodiimide (DCC) (Chapter 4, Section 1.4) or diisopropyl carbodiimide (DIC) (Chapter 4, Section 1.5) were used to perform the conjugation. However, aqueous-phase reactions can be performed using this approach just as easily as organic-based conjugations if the water soluble reagent EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide) is employed (Chapter 4, Section 1.1). The general protocols for using carbodiimides outlined in the referenced sections may be used to conjugate a carboxylate-containing PEG derivative to an amine-containing protein or other molecule. The formation of a carboxylate-containing PEG derivative can be done according to the following protocol (adapted from Atassi and Manshouri, 1991).

Protocol

1. Dissolve 1 g of mPEG (MW 5,000) in 5 ml of anhydrous pyridine by heating to 50°C.
2. To the stirring mPEG solution, add several 0.5-g aliquots of solid succinic anhydride over a period of several hours.

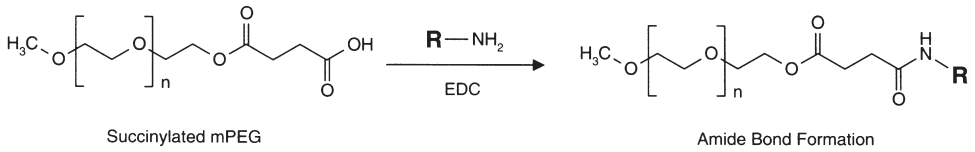

FIGURE 18.43 A succinylated mPEG derivative may be coupled to amine-containing molecules using a carbodiimide reaction to form an amide bond.

3. React for a further 2 h at 50°C.
4. Evaporate the pyridine solvent by using a flash evaporator or a rotary evaporator under vacuum.
5. Redissolve the residue in water (the solution may have to be heated to fully dissolve) and again evaporate to dryness. Repeat until the odor of pyridine is nearly gone.
6. Remove remaining reactants by dialysis against water using a membrane having a molecular weight cut-off of 1000.

CDI Activation and Coupling

N,N′-Carbonyldiimidazole (CDI) is a highly reactive carbonylating compound which was first shown to be an excellent amide bond forming agent in peptide synthesis (Paul and Anderson, 1962). Later it was used to activate both carboxylic groups and hydroxyls in the immobilization of amine-containing ligands to prepare affinity chromatography supports (Bartling *et al.*, 1973; Hearn, 1987) (see Chapter 15, Section 2.1).

The activation of a carboxylate group with CDI proceeds to give an intermediate acyl derivative with imidazole as the active leaving group. In the presence of a primary amine-containing compound, the nucleophile attacks the electron-deficient carbonyl, displacing the imidazole and forming a stable amide bond.

For hydroxyl-containing compounds, CDI will react to form an intermediate imidazolyl carbamate which in turn can react with *N*-nucleophiles to give an *N*-alkyl carbamate linkage. Proteins normally couple through their N-terminals (α-amine) and lysine side chain (ε-amine) functional groups. The final bond is an uncharged, urethane derivative having excellent chemical stability (Figure 18.44). The result of CDI activation of PEG and subsequent coupling to a protein or other amine-containing molecule is a linkage identical to that obtained using succinimidyl carbonate chemistry, described previously (Section 1.2).

CDI-activated PEG is stable for years in a dried state or in organic solvents devoid of water or other nucleophiles. The activated polymer will also have an excellent half-life to hydrolysis even in the coupling environment. Unlike some activation chemistries which degrade rapidly and have half-lives on the order of minutes, imidazole carbamates have half-lives measured in hours. For instance, an agarose chromatography support activated with CDI will take up to 30 h at pH 8.5 to 9.0 for complete loss of activity. The hydrolysis of CDI–PEG derivatives causes the release of CO_2 and imidazole. The hydrolyzed product thus reverts back to the original hydroxylic PEG compound, leaving no residual groups to cause potential sites for nonspecific interactions.

The optimal coupling condition for a CDI–PEG or CDI–mPEG reaction is in an alkaline pH environment, typically above pH 8.5. The coupling reaction proceeds at greatest efficiency when the target molecule is reacted at about 1 pH value above its pI or pK_a. The reaction can be performed directly in an organic solvent environment if the molecule to be modified demonstrates poor solubility in aqueous systems. The advantage of an organic coupling reaction is that there is no competing hydrolysis of the active groups, so very high modification yields of PEG can be realized.

There are a few precautions that should be noted when performing a CDI activation and coupling experiment. First, CDI itself is extremely unstable to aqueous environments, much more so than the active imidazolyl carbamate that is formed after PEG activation. Therefore, the activation step must be carried out in a solvent that is as free of water as possible. If unacceptable amounts of water are present, CDI will be immediately broken down to CO_2 and imidazole. The evolution of bubbles upon addition of CDI to a PEG solution is the tell-tale sign of high water content. Only freshly obtained solvents analyzed to be extremely low in moisture or those dried over a molecular sieve should be used. A water content of less than 0.1% in the solvent is usually acceptable for a CDI activation procedure.

A second precaution is to carry out the activation step in a fume hood away from sources of ignition. Most CDI activation protocols use flammable or toxic solvents and care should be taken in handling and disposing of them.

The coupling reaction using CDI–mPEG or CDI–PEG derivatives is slower than that obtained using NHS ester or succinimidyl carbonate coupling methods. Therefore, the reaction times used with CDI chemistry are typically on the order of 1 to 2 days at 4°C at a pH of about 8.5. Increasing the pH of the reaction to pH 9 or pH 10 will speed up the coupling. In addition, performing the reaction at room temperature also helps in

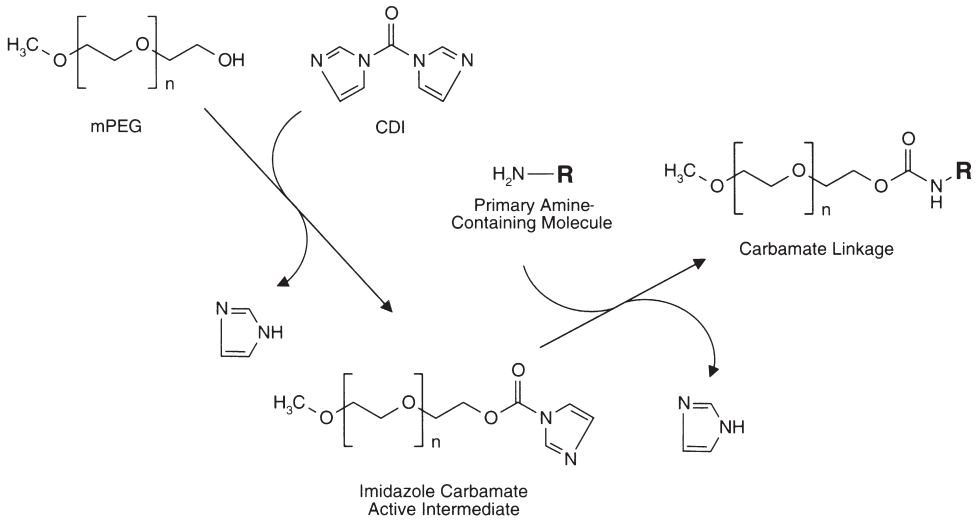

FIGURE 18.44 *N,N′*-Carbonyl diimidazole (CDI) may be used to activate the terminal hydroxyl of mPEG to an imidazole carbamate. Reaction of this intermediate reactive group with an amine-containing compound results in the formation of a stable carbamate linkage.

this regard. If the molecule to be modified is stable at alkaline pH values and room temperature, then these conditions may be used to decrease the time of the suggested protocol.

The following method is adapted from Beauchamp *et al.* (1983).

Protocol for the Activation of mPEG with CDI

1. Dissolve mPEG (MW 5000) in dry dioxane at a concentration of 50-m*M* (0.25 g/ml) by heating to 37°C.
2. Add solid CDI to a final concentration of 0.5-*M* (81 mg/ml).
3. React for 2 h at 37°C with stirring.
4. To remove excess CDI and reaction byproducts, Beauchamp *et al.* (1983) dialyzed against water at 4°C. However, the imidazole carbamate groups on mPEG formed during the activation process are subject to hydrolysis in aqueous environments. A better method may be to precipitate the activated mPEG with diethyl ether as in the protocol described previously for succinimidyl carbonate activation (Section 1.2).
5. Finally, dry the isolated product by lyophilization (if the water dialysis method is used) or by use of a rotary evaporator (if the ether precipitation method is used).

Protocol for the Coupling of CDI–mPEG to Proteins

1. Dissolve the protein to be PEGylated in 10-m*M* sodium borate, pH 8.5, at a concentration of 1–10 mg/ml. Higher pH values may be used to increase the reaction rate—for instance, 0.1-*M* sodium carbonate, pH 9 to 10.
2. Add CDI–mPEG to this solution with stirring to bring the final concentration of the activated polymer to 180-m*M*. Note: Other ratios of polymer-to-protein may be used, depending on the modification level desired. Some optimization of the derivatization level may have to be carried out to obtain conjugates having the best amount of polymer substitution with retention of protein activity.
3. React for 48 h at 4°C. If higher pH or room temperature conditions are used, the reaction time can be decreased to 24 h.
4. Remove unconjugated mPEG and reaction byproducts by dialysis or gel filtration.

Miscellaneous Coupling Reactions

PEG or mPEG may be conjugated to proteins or other molecules using other coupling chemistries in addition to the ones mentioned in the previous sections. Almost any activation method that can be built off of the terminal hydroxyl(s) of PEG may be employed to PEGylate target molecules. For instance, Bergström *et al.* (1992) created an epoxy derivative of the polymer by reaction with epichlorohydrin under alkaline conditions. The reactive alkyl halogen end of epichlorohydrin first is coupled to the hydroxyls of PEG to give the terminal glycidyl ether derivative (Figure 18.45). The epoxy-functionalized polymer then could be used to covalently modify a poly(ethylene imine)-coated polystyrene surface to prevent nonspecific protein adsorption. This type of derivative could also be used to modify other amine-, hydroxyl-, or sulfhydryl-containing molecules (Chapter 3, Section 4.1).

Creation of a sulfhydryl-reactive PEG derivative was carried out by Goodson and Katre (1990) by reacting an

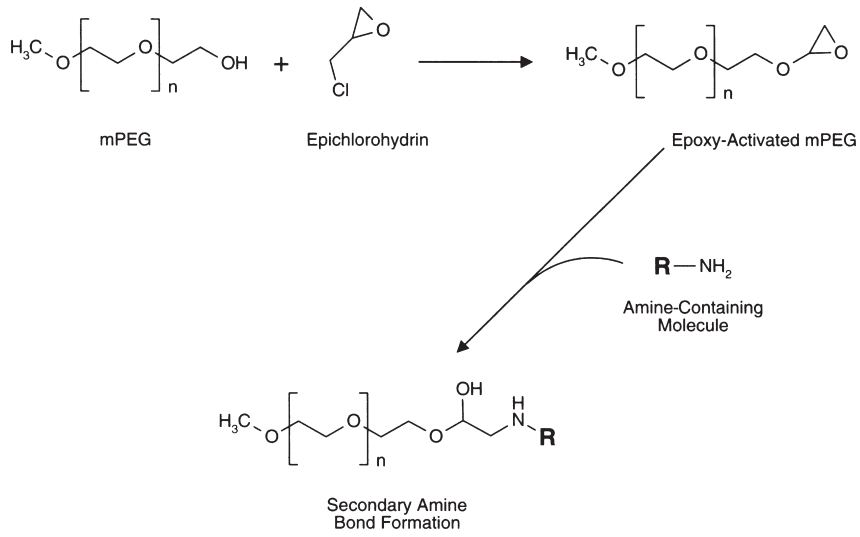

FIGURE 18.45 Epichlorohydrin can be used to activate the hydroxyl group of mPEG, creating an epoxy derivative. Reaction with amine-containing molecules yields secondary amine bonds.

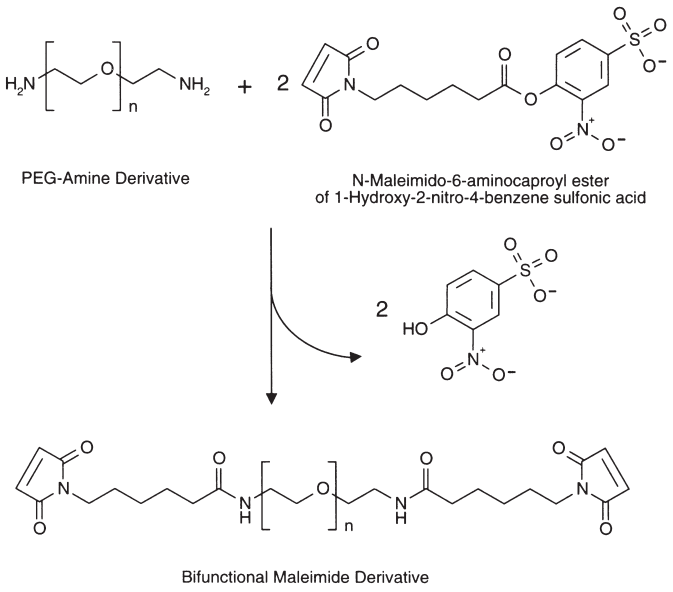

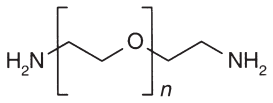

FIGURE 18.46 A PEG-diamine compound may be reacted with this heterobifunctional crosslinker to form amide bond derivatives terminating in maleimide groups. This results in a homobifunctional reagent capable of crosslinking thiol molecules. Subsequent reaction with sulfhydryl-containing molecules yields thioether linkages. Other amine- and thiol-reactive heterobifunctional crosslinkers may also be used in this manner to create bifunctional PEG derivatives.

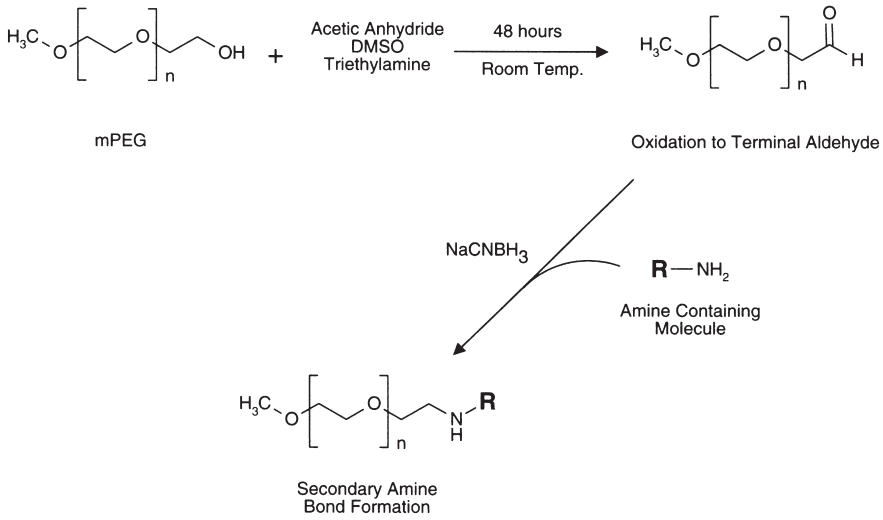
active ester–maleimide heterobifunctional crosslinker with the amino groups of a PEG-amine polymer (Pillai and Mutter, 1980). Amine-terminal derivatives of discrete PEG-type polymers are available from Thermo Fisher or Quanta BioDesign (Chapter 15, Section 2.8). Reaction with the *N*-maleimido-6-aminocaproyl ester of 1-hydroxy-2-nitro-4-benzene sulfonic acid results in an amide bond derivative (Figure 18.46). This creates terminal maleimide groups on each PEG-amine molecule. Maleimide compounds can be used in a site-directed coupling procedure to specifically PEGylate at the sulfhydryl groups of proteins and other molecules (Chapter 3, Section 2.2).

In another approach, Wirth *et al.* (1991) and Chamow *et al.* (1994) transformed the terminal hydroxyl group of mPEG into an aldehyde residue by the Moffatt oxidation procedure (Harris *et al.*, 1984). In this reaction, the hydroxyl is treated with acetic anhydride in dimethyl sulfoxide (DMSO) containing triethylamine, converting it to the aldehyde (Figure 18.47). After stirring at room temperature for 48 h, the aldehyde derivative is isolated by precipitation with ether and ethyl acetate. An aldehyde can be conjugated to proteins or other amine-containing molecules by reductive amination using sodium cyanoborohydride (Chapter 4, Section 4). The advantage of an aldehyde-PEG derivative over the other amine-reactive methods described previously is that the active group will not hydrolyze or readily degrade before the coupling reaction is initiated. In addition, reductive amination is a reasonably mild conjugation technique well tolerated by most proteins.



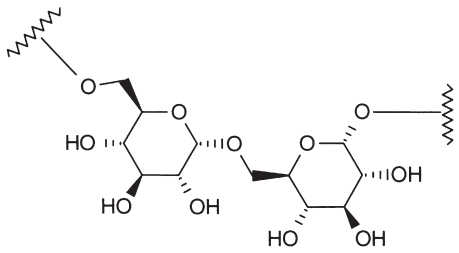


FIGURE 18.47 A terminal aldehyde function on mPEG may be formed through an oxidative process at elevated temperatures. This derivative may be used to modify amine-containing molecules by reductive amination.

2.2. Dextran and Carbohydrate Polymers

Dextran is a naturally occurring polymer that is synthesized in yeasts and bacteria for energy storage. It is mainly a linear polysaccharide consisting of repeating units of D-glucose linked together in glycosidic bonds (Chapter 2, Section 2.1), wherein the carbon-1 of one monomer is attached to the hydroxyl group at the carbon-6 of the next residue. This configuration is the same as that found in the α-1,6 linked disaccharide isomaltose. The same disaccharide is found at the branch points of glycogen and amylopectin. Occasional branch points may also be present in a dextran polymer, occurring as α-1,2, α-1,3, or α-1,4 glycosidic linkages. The branch type and degree of branching vary by species.

Isomaltose (a-1,6) Repeating Unit of Dextran Polymer Chains

The hydroxylic content of the dextran sugar backbone makes the polymer very hydrophilic and easily modified for coupling to other molecules. Unlike PEG, discussed previously, which has modifiable groups only at the ends of each linear polymer, the hydroxyl functional groups of dextran are present on each monomer in the chain. The monomers contain at least three hydroxyls (four on the terminal units) that may undergo derivatization reactions. This multivalent nature of dextran allows molecules to be attached at numerous sites along the polymer chain.

Soluble dextran of molecular weight 10,000 to 500,000 has been used extensively as a modifying or crosslinking agent for proteins and other molecules (Goodarzi *et al.*, 2012). It has been used as a drug carrier to transport greater concentrations of antineoplastic pharmaceuticals to tumor sites *in vivo* (Bernstein *et al.*, 1978; Heindel *et al.*, 1990; Vaidya *et al.*, 2011; Jain *et al.*, 2012), as conjugated to biotin to make a sensitive anterograde tracer for neuroatomic studies (Brandt and Apkarian, 1992), as a hapten carrier to illicit an immune response against coupled molecules (Dintzis *et al.*, 1989; Shih *et al.*, 1991), as an inducer of B cell proliferation by coupling anti-Ig antibodies (Brunswick *et al.*, 1988), as a multifunctional linker to crosslink monoclonal antibody conjugates with chemotherapeutic agents (Heindel *et al.*, 1991), and as a stabilizer of enzymes and other proteins (Zlateva *et al.*, 1988; Nakamura *et al.*, 1990). As is true of PEG conjugates with proteins, dextran modification of macromolecules provides increased circulatory half-life *in vivo*, decreased immunogenicity, and a heat and protease protective effect when coupled at sufficient density (Mumtaz and Bachhawat, 1991).

The following sections describe the major activation and coupling methods used with dextran polymers. The reactive derivatives may be used to couple with proteins and other molecules containing the appropriate functional groups.

Polyaldehyde-Dextran; Activation and Coupling

The dextran polymer contains adjacent hydroxyl groups on each glucose monomer. These diols may be

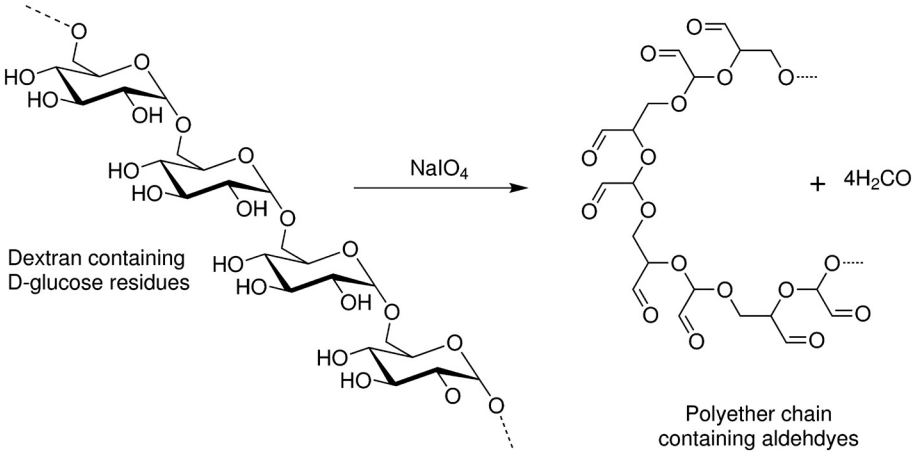

FIGURE 18.48 Dextran polymers can be oxidized with sodium periodate to create a polyaldehyde derivative. Note that additional oxidation may occur to cleave off another carbon atom (the C-3) and create an aldehyde on the adjacent C-4–OH group.

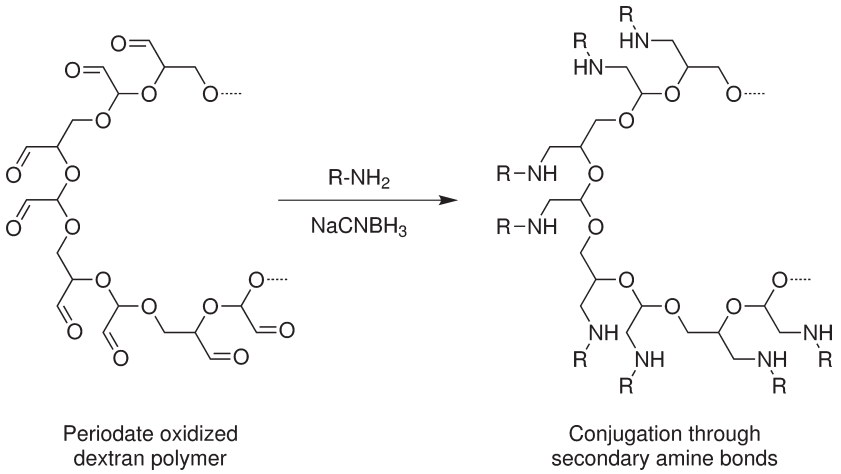

FIGURE 18.49 Polyaldehyde dextran may be used as a multifunctional crosslinking agent for the coupling of amine-containing molecules. Reductive amination creates secondary amine or tertiary amine linkages.

oxidized with sodium periodate to cleave the associated carbon–carbon bonds and produce aldehydes (Chapter 2, Section 4.4). This procedure results in two aldehyde groups formed per glucose monomer, thus producing a highly reactive, multifunctional polymer able to couple with numerous amine-containing molecules (Bernstein *et al.*, 1978) (Figure 18.48). Polyaldehyde dextran may be conjugated with amine groups by Schiff base formation followed by reductive amination to create stable secondary (or tertiary amine) linkages (Chapter 3, Section 5.4) (Figure 18.49).

Proteins may be modified with oxidized dextran polymers under mild conditions using sodium cyanoborohydride as the reducing agent. The reaction proceeds primarily through ε-amino groups of lysine located at the surface of the protein molecules. The optimal pH for the reductive amination reaction is an alkaline environment between pH 7 and 10. The rate of reaction is greatest at pH 8 to 9 (Kobayashi and Ichishima, 1991), reflecting the efficiency of Schiff base formation at this pH.

Polyaldehyde dextran can be used to couple many small molecules, such as drugs, to a targeting molecule like an antibody. The multivalent nature of the oxidized dextran backbone provides more sites for conjugation than possible using direct coupling of the drug with the antibody itself. Similarly, detection molecules such as fluorescent probes can be conjugated in greater amounts using a dextran carrier than is feasible with direct modification of a protein.

The following protocol for creating the polyaldehyde dextran derivative is based on the method of Berstein *et al.* (1978).

Protocol for Oxidizing Dextran with Sodium Periodate

1. Dissolve sodium periodate ($NaIO_4$) (Sigma) in 500 ml of deionized water at a concentration of 0.03-*M* (6.42 g). Protect from light.
2. Dissolve dextran (Polysciences) of molecular weight between 10,000 and 40,000 in the sodium periodate solution with stirring.

3. React overnight at room temperature in the dark.
4. Remove excess reactant by extensive dialysis against water. The purified polyaldehyde dextran may be lyophilized for long-term storage.

The degree of oxidation may be assessed by measurement of the aldehydes formed. Zhao and Heindel (1991) suggest derivatizing the polyaldehyde dextran with hydroxylamine hydrochloride and measuring the amount of HCl released by titration. However, this may be tedious and time consuming. A simpler method may be to take advantage of the fact that periodate-oxidized sugars are capable of reducing Cu^{2+} to Cu^{1+}, which can be detected using the bicinchoninic acid (BCA) reagent (Thermo Fisher) (Smith *et al.*, 1985). The formation of Cu^{1+} is in direct proportion to the amount of aldehydes present in the polymer. BCA will form a purple-colored complex with Cu^{1+} which can be measured at 562 nm.

Protocol for Coupling Polyaldehyde Dextran to Proteins

1. Dissolve or buffer-exchange the periodate-oxidized dextran in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 10 to 25 mg/ml. Other buffers having a pH range of 7 to 10 may be used with success, as long as they do not contain competing amines (such as Tris). A reaction environment of pH 8–9 (0.1-*M* sodium bicarbonate) will give the greatest yield of reductive amination coupling.
2. Add 10 mg of the protein to be coupled to the dextran solution. Other ratios of dextran-to-protein may be used as appropriate. For instance, if more than one protein or a protein plus a smaller molecule are both to be conjugated to the dextran backbone, the amount of protein added initially may have to be scaled back to allow the second molecule to be coupled latter. Many times, a small molecule such as a drug will be coupled to the dextran polymer first, and then a targeting protein such as an antibody conjugated secondarily. The optimal ratio of components forming the dextran conjugate should be determined experimentally to obtain the best combination possible.
3. In a fume hood, add 0.2 ml of 1-*M* sodium cyanoborohydride (Aldrich) to each milliliter of the protein/dextran solution. Mix well. *Caution: cyanoborohydride is extremely toxic and should be handled only in well-ventilated fume hoods. Dispose of cyanide-containing solutions according to approved guidelines.*
4. React for at least 6 h at room temperature. Overnight reactions may also be done.
5. To block excess aldehydes, add 0.2 ml of 1-*M* Tris or 1-*M* ethanolamine, pH 8, to each milliliter of the reaction. Note: If a second molecule is to be coupled after the initial protein conjugation, don't block the remaining aldehydes until the second molecule is coupled.
6. React for an additional 2 h at room temperature.
7. Purify the protein–dextran conjugate from unconjugated protein and dextran by gel filtration using a column of Sephacryl S-200 or S-300. Small molecules may be removed from a dextran conjugate by dialysis.

Carboxyl, Amine, and Hydrazide Derivatives

Dextran derivatives containing carboxyl- or amine-terminal spacer arms may be prepared by a number of techniques. These derivatives are useful for coupling amine- or carboxylate-containing molecules through a carbodiimide-mediated reaction to form an amide bond (Chapter 4, Section 1). Amine-terminal spacers can also be used to create secondary reactive groups by modification with a heterobifunctional crosslinking agent (Chapter 6).

This type of modification process has been used to form sulfhydryl-reactive dextran polymers by coupling amine spacers with crosslinkers containing an amine-reactive end and a thiol-reactive end (Brunswick *et al.*, 1988; Noguchi *et al.*, 1992). The result was a multivalent sulfhydryl-reactive dextran derivative that could couple numerous sulfhydryl-containing molecules per polymer chain.

Several chemical approaches may be used to form the amine- or carboxyl-terminal dextran derivative. The simplest procedure may be to prepare polyaldehyde dextran according to the procedure of Section 2.1 and then make the spacer arm derivative by reductively aminating an amine-containing organic compound onto it. For instance, short diamine compounds such as ethylene diamine or diaminodipropylamine (3,3′-iminobispropylamine) can be reacted in large excess with polyaldehyde dextran to create numerous modifications along the polymer having terminal primary amines. Carboxyl-terminal derivatives may be prepared similarly by coupling molecules such as 6-aminocaproic acid or β-alanine to polyaldehyde dextran. Alternatively, an amine-terminal spacer may be reacted with succinic anhydride to form the carboxylate derivative (Chapter 2, Section 4.2).

Another approach uses reactive alkyl halogen compounds containing a terminal carboxylate group on the other end to form spacer arms off the dextran polymer from each available hydroxyl. In this manner, Brunswick *et al.* (1988) used chloroacetic acid to modify the hydroxyl groups to form the carboxymethyl derivative. The carboxylates then were aminated with ethylenediamine to create an amine-terminal derivative (Inman, 1985). Finally, the amines were modified with iodoacetate to form a sulfhydryl-reactive polymer (Figure 18.50).

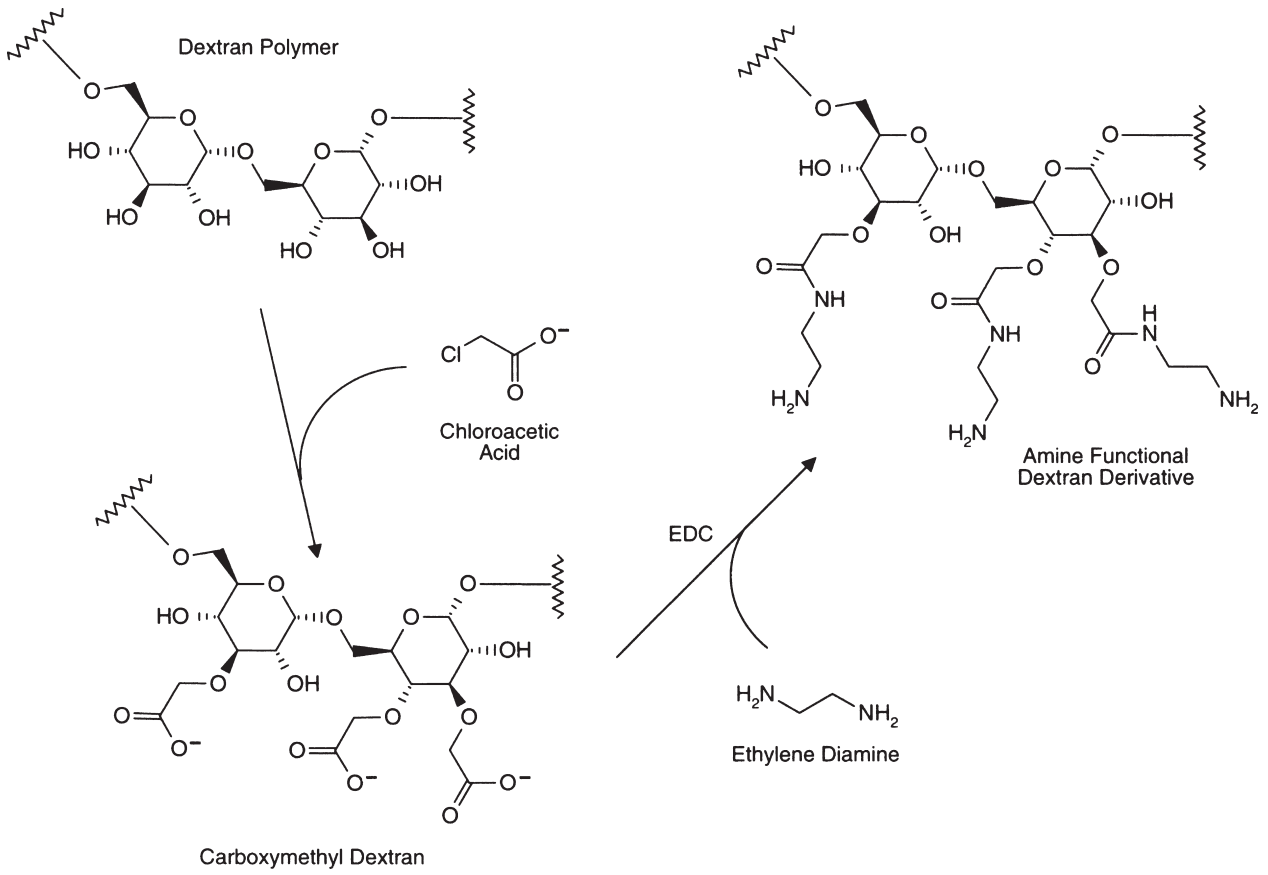

FIGURE 18.50 An amine derivative of dextran may be prepared through a two-step process involving the reaction of chloroacetic acid with the hydroxyl groups of the polymer to create carboxylates. Next, ethylene diamine is coupled in excess using a carbodiimide-mediated reaction to give the primary amine functional groups.

In a somewhat similar scheme, Noguchi *et al.* (1992) prepared a carboxylate spacer arm by reacting 6-bromohexanoic acid with a dextran polymer. The carboxylate then was aminated with ethylene diamine to form an amine-terminal spacer (Figure 18.51). This dextran derivative was finally reacted with *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) (Chapter 6, Section 1.1) to create the desired sulfhydryl-reactive polymer (Section 2.4, this chapter). The SPDP-activated polymer could then be used to prepare an immunoconjugate composed of an antibody against human colon cancer conjugated with the drug mitomycin-C.

Hydrazide derivatives may also be prepared from a periodate-oxidized dextran polymer or from a carboxyl-containing dextran derivative by reaction with *bis*-hydrazide compounds (Chapter 5, Section 8). A hydrazide terminal spacer provides reactivity toward aldehyde- or ketone-containing molecules. Thus, the hydrazide–dextran polymer can be used to conjugate specifically glycoproteins or other polysaccharide-containing molecules after they have been oxidized with periodate to form aldehydes (Chapter 2, Section 4.4).

The following protocols may be used to create carboxyl-, amine-, or hydrazide-containing derivatives of dextran.

Protocol for Preparation of Amine or Hydrazide Derivatives by Reductive Amination

1. Prepare polyaldehyde dextran according to the method of Section 2.1.
2. To make an amine derivative of dextran, dissolve ethylenediamine (or another suitable diamine) in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 3 M. Note: Use of the hydrochloride form of ethylenediamine is more convenient, since it avoids having to adjust the pH of the highly alkaline free-base form of the molecule. Alternatively, to prepare a hydrazide-dextran derivative, dissolve adipic acid dihydrazide (Chapter 5, Section 8.1) in the coupling buffer at a concentration of 30 mg/ml (heating under a hot water tap may be necessary to completely dissolve the hydrazide compound). Adjust the pH to 7.2 with HCl and cool to room temperature.
3. Dissolve polyaldehyde dextran in the ethylenediamine (or adipic dihydrazide) solution at a concentration of 25 mg/ml.

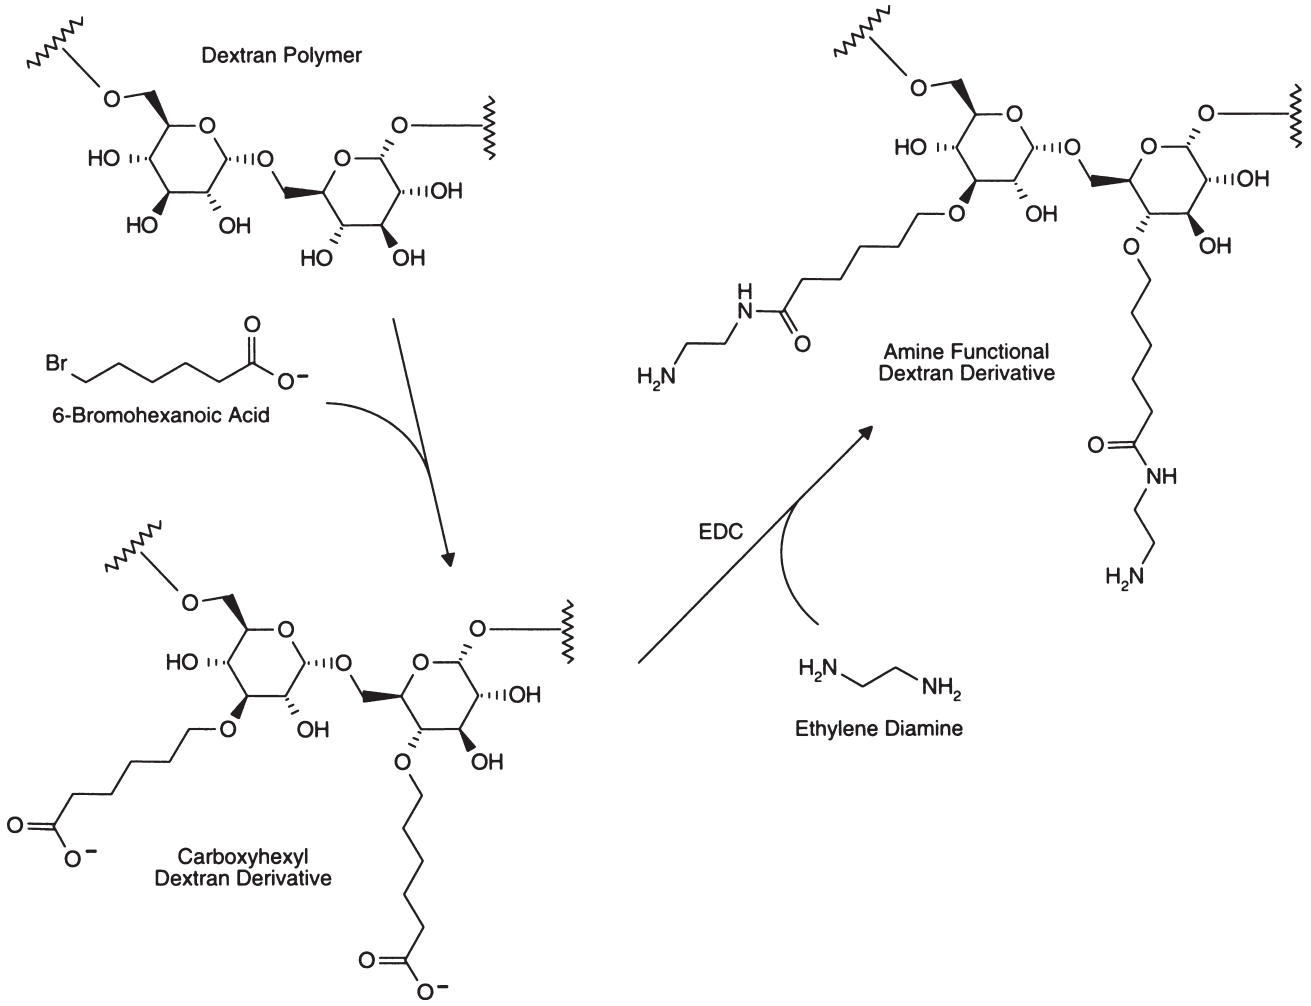

FIGURE 18.51 Amino-dextran derivatives may be prepared by the reaction of 6-bromohexanoic acid with the hydroxyl groups of the polymer followed by coupling of ethylene diamine using EDC.

4. In a fume hood, add 0.2 ml of 1-*M* sodium cyanoborohydride to each ml of the diamine/dextran solution. Mix well. *Caution: Cyanoborohydride is extremely toxic and should be handled only in well-ventilated fume hoods. Dispose of cyanide-containing solutions according to approved guidelines.*
5. React for at least 6 h at room temperature. Overnight reactions may also be done.
6. Remove excess diamine and reaction byproducts by dialysis.

The ethylenediamine–dextran derivative may be used for the coupling of carboxylate-containing molecules by the carbodiimide reaction, for the coupling of amine-reactive probes, or to modify further using heterobifunctional crosslinkers. The hydrazide–dextran derivative may be used to crosslink aldehyde-containing molecules, such as oxidized carbohydrates or glycoproteins.

Protocol for the Modification of Dextran with Chloroacetic Acid

1. In a fume hood, prepare a solution consisting of 1-*M* chloroacetic acid in 3-*N* NaOH.
2. Immediately add dextran polymer to a final concentration of 40 mg/ml. Mix well to dissolve.
3. React for 70 min at room temperature with stirring.
4. Stop the reaction by adding 4 mg/ml of solid NaH_2PO_4 and adjusting the pH to neutral with 6-*N* HCl.
5. Remove excess reactants by dialysis.

The carboxymethyl–dextran derivative may be used to couple amine-containing molecules by the carbodiimide reaction. Heindel *et al.* (1994) prepared the lactone derivative of carboxymethyl–dextran by refluxing for 5 h in toluene or other anhydrous solvents. The lactone derivative is highly reactive toward amine-containing molecules, thus creating a preactivated polymer for conjugation purposes.

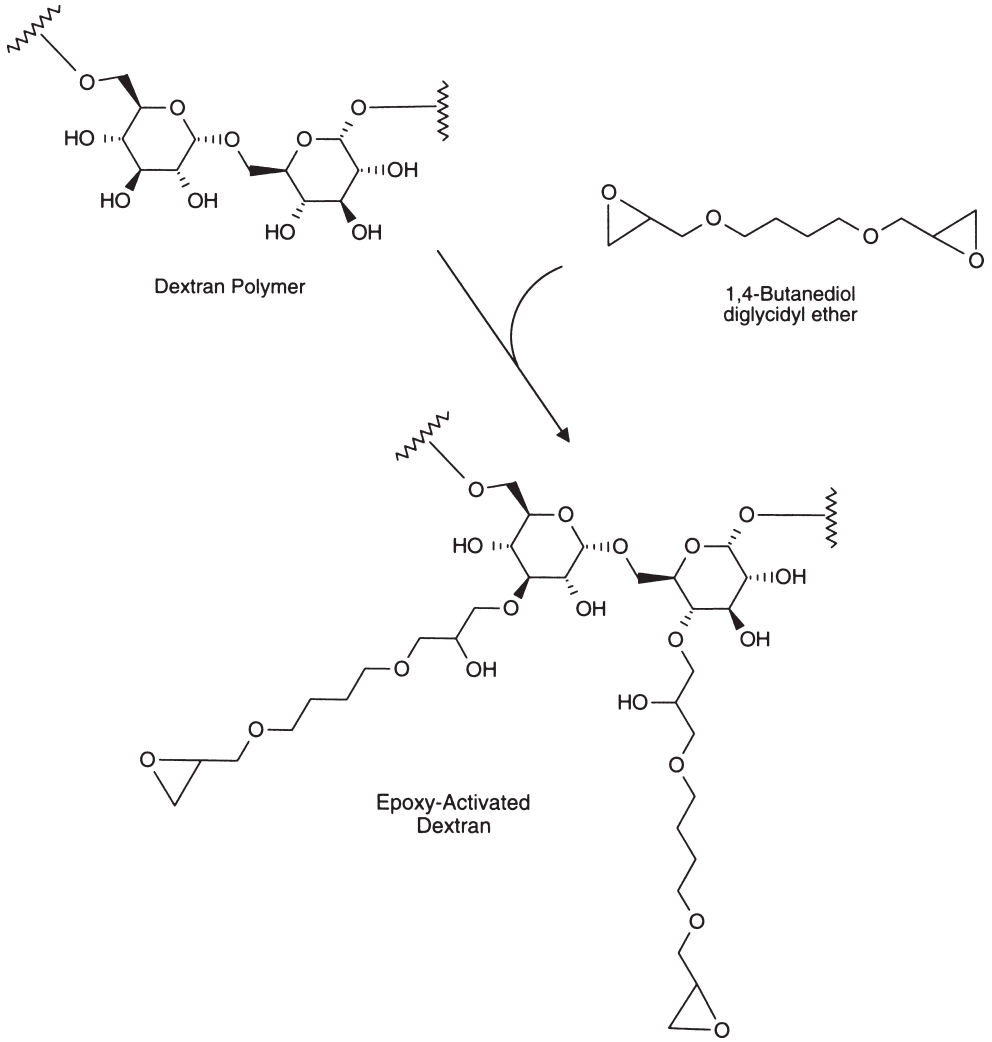

FIGURE 18.52 An epoxy-functional dextran derivative may be prepared by the reaction of 1,4-butanediol diglycidyl ether with the hydroxyl groups of the polymer.

Epoxy Activation and Coupling

Epoxy activation of hydroxylic polymers is commonly used as a means to immobilize molecules on solid-phase chromatographic supports that contain hydroxyl groups (Sundberg and Porath, 1974). *bis*-oxirane compounds can also be used to introduce epoxide groups into soluble dextran polymers in much the same manner (Bölkicke *et al.*, 1988; Böcher *et al.*, 1992). The epoxide group reacts with nucleophiles in a ring-opening process to form a stable covalent linkage. The reaction can take place with primary amines, sulfhydryls, or hydroxyl groups to create secondary amine, thioether, or ether bonds, respectively (Chapter 3, Section 1.8).

Modification of dextran polymers with 1,4-butanediol diglycidyl ether results in ether derivatives of the dextran hydroxyl groups, which then contain hydrophilic spacers with terminal epoxy functions (Figure 18.52).

Protocol

1. In a fume hood, mix 1 part 1,4-butanediol diglycidyl ether with 1 part 0.6-*N* NaOH containing 2 mg/ml sodium borohydride.
2. With stirring, add 5 mg of dextran to each milliliter of the *bis*-epoxide solution. Mix well to dissolve.
3. React for 12 h at 25°C or 3 to 4 h at 37°C.
4. Extensively dialyze the solution against water to remove excess reactants. The activated dextran may be lyophilized for long-term storage.

The epoxide-activated dextran may be used to conjugate amine-, sulfhydryl-, or hydroxyl-containing molecules. The reaction of the epoxide groups with hydroxyls requires high pH conditions, usually in the range of pH 11 to 12. Amine nucleophiles react at more moderate alkaline pH values, typically needing buffer environments of at least pH 9 to 10. Sulfhydryl groups

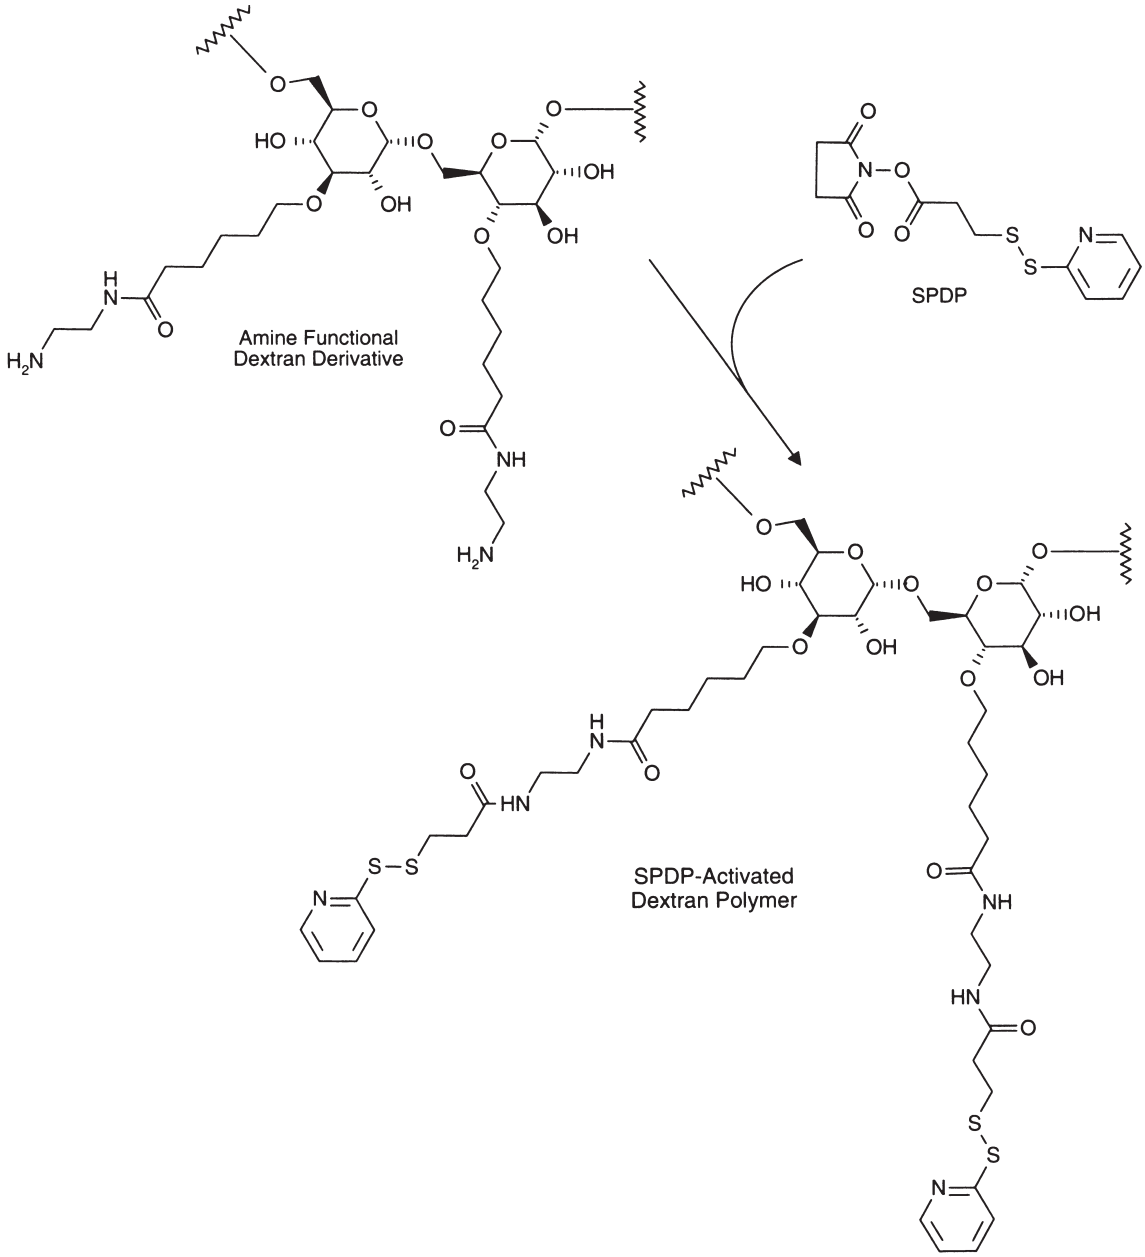

FIGURE 18.53 An amine-functionalized dextran derivative may be further reacted with SPDP to create a sulfhydryl-reactive product.

are the most highly reactive nucleophiles with epoxides, requiring a buffered system closer to the physiological range, pH 7.5 to 8.5, for efficient coupling.

Sulfhydryl-Reactive Derivatives

Sulfhydryl-reactive dextran derivatives may be prepared through the use of heterobifunctional crosslinking agents (Chapter 6). In particular, crosslinkers containing pyridyl disulfide, maleimide, or iodoacetyl groups on one end are quite effective in directing a conjugation reaction to thiols. Both maleimide and iodoacetyl activation procedures will yield nonreversible bonds with sulfhydryl-containing molecules. Pyridyl disulfide compounds, by contrast, react with thiols to form cleavable disulfide bonds that can be reversed by reduction.

Noguchi *et al.* (1992) used an amine-terminal spacer arm derivative of dextran to react with SPDP (Chapter 6, Section 1.1) in the creation of a pyridyl disulfide-activated polymer (Figure 18.53). Coupling of thiol-containing molecules to this activated dextran will result in the formation of disulfide linkages, which can be cleaved by the addition of 50-m*M* DTT. Brunswick *et al.* (1988) used a different amine-terminal spacer arm derivative of dextran and subsequently coupled iodoacetate

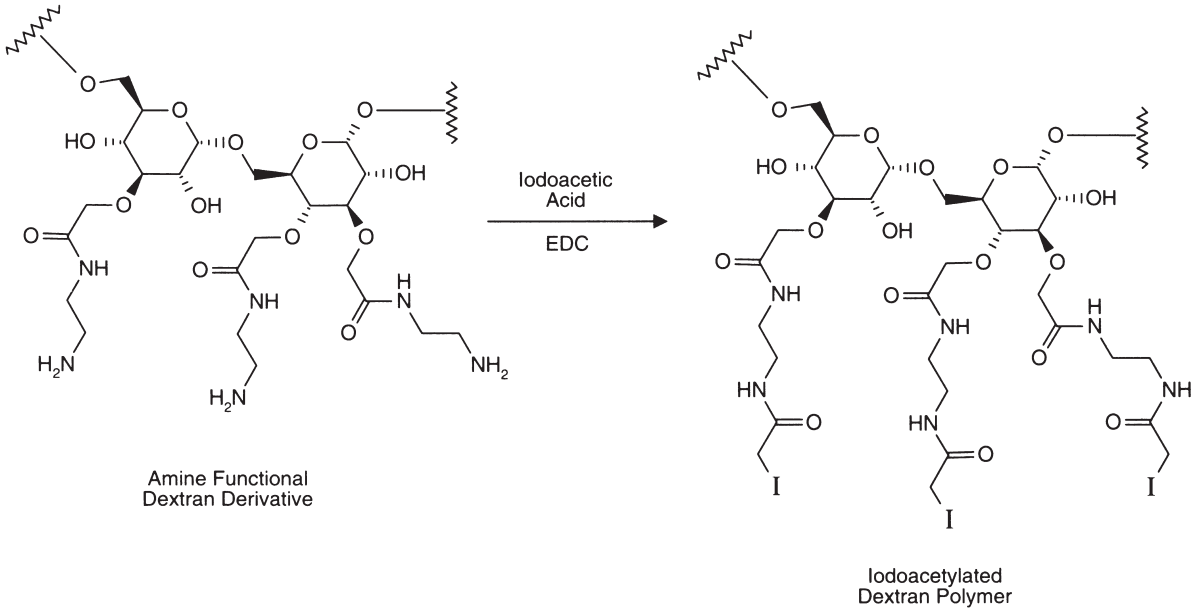

FIGURE 18.54 An amine-derivative of dextran may be coupled with iodoacetic acid using a carbodiimide reaction to produce a sulfhydryl-reactive iodoacetamide polymer.

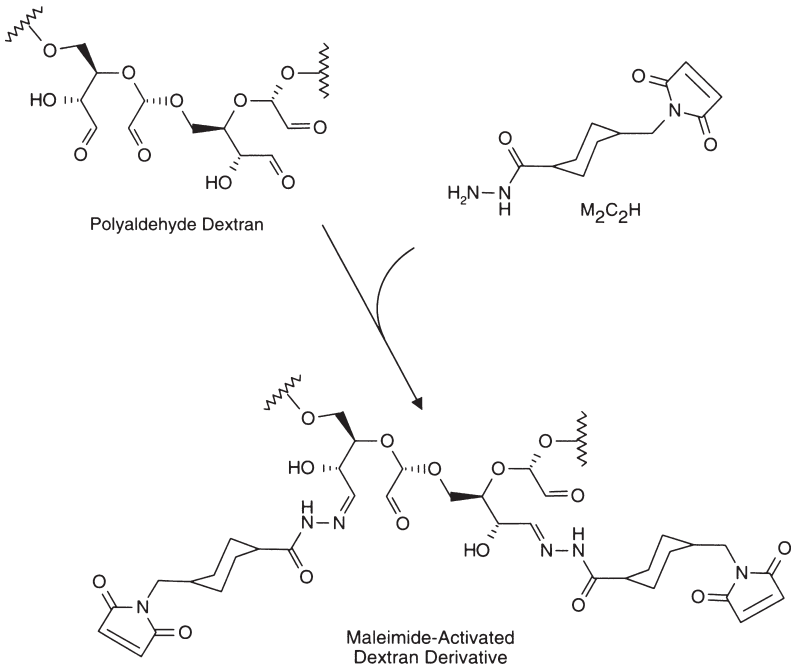

FIGURE 18.55 Polyaldehyde dextran may be modified with the hydrazide end of M_2C_2H to create a thiol-reactive polymer.

to form a sulfhydryl-reactive polymer (Figure 18.54). Conjugation to this activated polymer with thiol-containing molecules results in stable thioether linkages, which cannot be cleaved by reduction. Heindel *et al.* (1991) used a third approach to form a thiol-reactive polymer. They modified polyaldehyde dextran with a heterobifunctional crosslinker containing a hydrazide group on one end and a maleimide group on the other (Chapter 6, Section 2). The hydrazides reacted with the aldehyde groups to form hydrazone linkages, leaving the maleimide ends free to result in a thiol-reactive dextran derivative (Figure 18.55). Coupling thiol-containing molecules to this derivative will result in the formation of thioether bonds.

CHAPTER

19

Vaccines and Immunogen Conjugates

This chapter involves the design, preparation, and use of conjugate vaccines or hapten–carrier conjugates used to elicit an immune response toward a coupled hapten. The chemical reactions discussed for these conjugations are useful for coupling peptides, proteins, carbohydrates, oligonucleotides, and other small organic molecules to various carrier macromolecules. The resultant conjugates are important in antibody production, immune response research, and in the creation of vaccines.

1. THE BASIS OF IMMUNITY

The essence of adaptive immunity is the ability of an organism to react to the presence of foreign substances and produce components (antibodies and cells) capable of specifically interacting with and protecting the host from their invasion. An "antigen" or "immunogen" is the name given to a substance that is able to elicit this type of immune response and is also capable of interacting with the sensitized cells and antibodies that are manufactured against it (Abbas *et al.*, 2011; Murphy *et al.*, 2011).

The immune system has two basic components which respond to the challenge of a foreign substance: a cellular response mediated by T lymphocytes and a humoral response mediated by secreted proteins called antibodies produced by B lymphocytes, also called plasma cells. The B lymphocytes recognize antigens through cell-surface immunoglobulins that bind to discrete chemical and structural epitopes on the antigen molecule. Each B cell possesses surface immunoglobulin of a single type (i.e., is monoclonal) and has a binding capability that is directed against a discrete epitopic target.

Antigen binding by a complementary immunoglobulin molecule on the surface of B cells starts a process of cellular internalization of the foreign substance by pinocytosis. Once internalized by endosomes, systematic processing of the antigen takes place which breaks it down into smaller components.

At this point, the endosome may fuse with vesicles containing newly synthesized or recycling major histocompatibility complex (MHC) antigens. Some of the partially degraded antigenic fragments may form a complex with the MHC and be transported back to the cell surface. There they are "presented" to the circulating T helper (T_h) cells which contain receptors able to bind specifically to particular structural and chemical characteristics of the degraded antigen–MHC complex. If a T_h cell recognizes and binds to the presented antigen on the surface of the antigen-presenting cells (APCs), the T_h cell proliferates and begins to produce various lymphokines. Finally, the recognition and binding of the presented antigen by the T_h cells, coupled with the release of lymphokines, stimulates the associated B cells to proliferate and produce antibodies which recognizes the intact antigen (Germain, 1986; Pier *et al.*, 2004).

Antigens are usually macromolecules or macromolecular complexes that contain distinct antigenic sites or "epitopes," which can be recognized and interact with the various components of the immune system. They can exist as individual molecules composed of synthetic organic chemicals, proteins, lipoproteins, glycoproteins, RNA, DNA, and polysaccharides—or they may be parts of cellular structures (bacteria or fungi) or viruses (Male *et al.*, 1987; Harlow and Lane, 1988).

Small molecules like short peptides, although normally able to interact with the products of an immune response, often cannot cause a response on their own. These "haptens," as they are called, are actually incomplete antigens, and while not able by themselves to cause immunogenicity or to elicit antibody production, they can be made immunogenic by coupling them to a suitable carrier molecule (Figure 19.1). Carriers are typically antigens of higher molecular weight that are able to cause an immunological response when administered *in vivo*.

Antibodies are typically able to recognize peptide sequences as small as five to six amino acids in length. For instance, IgE auto-antibodies were found to have clinical significance in multiple sclerosis by binding

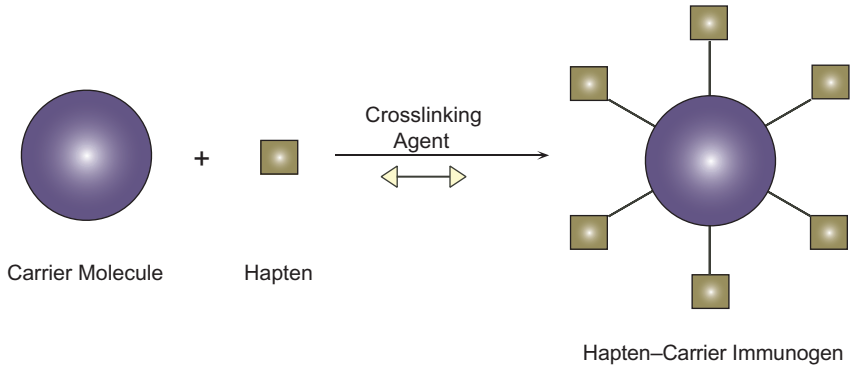

FIGURE 19.1 Immunogens are made by the conjugation of a hapten molecule to a carrier using a conjugation reagent.

specifically to short 5- and 6-amino acid epitopes on the surface of myelin proteins (Mikol *et al.*, 2006).

In an immune response, antibodies are produced and secreted by the B lymphocytes in conjunction with the T_h cells. In the majority of hapten–carrier systems, the B cells end up producing antibodies that are specific for both the hapten and the carrier. In these cases, the T lymphocytes will have specific binding domains on the carrier, but will not recognize the hapten alone. In a kind of synergism, the B and T cells cooperate to induce a hapten specific antibody response. After such an immune response has taken place, if the host is subsequently challenged with only the hapten, usually it will respond by producing hapten-specific antibodies from memory cells formed after the initial immunization. For a review of immunobiology, see Janeway (2004).

Synthetic haptens mimicking some critical epitopic structures on larger macromolecules are often conjugated to carriers to create an immune response to the larger "parent" molecule. For instance, short peptide segments can be synthesized from the known sequence of a viral coat protein and coupled to a carrier to induce immunogenicity toward the native virus. This type of synthetic approach to immunogen production has become the basis of much of the current research into the creation of vaccines.

The complete picture of the immune system is much more complex than this brief discussion can justly describe. In many instances, merely creating a B cell response by using synthetic peptide–carrier conjugates, however well designed, will not always guarantee complete protective immunity toward an intact antigen. The immune response generated by a short peptide epitope from, say, a larger viral particle or bacterial cell may only be sufficient to generate memory at the B cell level. In these cases, it is generally now accepted that a cytotoxic T cell response is a more important indicator of protective immunity. Designing peptide immunogens with the proper epitopic binding sites for both B cell and T cell recognition is one of the most challenging research areas in immunology today.

Hapten–carrier conjugates are also being used to produce highly specific monoclonal antibodies that can recognize discrete chemical epitopes on the coupled hapten. The resulting monoclonals are often used to investigate the epitopic structure and interactions between native proteins. In many cases, the haptens used to generate these monoclonals are again small peptide segments representing crucial antigenic sites on the surface of larger proteins. Monoclonals developed from known peptide sequences will interact in highly defined ways with the protein from which the sequence originated. These antibodies can then be used, for example, as competitors to the natural interactions between a receptor and its ligand. Thus, using antibodies generated from hapten–carrier conjugates, information can be obtained as to the precise sites of binding between macromolecules.

The preparation of hapten–carrier conjugates using peptide sequences can be controlled to produce immunogens that generate high-affinity antibodies when administered *in vivo*. Pedersen *et al.* (2006) determined that antibody titers increased in response to increasing the peptide-to-carrier ratio of conjugation. However, just the opposite effect was found for generating high affinity antibodies. The lower the peptide-to-carrier conjugation ratio, the higher the relative affinity of the antibodies produced. In addition, it was also found that coupling peptides to the carrier through a central amino acid residue caused higher antibody titers than using a terminal amino acid residue for conjugation. For this reason, for the preparation of particular immunogen conjugates, several ratios and methods of conjugation may have to be investigated to result in the optimal level and affinity of antibodies produced.

Also see Chapter 1, Section 3.6, for a review on the use of immunogen conjugates or conjugate vaccines for therapeutic applications, including the production of vaccines against infectious diseases and cancer.

2. TYPES OF IMMUNOGEN CARRIERS

The most commonly used carriers are typically immunogenic, large molecules that are capable of imparting immunogenicity to covalently coupled haptens. Some of the more popular ones are proteins, but other carriers may be composed of lipid bilayers (liposomes), synthetic or natural polymers (dextran, agarose, poly-L-lysine), synthetically designed organic molecules (i.e., dendrimers, see Chapter 8), and even inorganic particles (e.g., gold, see Chapter 14, Section 6). The liposome, polymer, and synthetic carriers may not be as immunogenic as the protein carriers, and this feature may be important for developing an immune response toward certain antigens which are difficult to get the immune system to recognize. The criteria for selecting a successful carrier molecule are the potential for imparting immunogenicity towards an associated hapten, the presence of suitable functional groups for conjugation, reasonable solubility properties even after derivatization (although this is not an absolute requirement, since precipitated molecules can be highly immunogenic), and lack of toxicity *in vivo*. The design of the appropriate vaccine delivery carrier is vitally important to developing a successful vaccine (Correia-Pinto *et al.*, 2012).

Some synthetic carriers are actually designed to have low immunogenicity on their own to minimize the potential for antibody production against them. When a hapten is coupled to these molecules, the immune response is directed principally toward the modification, not at the carrier. This design approach guides most of the immune response toward the desired target and minimizes the production of carrier-specific antibodies.

2.1. Protein Carriers

The first carrier molecules used for immunogen conjugation were proteins. A foreign protein administered *in vivo* by any one of a number of potential routes nearly ensured the elicitation of an immune response. In addition, protein carriers could be chosen to be highly soluble and possessed of abundant functional groups that could facilitate easy conjugation with a hapten molecule. When proteins are used as carriers in immunogen complex, the conjugates can be injected in any animal except the animal of origin for the carrier protein itself. In other words, the use of bovine serum albumin (BSA) would not be suitable for administration into cows, since self proteins would not be expected to elicit good immune responses, even when attached with hapten molecules.

The most common carrier proteins in use today are keyhole limpet hemocyanin (KLH; MW 4.5×10^5 to 1.3×10^7), bovine serum albumin (BSA; MW 67,000), aminoethylated (or cationized) BSA (cBSA), thyroglobulin (MW 660,000), ovalbumin (OVA; MW 43,000), and various toxoid proteins, including tetanus toxoid and diphtheria toxoid. Other proteins occasionally used include myoglobin, rabbit serum albumin, immunoglobulin molecules (particularly IgG) from bovine or mouse sera, tuberculin purified protein derivative, and synthetic polypeptides such as poly-L-lysine and poly-L-glutamic acid.

KLH

Perhaps the most popular carrier protein is KLH, which has been used as part of immunogen conjugates for antibody production, infectious disease vaccines, and anti-cancer vaccines (Chen *et al.*, 2011; Aarntzen *et al.*, 2012). The hemocyanin from keyhole limpets (the mollusk *Megathura crenulata*) is the oxygen-carrying protein of these primitive sea creatures. KLH is an extremely large, multi-subunit protein that contains chelated copper of non-heme origin. In concentrated solutions above pH 7.0, it displays a characteristic opalescent blue color that betrays its near insolubility and copper prosthetic groups. In acidic solutions, the blue color changes to green. At physiological pH, the protein exists in various subunit aggregate states of large molecular weight. For instance, in Tris buffer at pH 7.4 it is known to associate in five different aggregate forms (Senozan *et al.*, 1981). In highly alkaline or acidic environments, KLH disassociates into subunits (Hersckovits, 1988). The protein exhibits increased immunogenicity when it is disassociated into subunits, probably due to exposure of additional epitopic sites to the immune system (Bartel and Campbell, 1959). The intact protein usually creates considerable light-scattering or iridescent effects due to its size and almost colloidal nature in aqueous solutions. Subunits of KLH that are highly soluble in aqueous solution are available commercially (Thermo Fisher, Biosyn). KLH is a frequent choice for developing immunogen conjugates, especially for the treatment of cancer (Curigliano *et al.*, 2006; Sabbatini and Odunsi, 2007). The carrier has been used to conjugate sialyl-Tn, a glycan found on tumor cell-associated mucins, to treat metastatic breast cancer (the Theratope vaccine) (Miles *et al.*, 2011), and although the clinical trials of this vaccine did not prove efficacious, KLH continues to be used as an important carrier for anticancer agents. It is even used in the unconjugated form as an adjuvant to stimulate the immune system to respond to cancer (Aarntzen *et al.*, 2012).

Since keyhole limpets are marine creatures existing in a high-salt environment, native KLH maintains its best stability and solubility in buffers containing at least 0.9-*M* NaCl (not 0.9%). As the concentration of NaCl is decreased below about 0.6-*M*, the protein begins to precipitate and denature. Conjugation reactions using

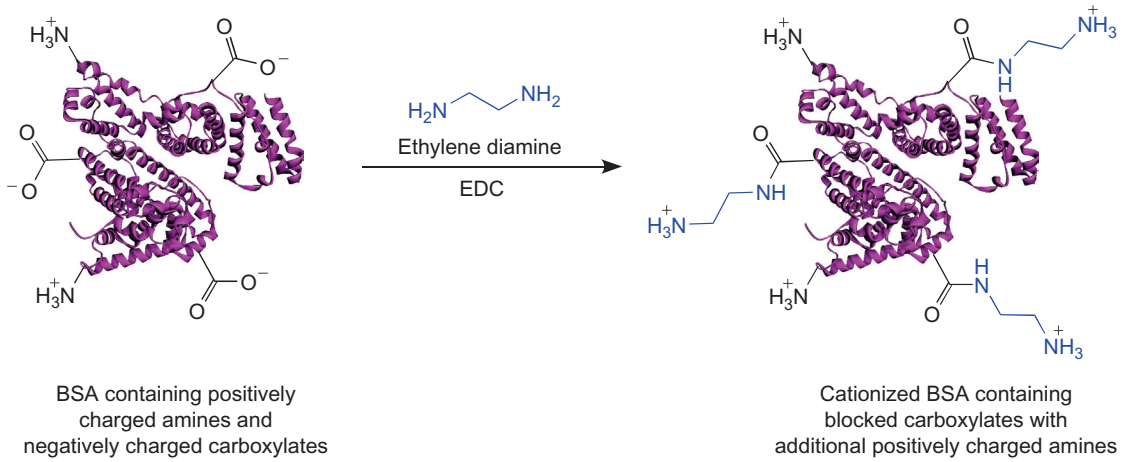

FIGURE 19.2 Cationized bovine serum albumin (cBSA) is formed by the reaction of ethylene diamine with native BSA using the water soluble carbodiimide EDC. Blocking of the carboxylate groups on the protein combined with the addition of terminal primary amines raises the pI of the molecule to highly basic values.

multi-subunit KLH, therefore, should be performed under high-salt conditions to preserve the solubility of the hapten–carrier complex. KLH used in the form of discrete subunits does not have this requirement of high salt to maintain solubility.

Native, multi-subunit KLH also should not be frozen. Freeze–thaw effects cause extensive denaturation and result in considerable amounts of insoluble material. Commercial preparations of native KLH are typically freeze-dried solids that no longer fully dissolve in aqueous buffers and do not display the protein's typical blue color due to loss of chelated copper. The partial denatured state of these products often makes conjugation reactions difficult.

KLH contains an abundance of functional groups available for conjugation with hapten molecules. On a per-mole basis (using an average multi-subunit MW of 5,000,000 Daltons), KLH has over 2000 amines from lysine residues, over 700 sulfhydryls from cysteine groups, and over 1900 tyrosine residues. Activation of the protein with succinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (SMCC) (Section 5, this chapter) typically results in 300 to 600 maleimide groups per molecule for coupling to sulfhydryl containing haptens.

The preparation of immunogen conjugates often requires the coupling of a sparingly soluble hapten to a carrier molecule. Pre-dissolving the hapten in an organic solvent and adding an aliquot of this solution to an aqueous reaction mixture is typically performed to maintain at least some solubility of the hapten in the conjugation solution. Dimethyl sulfoxide (DMSO) may be used for this purpose with KLH while maintaining very good solubility characteristics of the protein as well as the hapten. KLH is completely soluble in 50% (v/v) DMSO, becomes cloudy at a level of 60%, and definitely precipitates at 67%. Therefore, conjugation reactions may be performed by adding a volume of aqueous KLH to an equal volume of hapten dissolved in DMSO. Care should be taken, however, to avoid buffer salt precipitation upon addition of organic solvent.

BSA and cBSA

BSA (MW 67,000) and cationized BSA (cBSA) are highly soluble proteins containing numerous functional groups suitable for conjugation. Even after extensive modification with hapten molecules these carriers usually retain their solubility. The exception to this statement is when hydrophobic peptides or other sparingly soluble molecules are conjugated to the proteins. Modification of any carrier with numerous hydrophobic haptens may cause enough masking of the hydrophilic surface to result in precipitation. Depending on the degree of precipitation, such conjugates are often still useful in generating an immune response. To limit the production of insoluble complexes, however, the conjugation reaction can be scaled back to reduce the level of carrier modification and thus reduce or eliminate precipitation.

BSA possesses a total of 59 lysine ε-amine groups (with only 30–35 of these typically available for derivatization), one free cysteine sulfhydryl (with an additional 17 disulfides buried within its three-dimensional structure), 19 tyrosine phenolate residues, and 17 histidine imidazole groups. In addition, the presence of numerous carboxylate groups gives BSA its net negative charge (pI 5.1).

Cationized BSA is prepared by modification of its carboxylate groups with ethylenediamine (Chapter 2, Section 4.3) (Figure 19.2). Controlled aminoethylation using the water soluble carbodiimide EDC results in

blocking many of BSA's aspartic and glutamic acid side chains (and possibly the C-terminal carboxylate), forming an amide bond with a 2-carbon spacer containing a terminal primary amine group. Since the negative charge contributions of the native carboxylates are masked and positively charged amines are created in their place, the result of this process is a significant rise in the protein's pI. Cationization performed according to published procedures alters the net charge of BSA from a pI of about 5.1 (Cohn *et al.*, 1947) to over pI 11.0 (Muckerheide *et al.*, 1987).

The highly positive charge of cBSA dramatically increases its immunogenicity. The positive character of the molecule aids in its binding to antigen-presenting cells (APCs) *in vivo*, the first step in antibody production. The protein thus gets incorporated into the APCs faster than molecules having lower pI values. It also gets processed at an accelerated rate, producing a quicker immune response, and one that occurs with greater concentrations of specific antibody (Domen *et al.*, 1987; Muckerheide *et al.*, 1987b; Apple *et al.*, 1988; Domen and Hermanson, 1992; Chen *et al.*, 2002).

Cationized BSA used as a carrier protein also induces a similar increase in the production of antibodies against any attached hapten molecules. Even when haptens are coupled through cBSA's amine residues, the overall charge of the molecule remains basic enough to augment the immune response beyond that usually obtained using other carriers. This augmentation occurs even when the attached molecule is not merely a hapten, but a larger antigen macromolecule. Conjugation of a complete antigen (a molecule able to generate an immune response on its own) to cBSA causes an increased immune response against the antigen beyond that normally obtainable for the native antigen administered in unconjugated form (Domen and Hermanson, 1992). Bioconjugates of cBSA have been developed for polysaccharide-based glycoconjugate vaccines (Burtnick *et al.*, 2012), for vaccines strategies in overcoming atherosclerosis (de Jager and Kuiper, 2011), and to make cationic cBSA-nanoparticles for treatment of Parkinson's disease (Rodríguez *et al.*, 2011).

The effectiveness of cBSA as a carrier for peptides was investigated using arginine vasopressin (AV) as the hapten. Figure 19.3 shows the antibody concentration resulting after injection of the AV–cBSA conjugate intraperitoneally (i.p.) into BDF_1 female mice. As a control, native BSA was similarly conjugated with AV and administered in a second set of mice under identical conditions. The antibody concentrations in the sera were monitored periodically by enzyme-linked-immunosorbent assay (ELISA). The antibody response resulting from a set of mice injected with unconjugated peptide was subtracted in all cases. All injections were performed using 100 µg of conjugate mixed with an equal volume of alum (22.5 mg/ml aluminum hydroxide) as adjuvant.

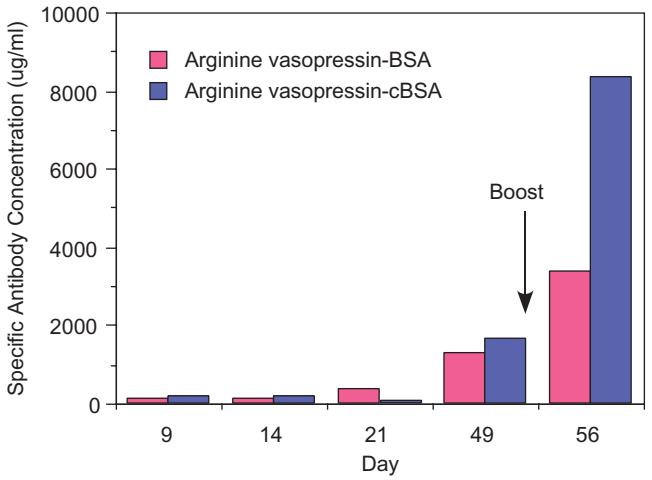

FIGURE 19.3 The effectiveness of a cationized carrier conjugate used as an immunogen can be seen by the comparison of specific antibody response in mice to arginine vasopressin (AV) coupled to both native BSA (nBSA) and cationized BSA (cBSA). The quantity injected was standardized according to the amount of arginine vasopressin (AV) present. The cationized carrier results in higher concentrations of antibody produced against the peptide than the immunogen made with native nBSA.

After the boost, the group of mice receiving the AV–cBSA conjugate generated over twice the antibody response as the group receiving the peptide conjugated to native BSA.

In a similar study, OVA conjugated to cBSA was compared to the same protein conjugated to native BSA (nBSA) and also OVA administered in an unconjugated form in mice. Figure 19.4 shows that before and after the boost, the OVA–cBSA conjugate resulted in much higher antibody concentrations than either the OVA–nBSA conjugate or OVA injected in an unconjugated form. Similar results were obtained for a conjugate of human IgG with cBSA (Figure 19.5).

A corollary to the use of cBSA as a carrier protein is that its increased immune response often abrogates the use of complete Freund's adjuvant, which is a source of concern because of its potential side-effects in animals. A relatively innocuous mixture with alum is usually all that is required as adjuvant to result in good antibody production.

As mentioned previously for KLH, DMSO may be used to solubilize hapten molecules that are rather insoluble in aqueous environments. Conjugation reactions may be performed in solvent/aqueous phase mixtures to maintain some solubility of the hapten once it is added to a buffered solution. BSA remains soluble in the presence of up to 35% DMSO, becomes slightly cloudy at 40%, and precipitates at 45% (v/v).

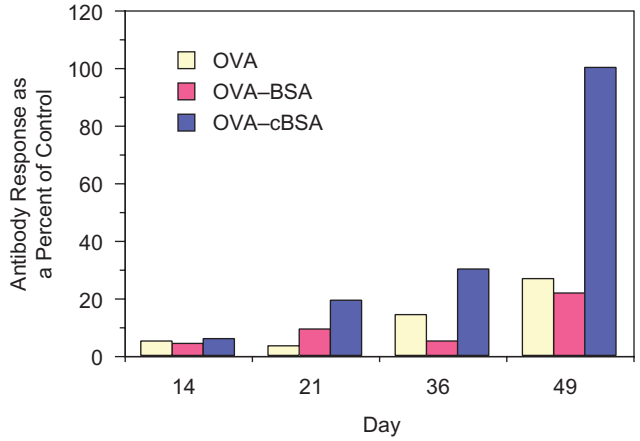

FIGURE 19.4 Cationized cBSA can even increase the specific antibody response to large proteins coupled to it. This graph shows a comparison of the relative antibody response in mice to injections of ovalbumin (OVA), either in an unconjugated form or conjugated to nBSA (native) or cationized (cBSA). The quantity injected was standardized according to the amount of ovalbumin OVA present. The highly basic cBSA molecule modulates the immune response to enhance the production of antibodies toward even full sized proteins conjugated with it.

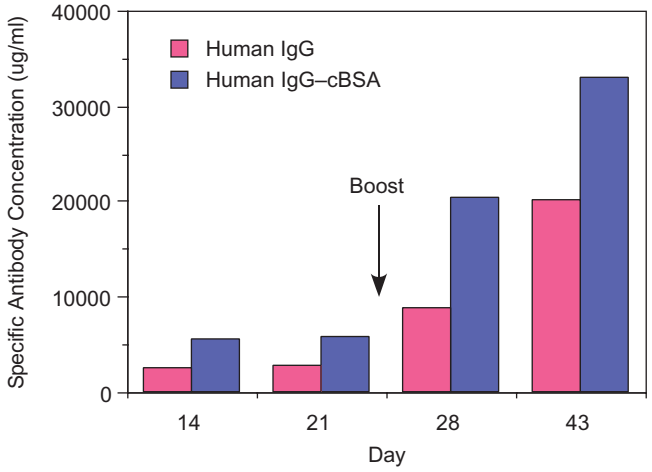

FIGURE 19.5 Human IgG was injected in mice in either an unconjugated form or crosslinked with cBSA. The quantity injected was standardized according to the amount of IgG present. A greater antibody response was obtained using the cBSA conjugate.

Thyroglobulin and OVA

Thyroglobulin and ovalbumin (OVA) are used less often as carriers, but they are particularly valuable as non-relevant carriers in ELISA tests designed to measure the antibody response after injection of an immunogen conjugate. Since an antibody response would be directed both against the carrier and the attached hapten, an ELISA performed to quantify specific antibody that only interacts with the hapten must not utilize the same carrier in the conjugate coated on the microplates. If the identical carrier conjugate is used for the ELISA as was used in the original immunization, the test results will be skewed by the contribution of carrier-specific antibodies. For this reason, a non-relevant carrier—one that is not recognized by the products of the immune response—must be coupled with hapten and used for the ELISA test.

Since OVA and BSA possess some immunologically similar epitopes, a population of the antibodies produced against one of them will often cross-react against the other. Therefore, OVA cannot function as a non-relevant carrier for BSA and *vice versa*. Either OVA or BSA, however, may be used as non-relevant carriers for KLH, thyroglobulin, or the various toxoid proteins used as immunogen conjugates.

OVA comprises about 75% of the total protein in hen egg whites. It is a phosphoprotein containing one *N*-glycosylation site and 386 amino acids. The protein contains 20 lysine residues, 14 aspartic acids, and 33 glutamic acid groups. This gives a total of 20 ε-amines, one N-terminal amine, 47 side-chain carboxylates, and one C-terminal carboxylate for conjugation reactions. The majority of acidic groups give the protein a pI of 4.63. Additional sites of modification include 4 sulfhydryl groups, 10 tyrosines, and 7 histidine residues. OVA is sensitive to temperature (above 56°C), electric fields, and vigorous mixing. Care should be taken in handling the protein to prevent denaturation and subsequent precipitation.

One advantage of OVA is its extreme solubility characteristics in the presence of DMSO. A sparingly soluble hapten molecule may be dissolved in this solvent and added to an aqueous OVA reaction mixture to maintain solubility of the molecule during conjugation. OVA is soluble at up to 70% DMSO, becomes cloudy at 75%, and precipitates at 80% (v/v).

Thyroglobulin is a prohormone protein which is synthesized and stored in the thyroid gland. Specific proteolytic action on the protein *in vivo* causes the release of triiodothyronine and thyroxine, low-molecular-weight amino acid derivatives that affect metabolic rate and oxygen consumption. Thyroglobulin is a large, multi-subunit protein composed of several polypeptide chains (MW 670,000). Its acidic pI (4.7) reflects the abundance of carboxylate groups. Thyroglobulin is also glycosylated, containing about 8 to 10% carbohydrate. Its use as an immunogen carrier protein is less frequent than that of KLH or BSA.

Tetanus and Diphtheria Toxoids

Toxoid proteins are biologically inactivated forms of native toxins. The most often used toxoid is tetanus toxoid, but diphtheria-derived toxoids and other proteins are also used occasionally (Anderson *et al.*, 1989). These carrier proteins have been used frequently for

pertussis and influenza vaccines (Halperin *et al.*, 2011; McCormick, 2012). Tetanus toxoid (MW 150,000) has 106 amine groups, 10 sulfhydryls, 81 tyrosine residues, and 14 histidines that may participate in conjugation reactions with hapten molecules (Bizzini *et al.*, 1970). Diphtheria toxoid is derived from a protein secreted by certain strains of *Corynebacterium diphtheriae*. Its molecular weight is approximately 63,000 Daltons (Collier and Kandel, 1971). Both protein toxoids can be used to couple haptens through any of the chemical reactions described in this section. They generate strong immunological responses *in vivo*.

2.2. Liposome Carriers

Liposomes are artificial structures composed of phospholipid bilayers exhibiting amphiphilic properties (Chapter 21). In complex liposome morphologies, concentric spheres or sheets of lipid bilayers are usually separated by aqueous regions that are sequestered or compartmentalized from the surrounding solution. The phospholipid constituents of liposomes consist of hydrophobic lipid tails connected to a head constructed of various glycerylphosphate derivatives. The hydrophobic interaction between the fatty acid tails is the primary driving force for creating liposomal bilayers in aqueous solutions.

The morphology of a liposome may be classified according to the compartmentalization of aqueous regions between bilayer sheets. If the aqueous regions are sequestered by only one bilayer each, the liposomes are called unilamellar vesicles (ULV). If there is more than one bilayer surrounding each aqueous compartment, the liposomes are termed multilamellar vesicles (MLV). ULV forms are further classified as to their relative size, although rather crudely. Thus, there can be small unilamellar vesicles (SUV; usually less than 100 nm in diameter) and large unilamellar vesicles (LUV; usually greater than 100 nm in diameter). With regard to MLV, however, the bilayer structures cannot easily be classified due to the almost infinite number of ways each bilayer sheet can be associated and interconnected with the next one. MLVs typically form large complex honeycomb structures that are difficult to classify or reproduce.

The overall composition of a liposome—its morphology, composition (including a variety of potential phospholipids and the degree of its cholesterol content), charge, and any attached functional groups—can affect the antigenicity of the vesicle *in vivo* (Allison and Gregoriadis, 1974; Alving, 1987; Therien and Shahum, 1989). When liposomes are used as carriers for immunization purposes, the haptens or antigens are usually attached covalently to the head groups using various phospholipid derivatives and crosslinking strategies (Derksen and Scherphof, 1985). Most often, these derivatization reactions are performed off of phosphatidylethanolamine constituents within the liposomal mixture. The primary amine modification of the glycerylphosphate head group of phosphatidylethanolamine provides an ideal functional group for activation and subsequent coupling of hapten molecules (Shek and Heath, 1983). Stock preparations of activated liposomes may be prepared and lyophilized to be used as needed in coupling hapten molecules (Friede *et al.*, 1993). Conjugates of liposomes with peptides or other molecules have been used to target cells *in vivo* for disease therapy (Du *et al.*, 2007). Liposomes are becoming more popular as conjugate vaccines for the treatment of cancer (Butts *et al.*, 2011; Wu *et al.*, 2011). All of the amine-reactive conjugation methods discussed in this section may be used with phosphatidylethanolamine-containing liposomes; however, see Chapter 21 for a more complete discussion of the unique considerations associated with conjugation of molecules to liposomes.

2.3. Synthetic Carriers

Synthetic molecules may be used as immunogen carriers if they are designed with the appropriate functional groups to facilitate the coupling of hapten molecules. These carriers may consist of simple polymers such as poly-L-lysine, poly-L-glutamic acid, Ficoll, dextran, polyethylene glycol (PEG), dendrimers, or other synthetic organic constructs (Lee *et al.*, 1980; Fok *et al.*, 1982; Boyle *et al.*, 1983; Hopp, 1984; Wheat *et al.*, 1985). Coupling of hapten molecules to the principle functional groups of these polymers can produce immunogenic conjugates that may be injected in animals to generate a specific antibody response. The advantage of a synthetic vaccine carrier is the potential for having little to no immune response to the carrier itself. This may be important if the hapten is relatively low in immunogenicity, such as is often the case when using tumor-associated carbohydrate antigens. If the carrier is too immunogenic, it could overwhelm and prevent a response to the carbohydrate antigen (Huang *et al.*, 2012). Thus, synthetic carrier molecules are becoming more important for developing vaccines against cancer and infectious diseases when the antigen target is a glycan associated with tumor cells or a polysaccharide associated with pathogens.

Poly-L-lysine may be coupled to carboxylate-containing molecules using the carbodiimide conjugation procedure to yield amide linkages (Chapter 4, Section 1). Homobifunctional or heterobifunctional crosslinking agents may also be used with poly-L-lysine, such as in the use of sulfo-SMCC (Chapter 6, Section 1.3). The polymer can be used as well for coupling hapten molecules and subsequent coating of microplates for ELISA procedures (Gegg and Etzler, 1993). Conversely,

poly-L-glutamic acid may be coupled to amine-containing haptens by the same carbodiimide protocol. Ficoll and dextran carriers may be activated by mild sodium periodate oxidation to generate reactive aldehyde groups (Chapter 2, Section 4.4, and Chapter 2, Section 2.1). Coupling to amine-containing haptens may then be performed by reductive amination (Chapter 3, Section 5). Polyethylene glycol chemistry involves alternate activation and coupling schemes that are addressed in Chapter 18.

A unique synthetic molecule that can be used as a carrier is the so-called multiple antigenic peptide (MAP) (Posnett *et al.*, 1988; Tam, 1988; Kowalczyk *et al.*, 2011). The MAP core structure is composed of a scaffolding of sequential levels of poly-L-lysine. The dendritic molecule is constructed from a divalent lysine compound to which two additional levels of lysine are attached. The final MAP compound consists of a symmetrical, octavalent primary amine surface to which hapten molecules may be attached. Coupling of up to eight peptide haptens to the MAP core yields a highly immunogenic complex having a molecular weight typically greater than 10,000. The nature of the MAP carrier makes it ideal for remarkably defined conjugates useful in vaccine development (Jayaprakash Babu *et al.*, 2011; Shreewastav *et al.*, 2012).

One particularly novel carrier was reported to consist of 50- to 70-nm colloidal gold particles of the type often used in cytochemical labeling techniques for microscopy (Pow and Crook, 1993) (Chapter 14, Section 6). Adsorption of peptide antigens onto gold and subsequent injection of the complex into rabbits in an adjuvant mixture resulted in rapid production of antibodies of extremely high titer. The resultant antibodies could be used in immunocytochemistry at dilutions from 1-in-250,000 down to 1-in-1,000,000, which is orders of magnitude beyond the dilutions typically used with lower-titer antibodies.

Gold nanoparticle vaccines are becoming more popular in developing effective anticancer and infectious disease treatments (Wang *et al.*, 2011; Barhate *et al.*, 2012; Gregory *et al.*, 2012; Lee *et al.*, 2012).

3. CARBODIIMIDE-MEDIATED HAPTEN–CARRIER CONJUGATION

The coupling chemistry used to prepare an immunogen from a hapten and carrier protein is an important consideration for the successful production and correct specificity of the resultant antibodies. The choice of crosslinking methodology is governed by the functional groups present on the carrier and the hapten as well as the orientation of the hapten desired for appropriate presentation to the immune system. An associated concern is the potential for antibody recognition and cross-reactivity toward the crosslinking reagent used to effect the conjugation. If antibodies are generated against the crosslinker bridge connecting the carrier with the hapten, then this may dilute the desired antibody response against the hapten. The use of a zero-length crosslinking procedure mediated by the water soluble carbodiimide EDC eliminates this problem, since no bridging molecule is introduced between the hapten and carrier.

The reactions involved in an EDC-mediated conjugation are discussed in Chapter 4, Section 1.1. (Note: EDC is 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride, which has a molecular weight of 191.7 and is sometimes referred to as EDAC.) The carbodiimide first reacts with available carboxylic groups on either the carrier or hapten to form a highly reactive *O*-acylisourea intermediate. The activated carboxylic group can then react with a primary amine to form an amide bond, with release of the EDC mediator as a soluble isourea derivative. The reaction is quite efficient with no more than 2 h required for it to go to completion and form a conjugated immunogen.

Since most peptide haptens contain either amines or carboxylic groups available for coupling, EDC-mediated immunogen formation may be the simplest method for the majority of hapten–carrier protein conjugations. Figure 19.6 shows the coupling of a carrier protein to a short peptide molecule through its amine terminus. It should be kept in mind, however, that this type of conjugation may occur at either the C- or N-terminal of the peptide or at any carboxyl- or amine-containing side chains. Therefore, this method probably should be avoided if a particularly interesting part of the peptide contains groups which may be blocked or undergo coupling using the carbodiimide reaction. Also, when using peptides rich in Lys, Glu, or Asp, an unacceptable level of hapten crosslinking may occur upon conjugation and thus change the antigenic structure of the resulting immunogen. However, some crosslinking or polymerization of the peptide on the surface of the carrier actually may be beneficial to the immunogenicity of the peptide, and thus create an even greater antibody response. Some investigators even advocate using no carrier protein when a peptide hapten is involved; merely polymerizing the peptide in the presence of EDC may result in a complex of high enough molecular weight to be immunogenic by itself. In general, EDC coupling is a very efficient, one-step method for forming a wide variety of peptide-carrier protein immunogens.

Figure 19.7 shows the results of an EDC conjugation study comparing a reaction performed at pH 4.7 (A) to one performed at pH 7.3 (B and C), with and without added sulfo-NHS (see Chapter 4, Section 1.2).

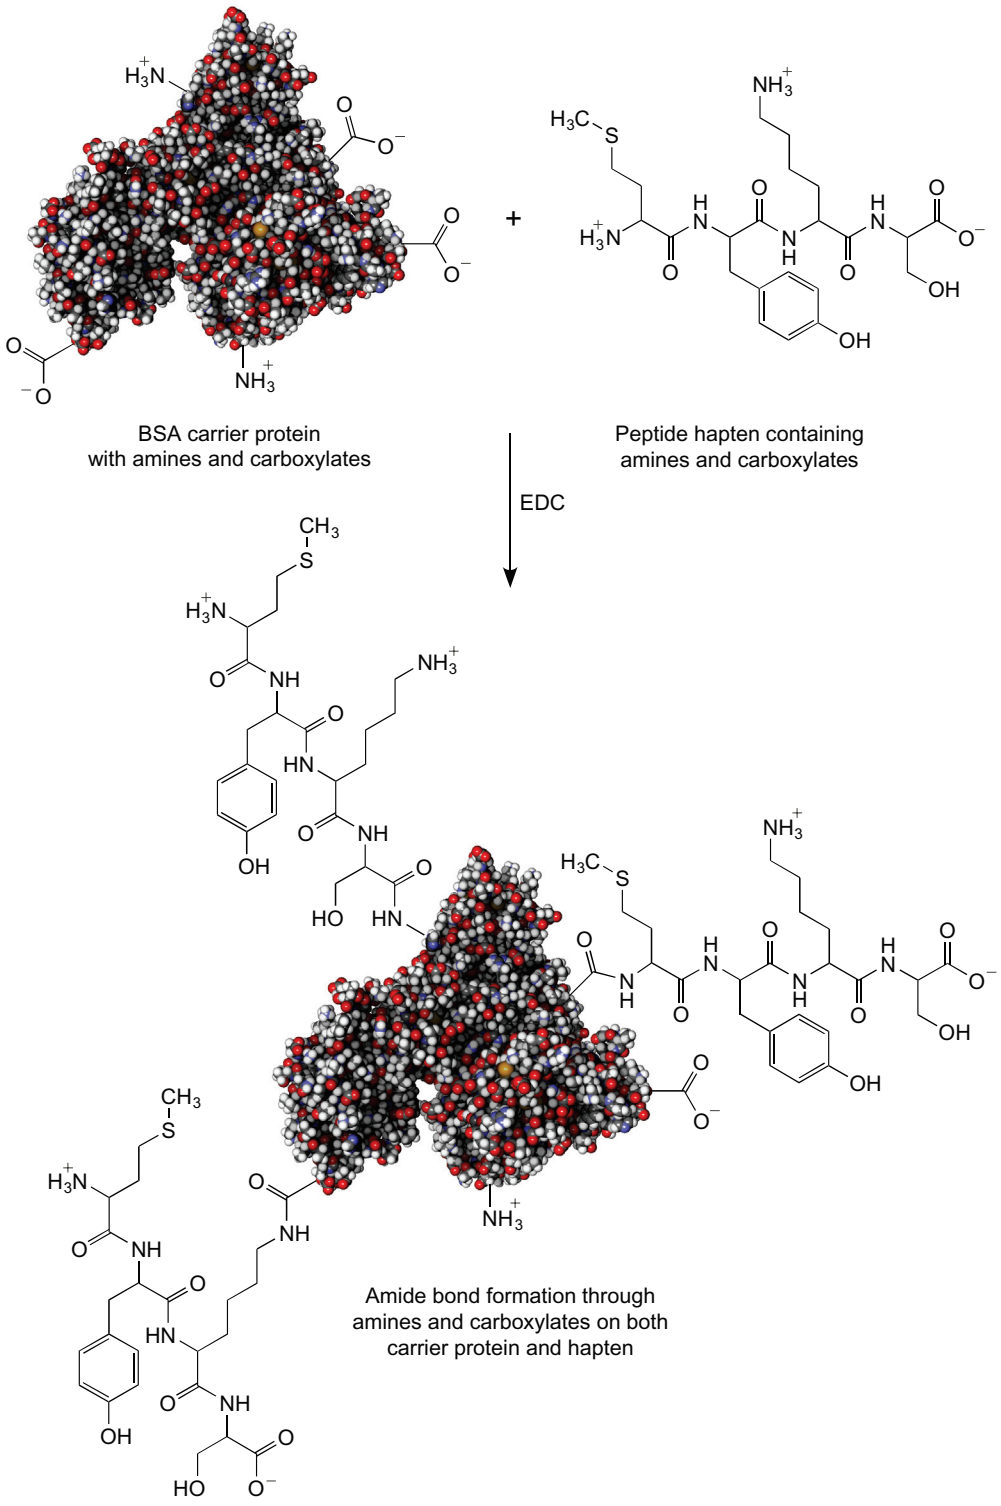

FIGURE 19.6 Peptide haptens are easily conjugated to carrier proteins using the water soluble carbodiimide EDC.

The graphs show the elution profiles of a gel filtration separation after conjugation. In each case, a blank run performed without the addition of EDC illustrates the separation of the protein carrier (the first peak) from the lower molecular weight peptide and reagent peak (the second peak). Decrease in the peptide peak is indicative of successful conjugation. Complete recovery of the total absorbance at 280 nm usually does not occur,

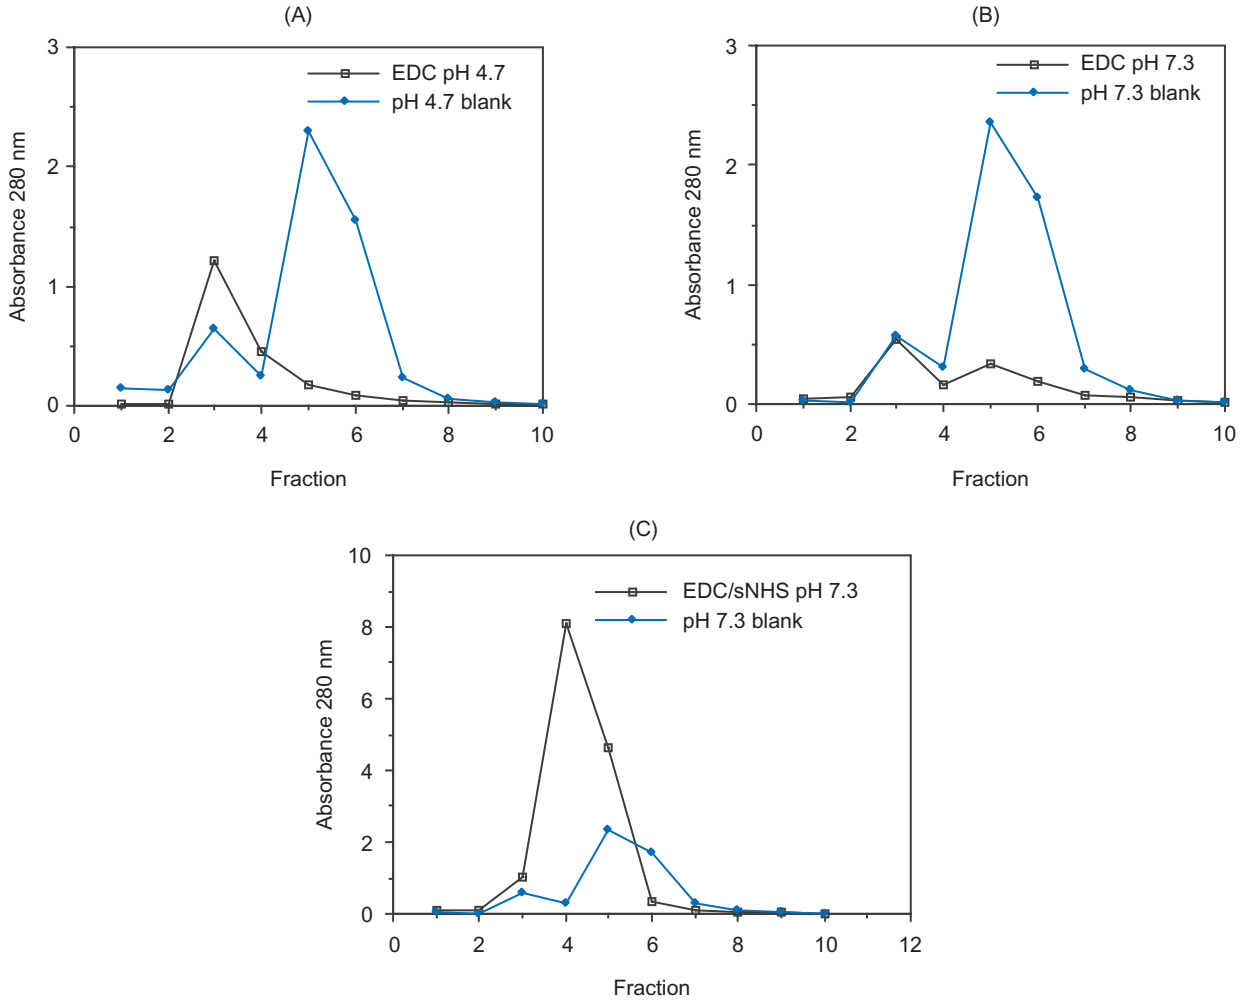

FIGURE 19.7 To assess the effectiveness of an EDC conjugation reaction of a peptide with a carrier protein, glycyl-tyrosine was coupled to BSA using various conditions. The graphs show a gel filtration profile on Sephadex G-25 after completion of the conjugation reaction. The first peak eluting off the column is the higher-molecular-weight, while the second peak is excess peptide. The elution profiles demonstrate that the carbodiimide reaction proceeds with nearly equal efficiency at pH 4.7 (A) or at pH 7.3 (B). In each graph, a comparison is shown between the separation of peptide and carrier without addition of EDC and the same mixture after reaction with EDC. Depletion of the peptide peak in the EDC-containing elution profiles indicates uptake of glycyl-tyrosine in the carrier conjugate. Some polymerization of peptide is also possible using this method, as evidenced by movement of the peptide peak toward higher-molecular-weight elution points. The addition of sulfo-NHS to the reaction caused precipitation problems as well as obscuring the analysis by size exclusion chromatography due to the absorbance of excess sulfo-NHS (C).

presumably due to a decrease in the peptide's absorptivity as it is conjugated or polymerized. Staros' method of adding sulfo-NHS to form an intermediate active ester that subsequently reacts with an amine to form the amide bond does not work as well due to excessive conjugation (causing precipitation in most cases) and interference from the eluting sulfo-NHS peak. The reaction proceeds with similar yields at either acid or neutral pH. Thus, the efficiency of an EDC conjugation reaction is approximately the same from pH 4.7 to physiological conditions.

Figure 19.8 shows the result of the conjugation of the dipeptide tyrosyl-lysine to BSA using various concentrations of EDC. Again, the elution profile shows the gel filtration pattern resulting after the reaction. The first peak is the protein carrier while the second is the peptide. Progressive decrease in the peptide peak with increasing amounts of EDC added to the reaction mixture correlates to increased conjugation yields. A side reaction to EDC conjugation of haptens that contain both an amine and a carboxylate group is hapten polymerization. This is revealed in the movement of the

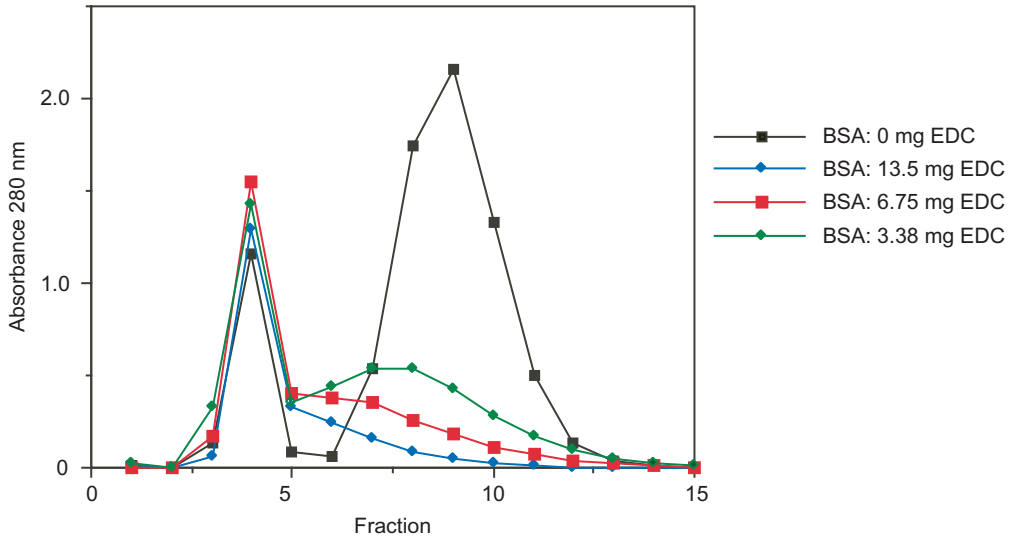

FIGURE 19.8 To study the conjugation of peptides to carriers using different levels of EDC, tyrosyl-lysine was conjugated to BSA and separated after the reaction by chromatography on a Sephadex G-25 column. As the EDC level was increased in the reaction, more peptide reacted and the peptide peak (the second peak) was depleted. The absorbance of the carrier peak (the first one) that elutes off the column was observed to increase as more peptide was conjugated.

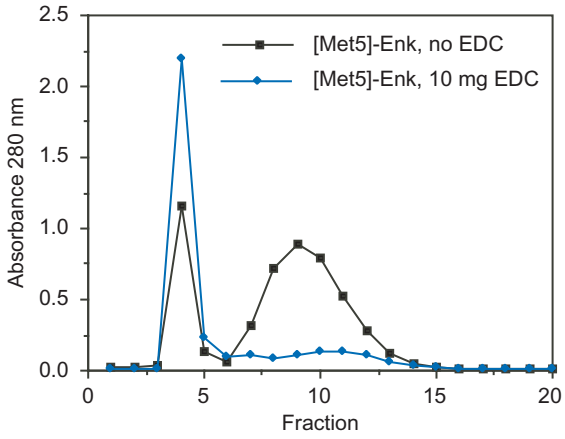

FIGURE 19.9 Conjugation of the biological peptide [Met5]-enkephalin to BSA using EDC. The graph shows the gel filtration profile (on Sephadex G-25) after completion of the conjugation reaction. A blank run with no added EDC was performed to illustrate the peak absorbance that would be obtained if no conjugation took place. With the addition of 10 mg of EDC to a reaction mixture consisting of 2 mg of BSA plus 2 mg of peptide, nearly complete conjugate formation was obtained.

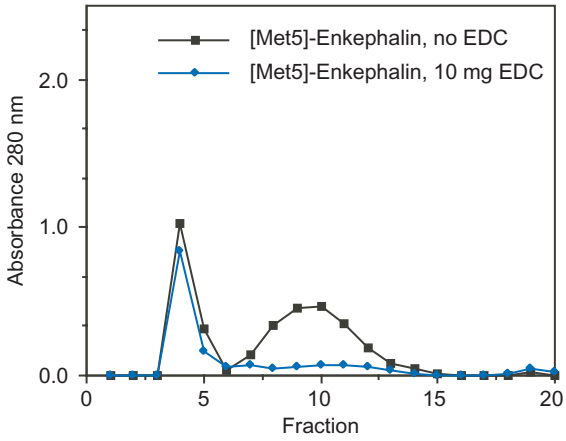

FIGURE 19.10 To illustrate the consistency of an EDC-mediated reaction, [Met5]-enkephalin was conjugated to ovalbumin (OVA) using conditions identical to those described for BSA in Figure 19.9. Note the similarity in the degree of conjugate formation.

peptide peak toward higher molecular weights (e.g., decreased time of elution) with increasing amounts of EDC added to the reaction.

Figure 19.9 illustrates the conjugation of [Met5]-enkephalin with BSA using EDC. The gel filtration profile after crosslinking reveals that the peptide peak effectively disappears upon complete conjugation with the carrier protein. With nicely soluble peptides such as this one, the immunogen remains freely soluble even at high modification levels. For less soluble peptides or haptens, reducing the amount of EDC addition may be necessary to maintain solubility in the conjugate.

To illustrate the similarity of an EDC conjugation reaction using a different carrier protein, but the same peptide, Figure 19.10 shows the gel filtration separation after conjugation of [Met5]-enkephalin to OVA. The uptake of peptide upon addition of EDC is almost

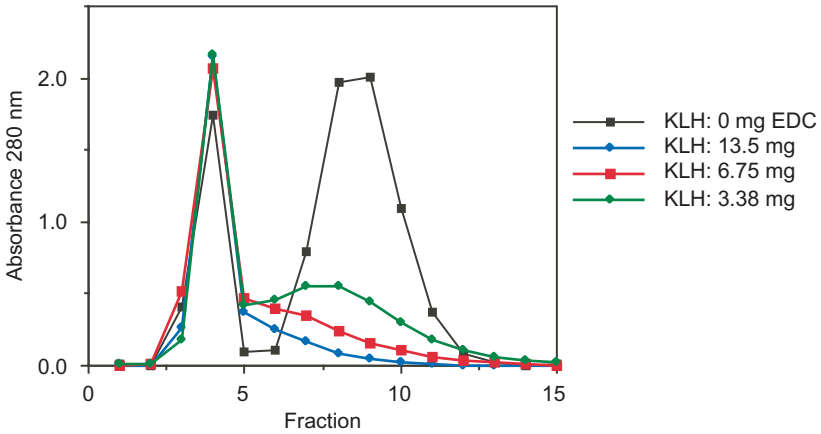

FIGURE 19.11 The EDC conjugation of tyrosyl-lysine to KLH is illustrated by the gel filtration pattern on Sephadex G-25 after the reaction. The first peak is the carrier protein and the second peak is the peptide. A blank containing no EDC is also shown to provide baseline peak heights that would be obtained if no crosslinking occurred. When more EDC was added, more peptide was conjugated, as evidenced by peptide peak depletion.

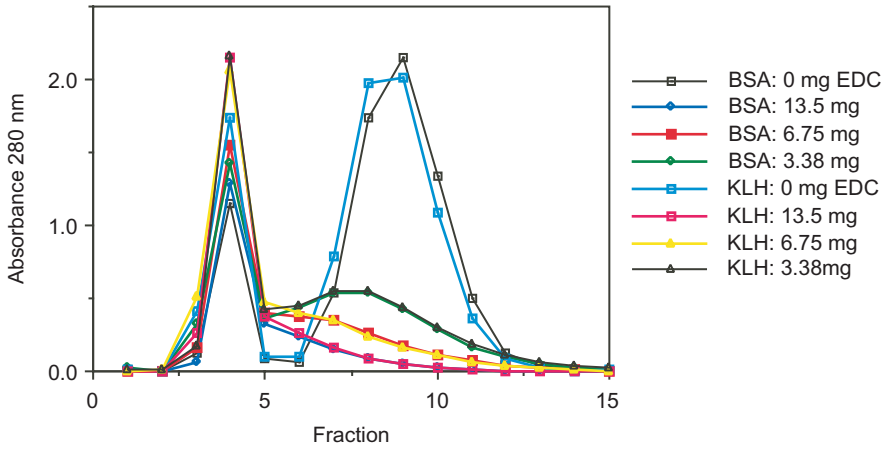

FIGURE 19.12 EDC conjugation reactions can be extraordinarily consistent using the same peptide crosslinked to two carrier proteins. This figure shows the gel filtration pattern on Sephadex G-25 after completion of the crosslinking reaction. Conjugation of tyrosyl-lysine to BSA and KLH are shown. The first peaks represent the carrier eluting from the column, while the second peaks are the excess peptide. Note the consistency of conjugation using the same levels of EDC addition.

identical to that observed when conjugating to BSA. This is logical, since on a per mass basis, there is very little difference between these proteins in the amount of amines or carboxylates available for conjugation.

Figure 19.11 shows the conjugation of tyrosyl-lysine to KLH using various concentrations of EDC. The elution profile shows the gel filtration pattern resulting after the reaction. Progressive decrease in the peptide peak (peak 2) with increasing amounts of EDC correlates to increased conjugation (or polymerization) yields. Despite the extremely high molecular weight of KLH compared to the other commonly used carriers, the conjugation reaction using EDC again proceeds with virtually identical results to the similar study shown in Figure 19.8 using BSA as the carrier. In fact, superimposing the two studies on the same graph demonstrates the reproducibility of an EDC-facilitated reaction (Figure 19.12).

Due to the high molecular weight of KLH and its solubility characteristics, the conjugation of this protein to some haptens can result in precipitation of the complex. This is especially true if the level of EDC addition is similar to the EDC concentrations used with lower molecular weight carriers such as BSA or OVA. Figure 19.13 shows the elution profile resulting from the gel filtration separation of KLH and the peptide [Met5]-enkephalin after an EDC reaction. To result in a soluble immunogen, only 0.1 to 0.2 times the amount of EDC was added as compared to similar BSA or OVA conjugation reactions. Even at levels this low, however, the

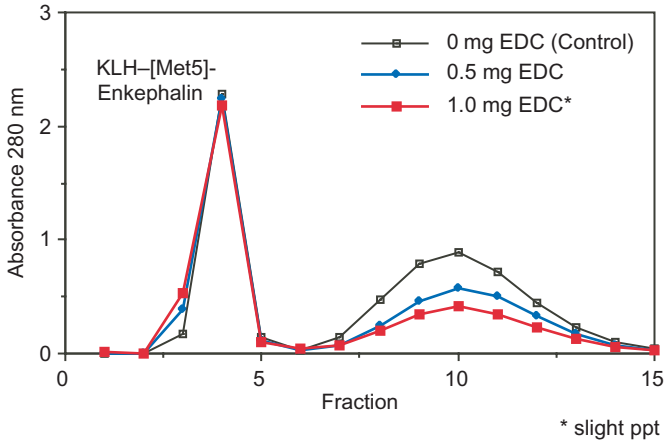

FIGURE 19.13 Conjugation to KLH can often cause precipitation due to the high-molecular weight of the carrier protein. The conjugation of [Met5]-enkephalin to KLH yields a soluble immunogen if the level of EDC addition is about 0.1-times that typically used with BSA as a carrier. This figure shows the gel filtration pattern on Sephadex G-25 after completion of the crosslinking reaction. The first peak is KLH and the second peak is excess peptide. Depletion of the peptide peak correlates to hapten–carrier conjugation.

coupling of peptide to the carrier is very efficient and results in an excellent immunogen.

These studies using EDC-facilitated conjugations were performed to develop an optimal protocol for the preparation of immunogens by carbodiimide crosslinking. For haptens (i.e., peptides) that display good solubility in aqueous solution, the level of reagent addition should result in a soluble immunogen conjugate; however, when using haptens that are sparingly soluble or insoluble in aqueous environments, the conjugation reaction may result in a precipitated complex. Precipitation can often be controlled by scaling back the level of EDC addition or limiting the time of the reaction. If a precipitated immunogen is not a problem (most precipitated, high-molecular-weight conjugates are very immunogenic), then the following protocol is applicable to the great majority of peptide-carrier protein conjugations. Thermo Fisher offers a kit containing all the reagents necessary for an EDC-mediated hapten-carrier conjugation.

Protocol

1. Dissolve the carrier protein in 0.1-*M* MES, 0.15-*M* NaCl, pH 4.7, at a concentration of 10 mg/ml. If using native, multi-subunit KLH, increase the NaCl concentration of all buffers to 0.9-*M* (yes, 0.9-*M*, not 0.9%) to maintain solubility of the protein. If using KLH subunits, the high salt concentration is not necessary. For neutral pH conjugations, substitute 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, for the MES buffer.
2. Dissolve up to 4 mg of the peptide or hapten to be coupled in 1.0 ml of the reaction buffer chosen in step 1. If the peptide to be coupled is already in solution, it may be used directly if it is in a buffer containing no other amines or carboxylic acids and is at a pH between 4.7 and 7.2. Note: If an assessment of the degree of peptide coupling is desired, measure the absorbance at 280 nm of the 1.0-ml peptide solution before proceeding to step 3. In some cases, a dilution of the peptide solution may be necessary to keep the absorbance on scale for the spectrophotometer. If the peptide is sparingly soluble in aqueous solution, it may dissolve in DMSO and an aliquot can be added to the carrier solution to aid in dissolution. See the previous discussion on carrier proteins to determine the levels of DMSO compatible with carrier protein solubility. Peptide haptens should be at least five to seven amino acids in length to obtain suitable immunogenicity and correct specificity of the resulting antibodies produced against them. Many immunogen conjugates use peptides that are slightly longer than the desired epitopic sequence to provide enough size to allow interaction with the components of the immune system.
3. Add 500 µl of the peptide solution to 200 µl of carrier protein. For greater reaction volumes, keep the molar ratio of peptide-to-carrier addition the same and proportionally scale up the amount of EDC added in the next step. If the peptide is initially dissolved in DMSO, much less peptide volume compared to protein volume should be used to maintain solubility (see discussion in step 2).
4. For conjugations using relatively low molecular weight proteins, such as BSA or OVA, add the peptide/carrier solution to a vial containing 10 mg of EDC (Thermo Fisher) and gently mix to dissolve. For high-molecular-weight KLH immunogens, first dissolve one vial containing 10 mg of EDC in 1 ml of deionized water, and immediately transfer 50 µl of this solution to the carrier/peptide solution. Gently mix.
5. Allow the reaction to continue at room temperature for 2 h.

   Note: Although the conjugation protocols have been optimized by preparing a number of different peptide–carrier conjugates, some peptide sequences or other haptens may cause precipitation of the carrier upon coupling. This may occur as a result of changing the carrier's solubility characteristics through surface modification or due to polymerization. A small amount of precipitation is not a problem and can easily be removed by centrifugation before the gel filtration step. If severe precipitation occurs, however, the amount of EDC added to the reaction may have to be scaled back to

eliminate or reduce it. With BSA or OVA conjugates, this may mean using as little as 1 to 3 mg of EDC instead of the recommended 10 mg. With native, multi-subunit KLH as a carrier, reducing the EDC levels to 0.1 mg may be necessary.

6. Purify the hapten–carrier conjugate by gel filtration or dialysis.

4. NHS ESTER-MEDIATED HAPTEN–CARRIER CONJUGATION

Hapten–carrier conjugation may be accomplished by the use of homobifunctional reagents containing NHS ester groups on both ends. The active esters are highly reactive toward amines on proteins and other molecules to form stable amide bonds. Crosslinking agents of various lengths may be used for this conjugation strategy, including the sulfo-NHS ester analogs which are more water soluble than the NHS esters without a sulfonic acid group (Chapter 5, Section 1).

Using homobifunctional NHS esters, amine-containing haptens may be conjugated to amine-containing carriers in a single step (Figure 19.14). The carrier is dissolved in a buffer having a pH of 7–9 (0.1-*M* sodium phosphate, pH 7.2, works well). The hapten molecule is added to this solution at a suitable molar excess to ensure multipoint attachment of the hapten to the carrier. A molar excess of 20 to 30 times that of the carrier concentration is a good starting point. Next, the NHS ester crosslinker is added to the solution to provide at least a 3-fold molar excess over that of the hapten. For crosslinkers insoluble in aqueous solution, first solubilize them in dimethylformamide (DMF) or DMSO at higher concentration, and then add an aliquot of this stock solution to the hapten–carrier solution. The conjugation reaction is complete within 2 h at room temperature. Some adjustment of the level of hapten and crosslinker addition may be necessary to avoid extensive precipitation of the conjugate, especially when using rather hydrophobic hapten molecules.

Another method of NHS ester-mediated hapten–carrier conjugation is to create reactive sulfo-NHS esters directly on the carboxylates of the carrier protein using the EDC/sulfo-NHS reaction described in Chapter 4, Section 1.2. A carbodiimide reaction in the presence of sulfo-NHS activates the carboxylate groups on the carrier protein to form amine-reactive sulfo-NHS esters. The activation reaction is performed at pH 6.0, since the amines on the protein will be protonated and therefore be less reactive toward the sulfo-NHS esters that are formed. In addition, the hydrolysis rate of the esters is dramatically slower at acid pH. Thus, the active species may be isolated in a reasonable time frame without significant loss in conjugation potential. To quench unreacted EDC, 2-mercaptoethanol is added to form a stable complex with the remaining carbodiimide, according to Carraway and Triplett (1970). In the following protocol, a modification of Grabarek and Gergely's (1990) two-step method, sulfo-NHS is used instead of NHS so that active ester hydrolysis is slowed even more (Anjaneyulu and Staros, 1987; Thelen and Deuticke, 1988). Subsequent conjugation with amine-containing hapten molecules yields hapten–carrier conjugates created by amide bond formation (Figure 19.15).

Protocol

1. Dissolve the carrier protein to be activated in 0.05-*M* MES, 0.5-*M* NaCl, pH 6.0 (reaction buffer), at a concentration of 1 mg/ml.
2. Add to the solution in step 1 a quantity of EDC and sulfo-NHS (both from Thermo Fisher) to obtain a concentration of 2-m*M* EDC and 5-m*M* sulfo-NHS. To aid in aliquoting the correct amount of these reagents, they may be quickly dissolved in water at a higher concentration, and then immediately pipette a volume into the protein solution to obtain the proper molar quantities.
3. Mix and react for 15 min at room temperature to form the sulfo-NHS esters.
4. Add 2-mercaptoethanol to the reaction solution to obtain a final concentration of 20-m*M*. Mix and incubate for 10 min at room temperature. Note: If the protein being activated is sensitive to this level of 2-mercaptoethanol, instead of quenching the reaction chemically the activation may be terminated by rapid desalting (see step 5).
5. If the reaction was quenched by the addition of 2-mercaptoethanol, the activated protein may be added directly to an amine-containing hapten molecule for conjugation. Alternatively, or if no 2-mercaptoethanol was added, the activated protein may be purified from reaction byproducts by gel filtration using a desalting resin. The desalting operation should be performed rapidly to minimize hydrolysis and recover as much active ester functionality as possible. The use of centrifugal spin columns may afford the greatest speed in separation (Thermo Fisher). After purification, add the activated protein to the hapten for conjugation. The hapten molecule should be dissolved in 0.1-*M* sodium phosphate, pH 7.5.
6. React for at least 2 h at room temperature.
7. Remove excess reactants by gel filtration or dialysis.

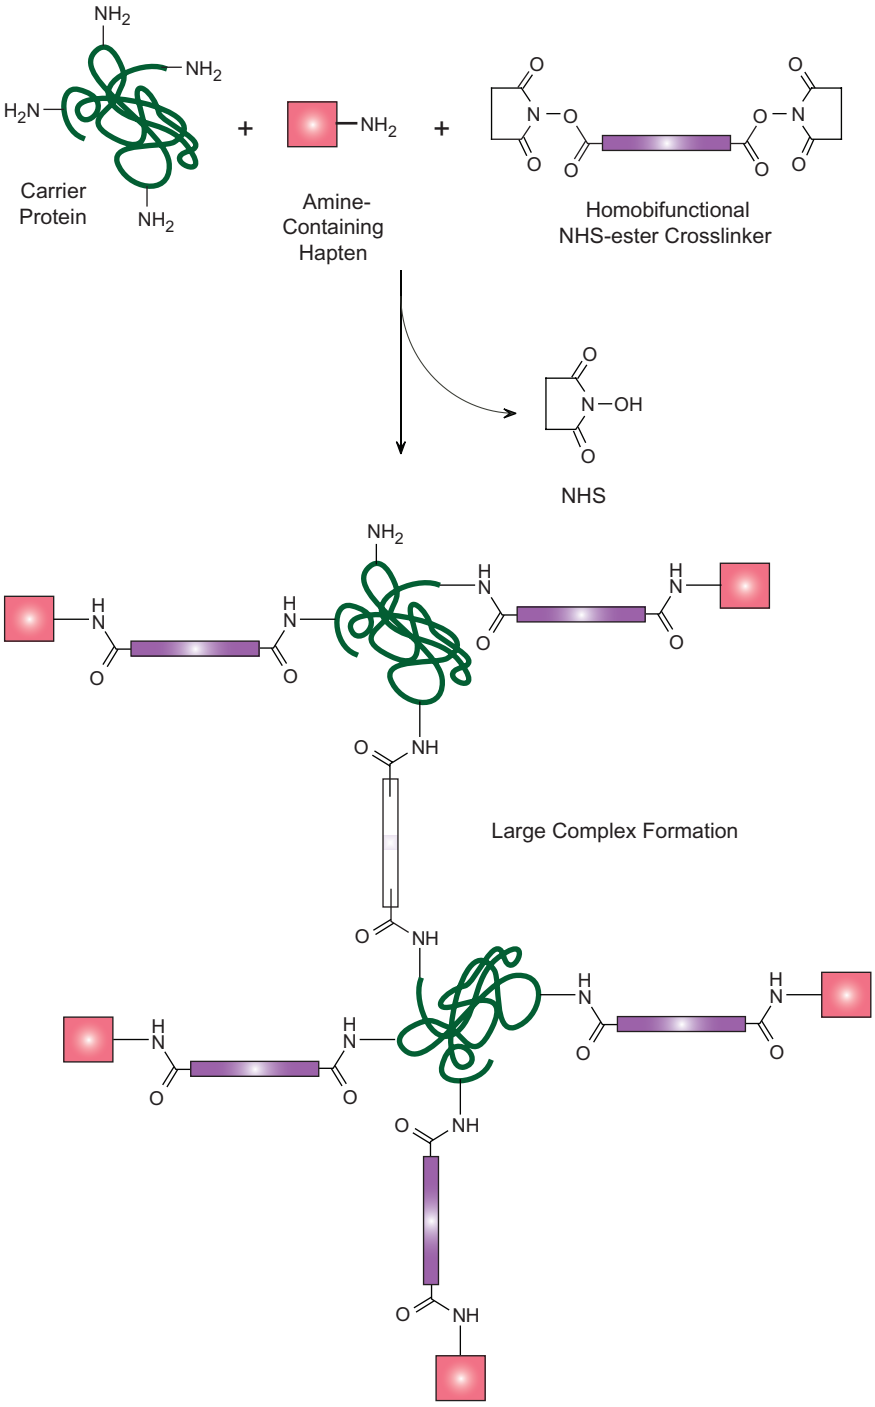

FIGURE 19.14 Hapten–carrier immunogen conjugates can be formed using homobifunctional NHS ester crosslinkers. The reaction may create large polymeric complexes, some of which could precipitate.

5. NHS ESTER–MALEIMIDE HETEROBIFUNCTIONAL CROSSLINKER-MEDIATED HAPTEN–CARRIER CONJUGATION

A common method for coupling haptens to carrier proteins involves the use of a heterobifunctional crosslinker containing an NHS ester and a maleimide group. This type of crosslinker allows better control over the coupling process than homobifunctional or zero-length conjugation methods by incorporating a two- or three-step reaction strategy directed against two different functional targets. In this approach, the carrier protein is first activated with the crosslinker through its

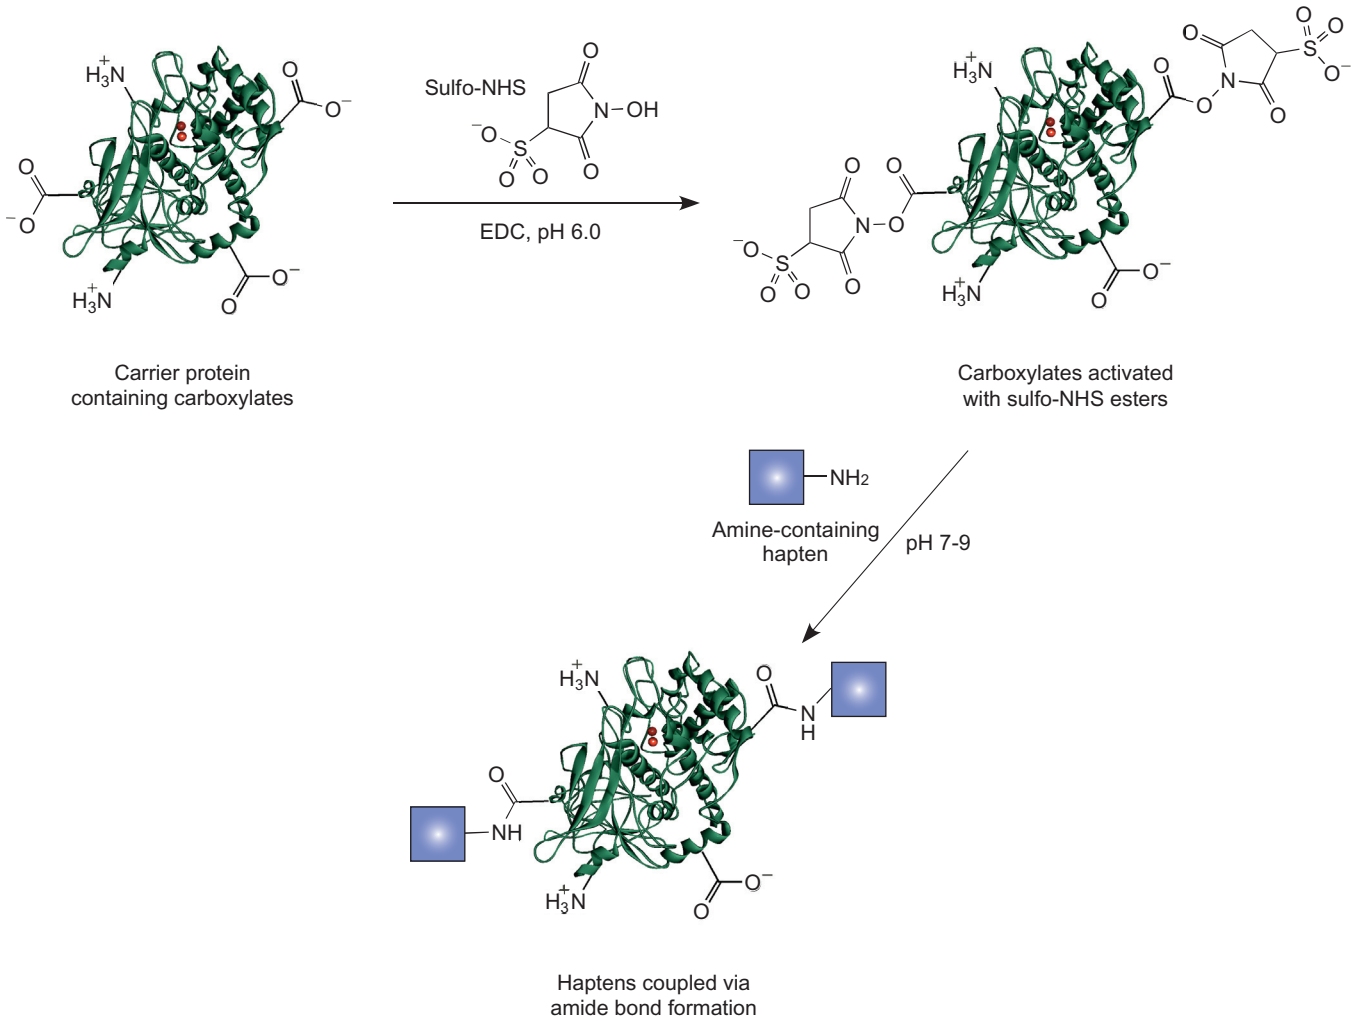

FIGURE 19.15 The carbodiimide EDC can be used in the presence of sulfo-NHS to create reactive sulfo-NHS ester groups on a carrier protein. Subsequent coupling with an amine-containing hapten can be performed to create amide bond linkages.

amine groups, purified to remove excess reactants, and then crosslinked to a hapten molecule containing a sulfhydryl group. One of the most useful reagents for this conjugation approach is sulfo-SMCC.

The reactions associated with a sulfo-SMCC conjugation are shown in Figure 19.16. (Note: sulfo-SMCC is sulfosuccinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate; MW = 436.37; see Chapter 6, Section 1.3.) This crosslinking reagent mediates the conjugation of a carrier protein through its primary amine groups to a peptide or other hapten through sulfhydryl groups. The active *N*-hydroxysulfosuccinimide ester (sulfo-NHS) end of sulfo-SMCC is first reacted with available primary amine groups on the carrier protein. This reaction results in the formation of an amide bond between the protein and the crosslinker with the release of sulfo-NHS as a byproduct. The carrier protein is then isolated by gel filtration to remove excess reagents. At this stage, the purified carrier possesses modifications generated by the crosslinker resulting in a number of reactive maleimide groups projecting from its surface. The maleimide portion of sulfo-SMCC is a thiol-reactive group that can be used in a secondary step to conjugate with a free sulfhydryl (i.e., a cysteine residue) on a peptide or other hapten, resulting in a stable thioether bond.

The use of sulfo-SMCC over the other common maleimide-containing crosslinkers such as *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS) or succinimidyl-4-(*p*-maleimidophenyl)butyrate (SMPB) provides the advantages of initial water solubility during the activation step and increased stability of the maleimide group prior to conjugation with a peptide. The improved stability ensures that the majority of the maleimide groups substituted on the carrier will survive the subsequent purification process without degradation. The relatively good stability of the maleimide group of

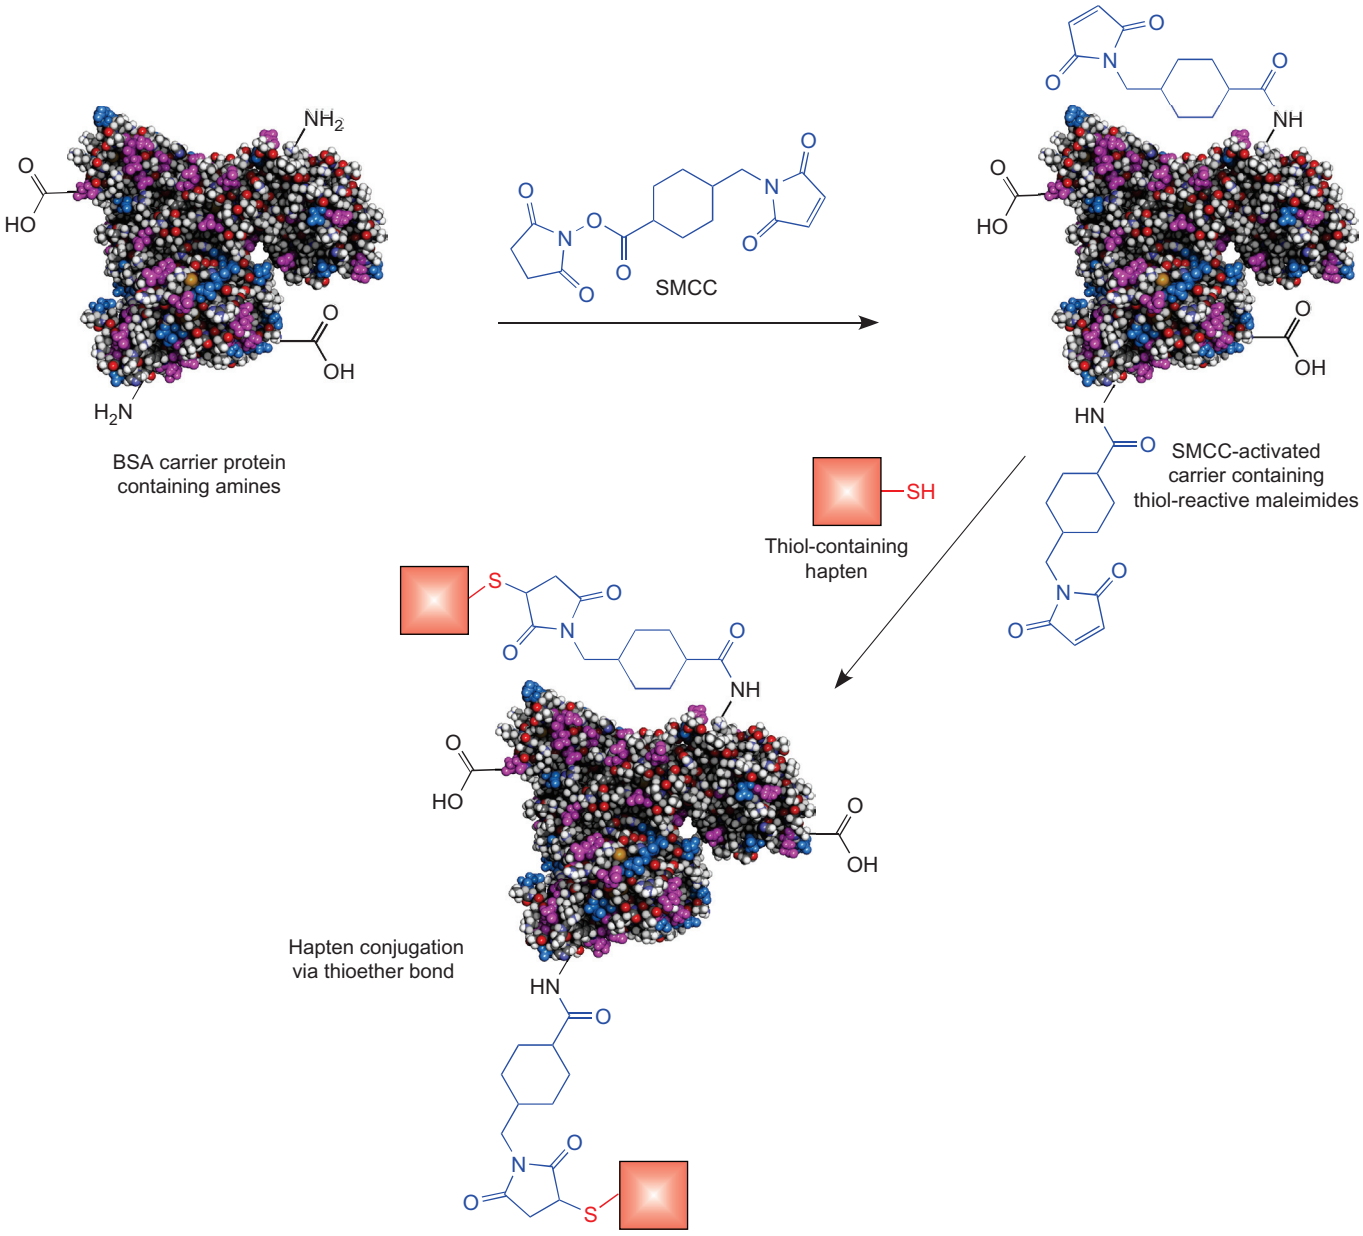

FIGURE 19.16 A common way of conjugating sulfhydryl-containing haptens to carrier proteins is to activate the carrier with sulfo-SMCC to create an intermediate maleimide derivative. The maleimide groups can then be coupled to thiol-containing haptens to form thioether bonds.

sulfo-SMCC is probably due to the neighboring steric effects of its cyclohexane ring. The faster hydrolysis rates of other maleimide type crosslinkers can be a significant problem, since they readily break down to the maleamic acid form, which is no longer reactive toward sulfhydryls (Figure 19.17).

A disadvantage to using SMCC or other NHS–maleimide type crosslinkers with hindered ring structures (such as MBS) is the relatively high immunogenicity of the cross-bridge. Studies have shown that a hapten-carrier

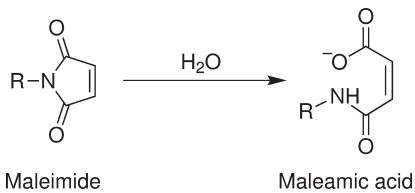

FIGURE 19.17 Maleimide groups may hydrolyze in aqueous solution to an open maleamic acid form that is unreactive with sulfhydryls.

complex formed from such crosslinkers generates significant antibody response against the spacer group itself, not just the hapten and carrier. To minimize the antibody population directed against the cross-bridge of the conjugate, the use of aliphatic straight-chain spacers will exhibit lower immunogenicity (Peeters *et al.*, 1989). However, perhaps a better choice for this type of conjugation is a polyethylene glycol (PEG)-based crosslinker containing an NHS ester on one end and a maleimide group on the other end (see Chapter 18, Section 1.2). A PEG group used as a cross-bridge in a heterobifunctional reagent to prepare immunogen conjugates will result in non-immunogenic modifications on the carrier protein and thus no antibody production against the polyether linker. Although SMCC (or sulfo-SMCC) is used in the following protocol, direct substitution of a PEG-based crosslinker will limit the immune response to the hapten and not generate unwanted antibodies to the cross-bridge.

Since many peptides do not naturally contain cysteine residues with free sulfhydryls, a terminal cysteine may be incorporated during peptide synthesis, or, where appropriate, disulfide groups may be reduced to generate them. Alternatively, thiolating reagents such as 2-iminothiolane (Traut's reagent) can be used to modify existing amino groups and introduce a sulfhydryl (see Chapter 2, Section 4.1). Caution must be taken when using this last technique, however, because multiple sites of modification may alter the immunogenic structure of the hapten.

If a terminal cysteine residue is added to a peptide during its synthesis, its sulfhydryl group provides a highly specific conjugation site for reacting with a sulfo-SMCC-activated carrier. All peptide molecules coupled using this approach will display the same basic conformation after conjugation. In other words, they will have a known and predictable orientation, leaving the majority of the molecule free to interact with the immune system. This method can therefore preserve the major epitopes on a peptide while still enhancing the immune response to the hapten by being covalently linked to a larger carrier protein. In addition, the well-known chemical reactivity of a sulfo-SMCC-mediated immunogen preparation permits covalent conjugation in a controllable fashion that can be highly defined for quality assurance purposes.

The process of carrier activation by sulfo-SMCC may be followed by performing a simple purification step after the reaction using a desalting resin. Figure 19.18 shows the gel filtration profiles for the separation of sulfo-SMCC-activated BSA and OVA. The first peak of both separations represents the elution point for the carrier protein, while the absorbance due to reaction by-products of the crosslinker is contained in the second peak (shown only as its leading edge). Activated proteins exhibit an increase in their absorbance at 280 nm over an identical sample with no added sulfo-SMCC due to their covalently attached maleimide groups. After isolation, the activated protein may be frozen and lyophilized to preserve maleimide coupling activity toward sulfhydryl-containing haptens. Thermo Fisher sells a number of maleimide-activated carrier proteins in lyophilized form for easy hapten conjugation.

After a carrier protein has been activated with sulfo-SMCC, it is often useful to measure the degree of maleimide incorporation prior to coupling an expensive hapten. Ellman's reagent may be used in an indirect method to assess the level of maleimide activity of sulfo-SMCC-activated proteins and other carriers. First, a sulfhydryl-containing compound such as 2-mercaptoethanol or cysteine is reacted in excess with the activated protein. The amount of unreacted sulfhydryls remaining in solution is then determined using the

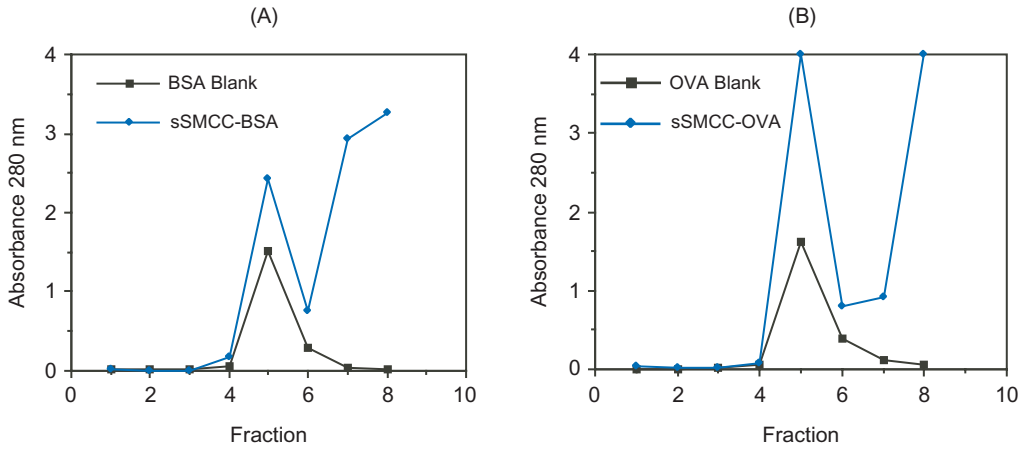

FIGURE 19.18 Carrier proteins may be activated with sulfo-SMCC to produce maleimide derivatives reactive with sulfhydryl-containing molecules. The graphs show the size exclusion separation on Sephadex G-25 of maleimide-activated BSA (A) and OVA (B) after reaction with sulfo-SMCC. The first peak is the protein and the second peak is excess crosslinker. The maleimide groups create increased absorbance at 280 nm in the activated proteins as compared with the blank separation performed without the addition of crosslinker.

Ellman's reaction (Chapter 2, Section 4.1). Comparison of the response of the sample to a blank reaction using the native, non-activated protein at the same concentration and a series of standards made from a serial dilution of the sulfhydryl compound employed in the assay gives the amount of sulfhydryl compound conjugated and thus an estimate of the original maleimide activity.

Figure 19.19 shows a plot of the results of such an assay performed to determine the maleimide content of activated BSA. This particular assay used 2-mercaptoethanol which is relatively unaffected by metal-catalyzed oxidation. For the use of cysteine or cysteine-containing peptides in the assay, however, the addition of EDTA is required to prevent disulfide formation. Without the presence of EDTA at 0.1-*M*, the metal contamination of some proteins (especially serum proteins such as BSA) is so great that disulfide formation proceeds preferential to maleimide coupling. Figure 19.20 shows a similar assay for maleimide-activated BSA using the more innocuous cysteine as the sulfhydryl-containing compound.

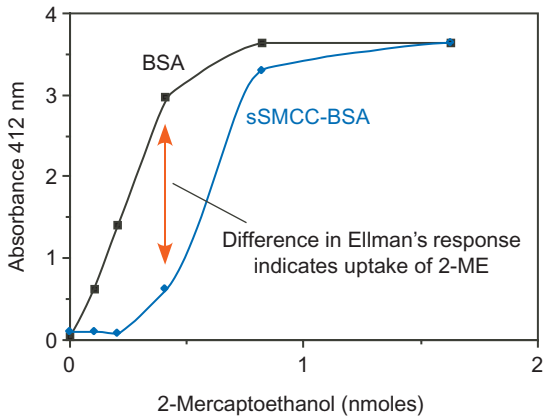

FIGURE 19.19 An Ellman's assay may be performed to determine the maleimide activation level of SMCC-derivatized proteins. Reaction of the activated carrier with different amounts of 2-mercaptoethanol will result in various levels of sulfhydryls remaining after the reaction. Detection of the remaining thiols using an Ellman's assay indirectly indicates the amount of sulfhydryl uptake into the activated carrier. Comparison of the Ellman's response to the same quantity of 2-mercaptoethanol plus an unactivated carrier indicates the absolute amount of sulfhydryl that reacted. Calculation of the maleimide activation level can then be performed.

Using this type of cysteine-uptake assay, it is possible to determine the percentage of maleimides that reacted over time. Thus, an indication of the reaction efficiency of a sulfhydryl-containing compound coupling with a maleimide-activated protein may be determined. Figure 19.21 shows the reaction rate for the coupling of cysteine to maleimide-activated BSA. Note that maximal coupling is obtained in less than 2 h, and over 80% yield is achieved in less than 30 min.

The following protocol describes the activation of a carrier molecule with sulfo-SMCC and its subsequent conjugation with a hapten. The preactivated carriers containing maleimide groups ready for coupling to a sulfhydryl-containing compound are commercially available in a stable freeze-dried form (Thermo Fisher). Substitution of GMBS (Chapter 6, Section 1.7) or a NHS–PEG_n–maleimide crosslinker (Chapter 18, Section 1.2) in the following protocol will provide straight-chain spacer arms with lower or no immunogenicity compared to the ring structure of SMCC's cross-bridge.

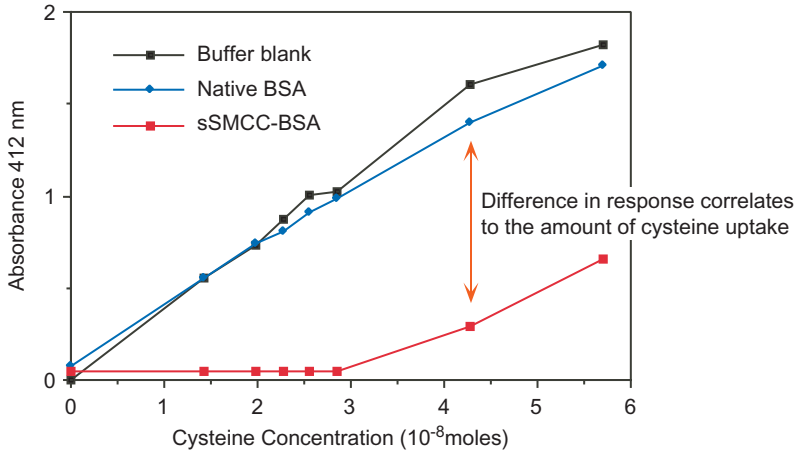

FIGURE 19.20 Cysteine may also be used in an Ellman's assay to determine the maleimide activation level of SMCC-derivatized proteins. Reaction of the activated carrier with different amounts of cysteine results in various levels of sulfhydryls remaining after the reaction. The coupling must be performed in the presence of EDTA to prevent metal-catalyzed oxidation of sulfhydryls. Detection of the remaining thiols using an Ellman's assay indirectly indicates the amount of sulfhydryl uptake into the activated carrier. Comparison of the Ellman's response to the same quantity of cysteine plus an unactivated carrier indicates the absolute amount of sulfhydryl that reacted. Calculation of the maleimide activation level then can be performed.

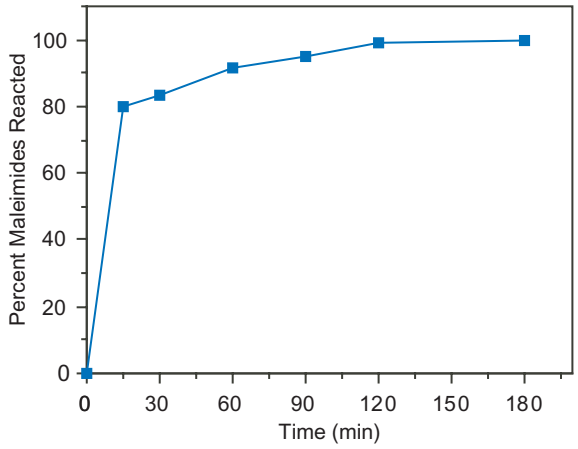

FIGURE 19.21 The rate of reaction of cysteine with maleimide-activated BSA was determined using an Ellman's assay to determine the remaining sulfhydryl groups after the reaction, which was performed according to Figure 19.20. Nearly all of the available maleimides are coupled with sulfhydryls within 2 h.

Protocol

1. Dissolve the carrier of choice at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 to 7.5 (activation buffer). Note: For use of native, multi-subunit KLH, increase the NaCl concentration to 0.9-*M*.
2. Dissolve sulfo-SMCC (Thermo Fisher) at a concentration of 10 mg/ml in the activation buffer. Immediately transfer the appropriate amount of this crosslinker solution to the vial containing the dissolved carrier protein. Note: The amount of crosslinker solution to be transferred is dependent on the level of activation desired. Suitable activation levels can be obtained for the following proteins by adding the indicated quantities of the sulfo-SMCC solution. The degree of sulfo-SMCC modification often determines whether the carrier will maintain solubility after activation and coupling to a hapten. Multimeric KLH in particular, is sensitive to the amount of crosslinker addition. KLH usually retains solubility at about 0.1 to 0.2 times the mass of crosslinker added to BSA. This level of addition still results in excellent activation yields, since KLH is significantly larger than most of the other protein carriers. Add the following quantities of sulfo-SMCC solution to each milliliter of carrier protein solution:
   a. BSA: 500 µl
   b. cBSA: 200 µl
   c. OVA: 500 µl
   d. KLH: 100 µl
   Carriers having molecular weights similar to those of BSA or OVA may be activated at the same level with good success. Cationized BSA requires less crosslinker addition due to its greater quantity of amines present.
3. React for 1 h at room temperature.
4. Immediately purify the activated carrier protein by gel filtration using a desalting resin with a bed volume equal to 15 times the volume of the activation reaction. To perform the chromatography use 0.1-*M* sodium phosphate, 0.15-*M* NaCl (0.9-*M* for KLH), 0.1-*M* EDTA, pH 7.2 to 7.5 (conjugation buffer). The EDTA is present to prevent metal-catalyzed sulfhydryl oxidation to disulfides, which will result in an inability to couple to the maleimide groups on the carrier. This is a particular problem when using BSA due to contaminating iron from hemolysis. Concentrations less than 0.1-*M* EDTA will not fully inhibit the oxidation reaction, especially if a cysteine-containing peptide is to be conjugated to the activated carrier. Apply the sSMCC/carrier reaction mixture to the column while collecting 0.5 to 1.0 ml fractions. Pool the fractions containing the activated carrier (the first peak to elute from the column), and discard the fractions containing excess sulfo-SMCC (the second peak). The activated carrier should be used immediately or freeze-dried to maintain maleimide stability.
5. Dissolve a sulfhydryl-containing hapten or peptide to be conjugated at a concentration of 10 mg/ml in the conjugation buffer. Other hapten concentrations may be used depending on its solubility. If an excess of the peptide solution is made at this time, an estimate of the degree of conjugation may be determined later (see section below). Add this solution to the pooled fractions containing the activated carrier at an equivalent mass ratio (1 mg hapten per milligram of the carrier). Alternatively, the peptide may be added in solid form directly to the activated carrier solution if it is known to be freely soluble and can be weighed out in the appropriate quantity.
6. Allow the conjugation reaction to proceed for 2 h at room temperature.
7. The hapten–carrier conjugate may now be mixed with adjuvant and used for injection purposes without further purification.

An estimate of the degree of conjugation may be made by assaying the amount of sulfhydryl present before and after the coupling reaction. A portion of the peptide solution before mixing with the activated carrier should be saved to compare with the reaction mixture after the conjugation is complete. The comparison is made using a solution of Ellman's reagent (5,5′-dithiobis-(2-nitrobenzoic acid)), which reacts with sulfhydryls to form a highly colored chromophore

having an absorbance maximum at 412 nm ($\varepsilon_{412\,nm} = 1.36 \times 10^4\,M^{-1}\,cm^{-1}$) (Chapter 2, Section 4.1). A generalized procedure is presented here. Modifications to this guideline may have to be made for each individual peptide to obtain the appropriate response to the Ellman's reagent. For reactions performed with very small quantities of peptide, the Ellman's assay may not be sensitive enough to measure the degree of conjugation.

1. Using a microtiter plate (96 well) dispense 200 µl of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 0.1-*M* EDTA, pH 7.2 (conjugation buffer), into each well to be used.
2. Add 10 µl of the peptide solution before conjugation to the appropriate wells in duplicate.
3. Add 10 µl of the reaction mixture after the conjugation reaction is complete to another set of wells in duplicate.
4. Add 20 µl of Ellman's reagent (1 mg/ml dissolved in the gel filtration purification buffer) to each well including one containing only buffer (220 µl) to use as a blank.
5. Incubate for 15 min at room temperature.
6. Measure the absorbance of all wells using a microplate reader with a filter set at 410 nm.

A comparison of the blank corrected values before and after conjugation should give an indication of the percent of peptide coupled. To be more quantitative, a standard curve must be run to focus in on the linear response range of the peptide–Ellman's reaction. Using cysteine as a representative sulfhydryl compound (similar in Ellman's response to a peptide having one free sulfhydryl), it is possible to obtain very accurate determinations of the amount which coupled to the activated carrier. Figure 19.20, discussed previously in this section, shows the results of this type of assay.

6. ACTIVE-HYDROGEN-MEDIATED HAPTEN–CARRIER CONJUGATION

Conjugation chemistry for the coupling of haptens to carrier molecules is fairly well defined for compounds having common functional groups to facilitate such attachment. The types of functional groups generally useful for this operation include easily reactive components such as primary amines, carboxylic acids, aldehydes, or sulfhydryls.

However, for hapten molecules containing no easily reactive functional groups, conjugation can be difficult or impossible using current technologies. To solve this problem, demanding organic synthesis is frequently required to modify the hapten molecule to contain a suitable reactive portion. Particularly, certain drugs, steroidal compounds, dyes, or other organic molecules often have structures that contain no available "handles" for convenient crosslinking.

Frequently, these difficult-to-conjugate compounds do have certain sufficiently active hydrogens that can be reacted with a carrier molecule using specialized reactions designed for this purpose. This section describes two choices for this conjugation problem, the diazonium procedure and the Mannich reaction. Both of them are able to crosslink haptens through any available active hydrogen to carrier molecules, resulting in immunogens suitable for injection.

6.1. Diazonium Conjugation

Diazonium coupling procedures have been used for many years in organic synthesis and for crosslinking or immobilization of active-hydrogen-containing compounds (Inman and Dintzis, 1969; Cuatrecasas, 1970) (see Chapter 15, Section 2.7). Diazonium derivatives can couple with haptens containing available phenolic or, to a lesser extent, imidazole groups in an electrophilic substitution reaction (Riordan and Vallee, 1972). They may also undergo minor secondary reactions with sulfhydryl groups and primary amines (Glazer *et al.*, 1975).

The most important reaction of a diazonium group, however, is with available tyrosine and histidine residues within peptide haptens, rapidly creating diazo linkages. This method of conjugation is especially useful for site-directed crosslinking of tyrosine-containing peptides. Since tyrosine is usually present only in limited quantities in a given peptide, use of diazonium conjugation can crosslink and orient all peptide molecules in an identical fashion on a carrier. The result is excellent reproducibility in preparation of the immunogen, and a consistent presentation of the peptide on the surface of the carrier to the immune system for antibody production.

Derivatives of carbohydrate antigens have also been coupled to carrier proteins through the use of an intermediate diazonium group (McBroom *et al.*, 1976). In this case, an aminophenyl glycoside was prepared by reaction of the reducing end of the oligosaccharide with β-(*p*-aminophenyl)ethylamine and then forming the diazotized derivative with sodium nitrite (Zopf *et al.*, 1978). Upon mixing with carrier proteins containing tyrosine residues, the carbohydrate derivative is coupled via a diazo bond.

Creation of a diazonium group on phenolic compounds or tyrosine side chain groups is possible by forming an intermediate nitrophenol derivative. Reaction of tyrosine-containing proteins and peptides with tetranitromethane effectively nitrates the ring in the *ortho* position (Vincent *et al.*, 1970). Reduction of the nitro group to an amine is then performed using sodium dithionite (sodium hydrosulfite; $Na_2S_2O_4$)

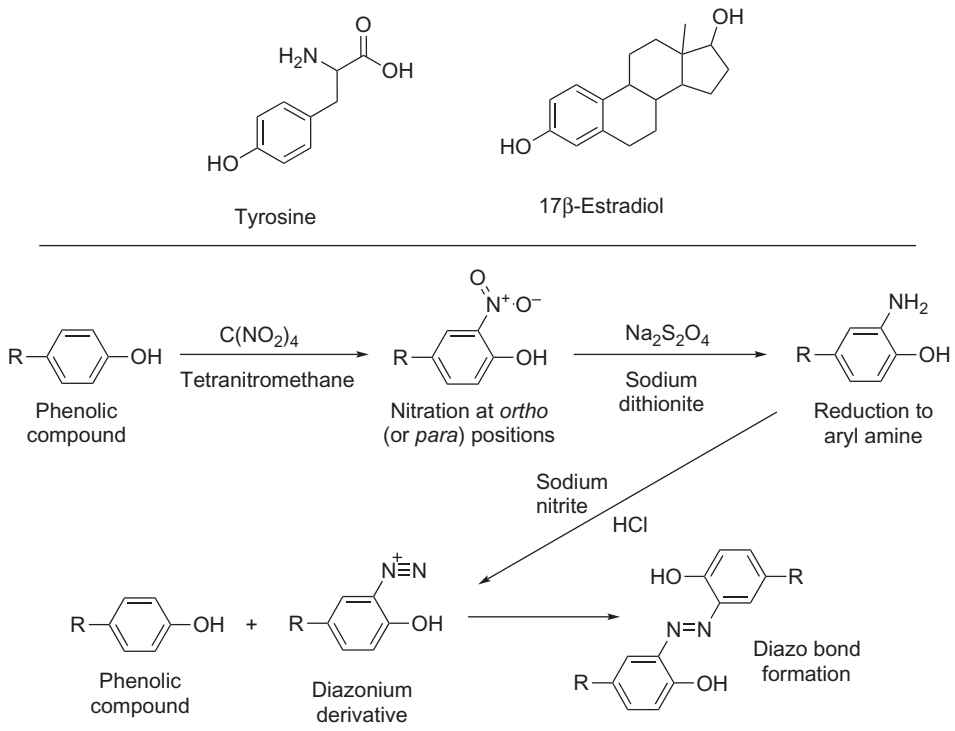

FIGURE 19.22 Phenolic compounds such as tyrosine and estradiol may be derivatized to contain reactive diazonium groups by nitration with tetranitromethane followed by reduction with sodium dithionite and finally diazotization with sodium nitrite in dilute HCl. The diazo groups rapidly react with active hydrogen containing molecules (such as other phenolic compounds) to create diazo linkages.

(Sokolovsky *et al.*, 1967) (Chapter 2, Section 4.3). The aminophenol derivative is finally reacted with sodium nitrite in acidic conditions to form the highly reactive diazonium group (Figure 19.22). Once created, the diazonium compound must be added immediately to the conjugation reaction, since the species is extremely unstable in aqueous environments.

The active diazonium is typically a colored compound, sometimes orange, dark brown, or even black in concentrated solutions. The conjugated immunogen is usually deeply colored due to the resultant diazo bond. The coupling reaction is performed at alkaline pH, optimally at pH 8 for histidine residues and pH 9 to 10 for tyrosine groups. In practice, however, it is not possible to target a histidine group in the presence of a tyrosine group without some cross-reactivity.

Diazo linkages are reversible bonds that may be cleaved by addition of 0.1-*M* sodium dithionite in 0.2-*M* sodium borate, pH 9. Release of the crosslinks can be followed by loss of the diazo bond color.

A simple, one-step conjugation reaction is possible with diazonium chemistry if a *bis*-aminophenyl compound is used as a homobifunctional crosslinking agent. Activation of the aminophenyl groups with sodium nitrite creates the requisite *bis*-diazonium derivative that can then couple with active-hydrogen-containing haptens and carriers. In this way, tyrosine-containing peptides can be conjugated with tyrosine-containing carrier proteins in a single step. Compounds useful for this procedure include *o*-tolidine and benzidine (Chapter 5, Section 9), both of which contain aromatic amines that can easily be diazotized (Figure 19.23).

From a practical perspective, however, any of the conjugation methods utilizing diazonium chemistry can be problematic. The rate of reaction of the diazonium species is so rapid that much of the total coupling potential can be lost through intramolecular crosslinking. As the diazonium groups are formed they may immediately crosslink to the active hydrogens present on the aminophenyl precursor molecules, even before addition of a second molecule to be conjugated. Even without addition of a second active-hydrogen-containing compound, the diazonium activated molecule will turn brown to black within an hour, indicating formation of diazo bonds and self-conjugation. For this reason, the reproducibility of conjugation reactions using this method can be poor.

The following protocol describes the use of diazotized *o*-tolidine for the crosslinking of active-hydrogen-containing haptens to active-hydrogen-containing carriers. Using a *bis*-diazonium compound is perhaps the simplest method of conjugation, but as in many

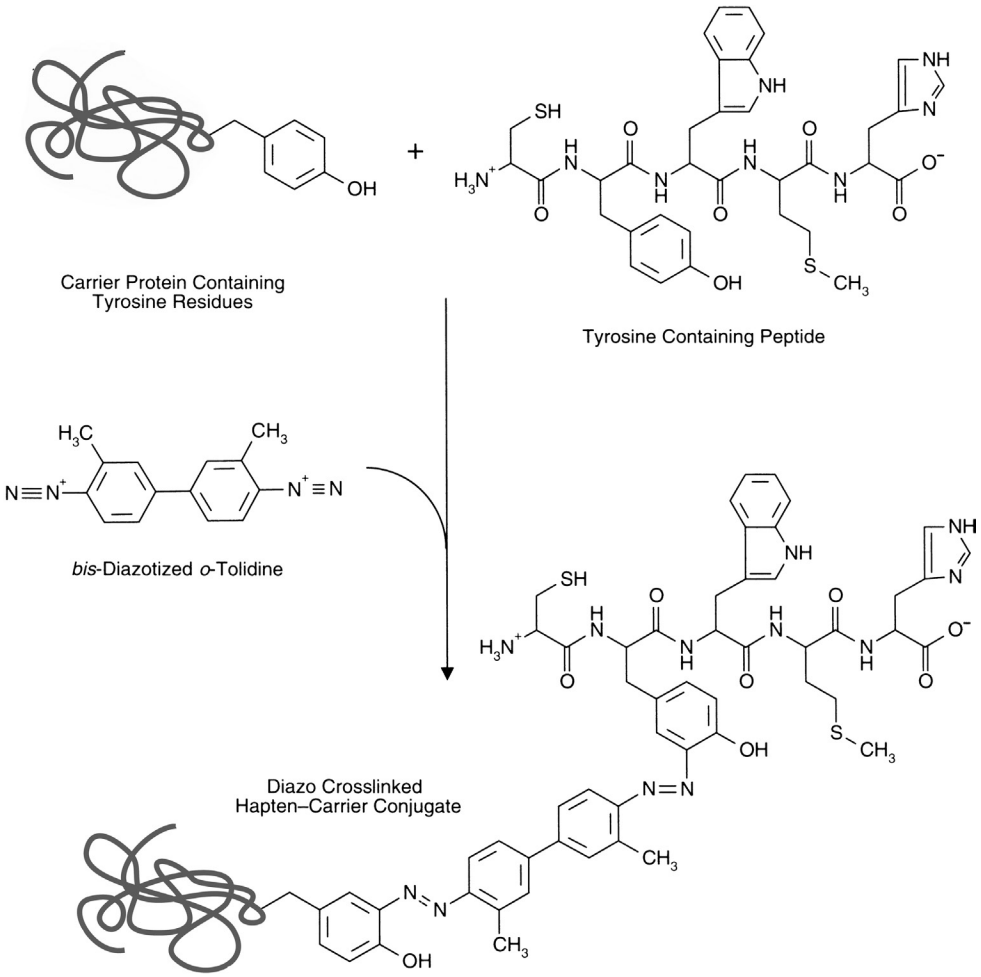

FIGURE 19.23 The conjugation of a tyrosine-containing carrier protein and a tyrosine-containing peptide may be performed using *bis*-diazotized tolidine to form diazo crosslinks.

one-step crosslinking procedures, it often results in some precipitation of the final product. Reaction conditions may have to be adjusted to prevent severe precipitation, however even an insoluble immunogen can be useful in generating an antibody response.

Caution: Both *o*-tolidine and benzidine are potential carcinogens. Protective clothing, gloves, and the use of a fume hood are recommended. Avoid all contact of the compounds with skin or clothing and do not inhale vapors or dust.

Protocol

1. Diazotization of *o*-tolidine: Weigh out 25 mg of *o*-tolidine and place in a small test tube or vial. Add 4.5 ml of 0.2-*N* HCl and mix to dissolve. Chill the solution on ice. Dissolve 17.5 mg of sodium nitrite into 0.5 ml of ice-cold deionized water, and add it to the vial containing the *o*-tolidine. The solution should begin to turn an orange color, progressively getting darker as the reaction continues. React for 1 h on ice, mixing periodically. At the completion of the diazotization reaction, aliquots of the solution may be stored at −20°C.
2. Dissolve 10 mg of carrier protein into 0.5 ml 0.15-*M* sodium borate, 0.15-*M* NaCl, pH 9.0.
3. Dissolve 5 to 10 mg of a peptide hapten containing at least one tyrosine residue per milliliter of 0.15-*M* sodium borate, 0.15-*M* NaCl, pH 9.0.
4. Mix 0.5 ml of the peptide solution with 0.5 ml of the carrier protein solution. Chill on ice. Add 0.4 ml of the *bis*-diazotized tolidine solution. There should be a color change from orange to red almost immediately. Continue the reaction for 2 h on ice in the dark.
5. Purify the conjugate by gel filtration or dialysis using PBS, pH 7.4. The preparation is now ready for immunization purposes.

6.2. Mannich Condensation

Another approach for crosslinking haptens to carriers when the hapten has no available common functional groups (amines, carboxylates, sulfhydryls, etc.), but does possess active hydrogens, is to use the Mannich reaction. Using this strategy an active hydrogen-containing compound can be condensed with formaldehyde and an amine in the Mannich reaction resulting in a stable alkylamine linkage. In particular, compounds containing replaceable hydrogens provided by the presence of certain activating chemical constituents can be aminoalkylated using this reaction (see Chapter 3, Section 5.5, and Chapter 5, Section 6.1 for additional information on active hydrogens).

In its simplest form, the Mannich reaction consists of the condensation of formaldehyde (or sometimes another aldehyde) with ammonia, in the form of its salt, and another compound containing an active hydrogen. Instead of using ammonia, however, this reaction can be performed with primary or secondary amines, or even with amides. An example is illustrated in the condensation of acetophenone, formaldehyde, and a secondary amine salt (the active hydrogens are shown underlined):

$$C_6H_5COC\underline{H}_3 + CH_2O + R_2NH \cdot HCl \rightarrow C_6H_5COCH_2CH_2NR_2 \cdot HCl + H_2O$$

The Mannich reaction provides a viable alternative to the diazonium conjugation method (discussed previously), because of the disadvantages inherent in the instability of both the diazonium group and the resultant diazo linkage. By contrast, conjugations performed through Mannich condensations will result in stable covalent bonds. The Mannich reaction has also been used successfully to immobilize affinity ligands onto chromatography supports and particles (see Chapter 15, Section 2.7) (Hermanson *et al.*, 1992).

The crosslinking scheme using this method can make use of the native ε- and N-terminal amines on carrier proteins as the source of primary amine for the condensation reaction. Formaldehyde and the desired hapten to be coupled containing an appropriately active hydrogen are then added to the conjugation reaction.

To increase the yield of conjugated hapten using this procedure, cationized BSA (cBSA) is used as the carrier protein in the method described below (see Section 2.1, this chapter for additional information on this carrier). The greater density of amine groups on cBSA available for participation in the Mannich reaction over that available on native proteins provides better results in coupling active hydrogen-containing haptens. The use of cBSA to facilitate Mannich-based conjugations has been used successfully in the study of the immune response to certain allergens (Liao *et al.*, 2011).

One note of caution should be regarded when using the Mannich reaction. The hapten to be coupled should not contain any amine groups or hapten polymerization may occur preferential to conjugation to the carrier. For instance, when performing site-directed coupling of tyrosine-containing peptides through their phenolic side chain, the diazonium reaction should be used instead of the Mannich procedure, otherwise peptide-to-peptide coupling may occur.

Protocol

1. In a vial or test tube are placed and mixed:
   a. 200 µl of a solution containing 10 mg/ml cationized BSA (cBSA, Thermo Fisher) in 0.1-*M* MES, 0.15-*M* NaCl, pH 4.7 (coupling buffer). The acidic conditions of this coupling buffer are optimal for the Mannich reaction.
   b. 200 µl of a solution consisting of 10 mg/ml of a hapten containing an active hydrogen. The solution can be made up in absolute ethanol in the case of water-insoluble haptens and is made up in coupling buffer in the case of water soluble haptens.
   c. 50 µl of additional absolute ethanol in the case of water-insoluble haptens.
   d. 50 µl of 37% formaldehyde (Sigma) solution. *Caution:* Use a fume hood and avoid contact or inhalation of vapors.
2. Incubate the reaction mixture in a water bath or oven at a temperature of 37 to 57°C for a period of 3 to 24 h.
3. To separate unconjugated hapten and formaldehyde from the synthesized conjugate, apply the entire volume of reactants to a desalting column containing a bed volume of at least 10 times the volume of the reaction mixture. PBS, pH 7.2, can be used for the desalting step. The purified conjugate is recovered in the void volume.

The yield of conjugation using the Mannich reaction is dependent on the reactivity of active hydrogens within the hapten molecule. It is often difficult to predict the relative reactivity of any given compound in this reaction. Thus, trial and error may be necessary to determine the suitability of the Mannich procedure.

Figure 19.24 shows the conjugation reaction of the dye phenol red to cBSA using the Mannich reaction. The active hydrogens that participate in the conjugation are *ortho* to the hydroxyl group on the phenol ring. After purification of the conjugate by gel filtration to remove any unconjugated dye and formaldehyde, a wavelength scan was performed to assess the degree of conjugate formation. Figure 19.25 shows the results of this scan. The protein solution appeared red after

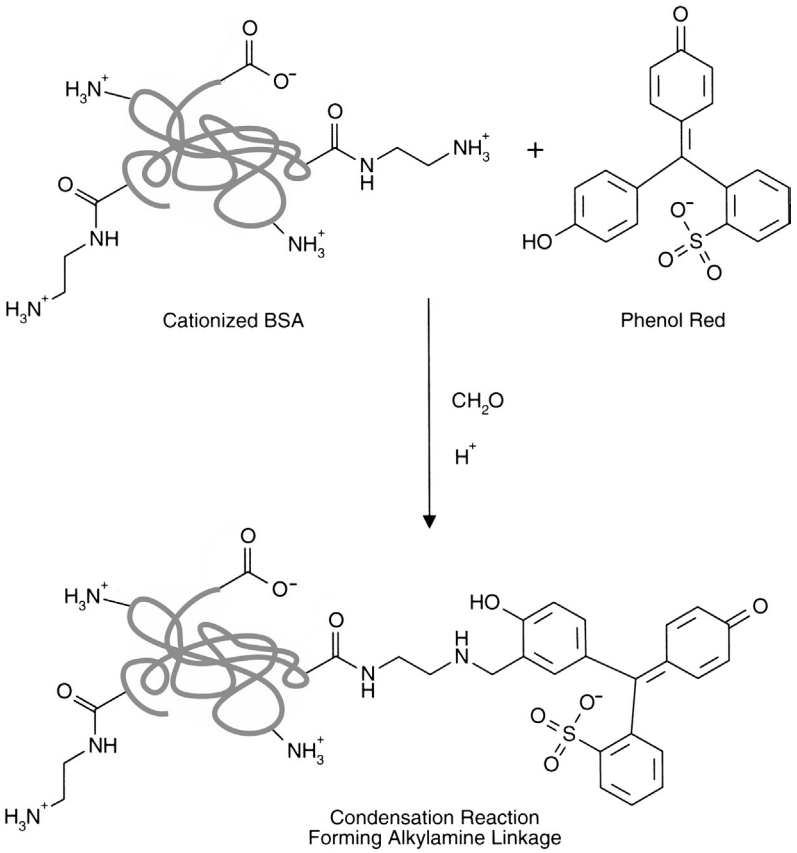

FIGURE 19.24 The conjugation of phenol red to cationized cBSA using the Mannich reaction.

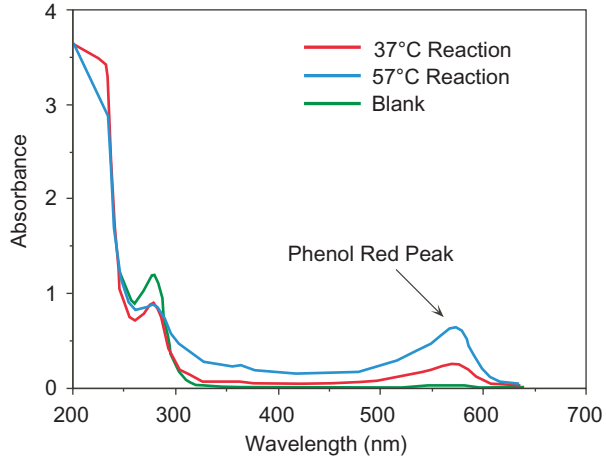

FIGURE 19.25 Absorbance scan comparing unconjugated cBSA with the same carrier that had been coupled with phenol red using the Mannich reaction. Two different reaction times are compared, indicating that extended reactions yield increased conjugate formation.

conjugation and desalting, indicating successful crosslinking had occurred.

The steroidal compound 17β-estradiol was also conjugated to cBSA using the Mannich reaction. Similar to phenol red, conjugation with estradiol occurs *ortho* to the hydroxyl group on its phenolic ring (Figure 19.26). After purification of the conjugate by gel filtration, it was injected in mice intraperitoneally using alum as adjuvant. Antibodies were successfully produced against the coupled estradiol. Controls consisting of unconjugated estradiol with and without mixed carrier molecules were also injected, but resulted in no antibody production.

7. GLUTARALDEHYDE-MEDIATED HAPTEN–CARRIER CONJUGATION

The homobifunctional crosslinking reagent glutaraldehyde can be used in a one- or two-step conjugation protocol to prepare hapten–carrier conjugates. Glutaraldehyde undergoes various cyclization and polymerization reactions in aqueous solution to form hemiacetal and aldol products (see Chapter 15, Section 2.1 for a detailed description of its reactions). These intermediates can react with primary amine groups on carrier proteins and haptens to covalently conjugate them together through direct linkages to its reactive hemiacetal forms or through double bond (Michael-type) addition products on aldol rings or polymers (Chapter 5,

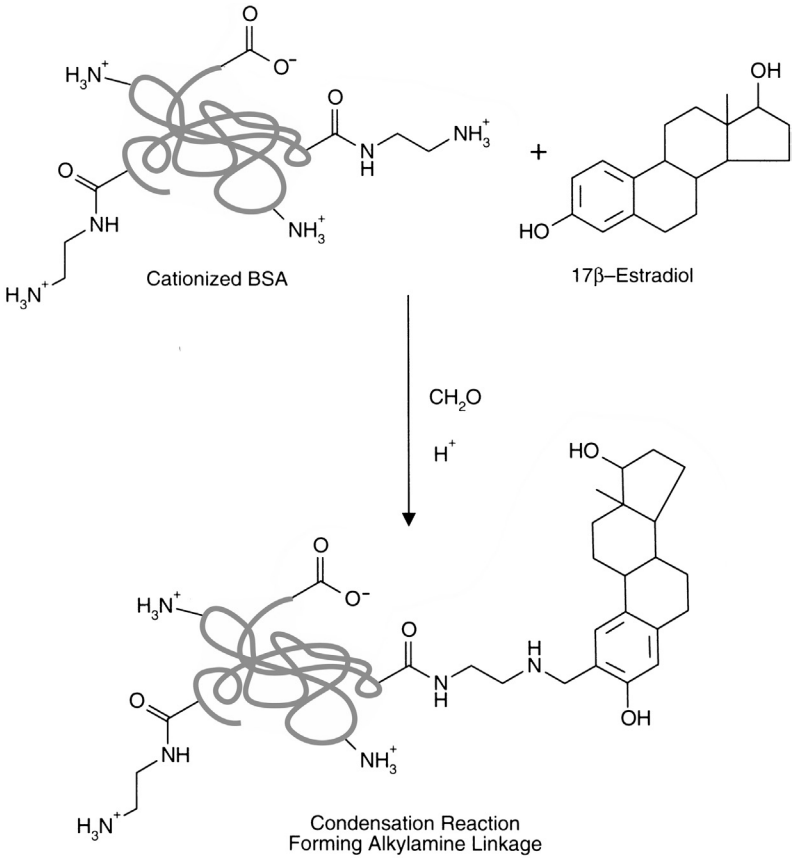

FIGURE 19.26 The conjugation of estradiol to cBSA using the Mannich reaction.

Section 6.2) (Korn *et al.*, 1972; Monsan *et al.*, 1975; Peters and Richards, 1977). One conjugation product, a quaternary pyridinium complex, can form as a crosslink between two lysine residues (Chapter 2, Section 4.4). Reduction of any Schiff bases formed during the reaction with sodium borohydride or sodium cyanoborohydride will result in stable secondary amine linkages.

The reaction of glutaraldehyde with protein carriers and peptide haptens involves mainly lysine ε-amine and N-terminal α-amino groups. The conjugates formed are usually of high molecular weight and may cause precipitation products. In addition, the orientation of the hapten on the carrier is indiscriminate with oligomers of the peptide predominating. However, despite the difficulties involved in controlling a glutaraldehyde-mediated crosslinking reaction, it still remains one of the most popular techniques for creating vaccine bioconjugates.

There are several different protocols commonly used in the literature to form glutaraldehyde conjugates. Some methods utilize a neutral pH environment in phosphate buffer (pH 6.8–7.5) while others use more alkaline pH conditions in carbonate buffer (pH 8–9) (Price *et al.*, 1993). In general, the higher pH conditions will result in aldol polymer formation of glutaraldehyde and create higher molecular weight conjugates. The concentration of glutaraldehyde in the reaction medium generally varies from 0.20% to 1% (Avrameas, 1969; Ford *et al.*, 1978; Jeanson *et al.*, 1988) with occasional use of very dilute solutions (0.05%). The lower concentrations of glutaraldehyde generate lower yields of conjugation and result in less stable conjugates (Briand *et al.*, 1985). In comparing the preparation of a peptide-carrier influenza A virus vaccine using glutaraldehyde conjugation *versus* an EDC-mediated conjugation process it was found that the glutaraldehyde vaccines were far more immunogenic (De Filette *et al.*, 2011).

The following procedure utilizes the one-step glutaraldehyde method. A two-step method may be used to somewhat limit polymerization of the conjugate (Chapter 20, Section 1.2). Varying the pH and the amount of glutaraldehyde added to the reaction can control the yield and molecular weight of the conjugates formed (see Chapter 15, Section 2.1).

Protocol

1. Dissolve the carrier protein (or another carrier that contains amine groups) in 0.1-*M* sodium carbonate, 0.15-*M* NaCl, pH 8.5, at a concentration of 2 mg/ml.
2. Add peptide hapten to the carrier solution to obtain a concentration of about 2 mg/ml. Alternatively, determine the molar ratio of peptide to carrier. Ratios

of 20:1 to 40:1 (peptide:carrier) usually result in good immunogens.

3. Add fresh glutaraldehyde to the peptide/carrier solution to obtain a 1% final concentration. Mix well. *Cautions:* Use of a fume hood is recommended when working with glutaraldehyde. Avoid contact with skin and clothing. Do not breathe vapors.
4. React for 2 to 4 h at 4°C. Periodically mix the solution or use a gentle rocker.
5. The conjugate may be stabilized by addition of a reductant such as sodium borohydride or sodium cyanoborohydride. Usually sodium cyanoborohydride is recommended for specific reduction of any Schiff bases that may have formed with the aldehyde groups, but since the conjugate has already formed at this point, the use of sodium borohydride will both reduce the associated Schiff bases and eliminate any remaining aldehyde groups. Add sodium borohydride to a final concentration of 10 mg/ml. Continue to react for 1 h at 4°C.
6. Purify the conjugate to remove excess reagents by gel filtration using a desalting resin or by dialysis. The presence of high molecular weight conjugates may cause some precipitation in the final product. If turbidity is evident, instead of using gel filtration, dialyze against PBS, pH 7.4.

8. REDUCTIVE AMINATION-MEDIATED HAPTEN–CARRIER CONJUGATION

Hapten molecules containing aldehyde residues may be crosslinked to carrier molecules by use of reductive amination (Chapter 4, Section 4). At alkaline pH values, the aldehyde groups form intermediate Schiff bases with available amine groups on the carrier. Reduction of the resultant Schiff bases with sodium cyanoborohydride or sodium borohydride creates a stable conjugate held together by secondary amine bonds.

Oligosaccharide haptens are especially amenable for coupling to carriers by reductive amination. Carbohydrate molecules may contain reducing ends that can be utilized for this purpose (Chapter 2, Section 2.1) (Gray, 1978), or aldehyde residues may be specifically created from other functional groups (Chapter 2, Section 4.4). Often, mild oxidation using sodium periodate can be used to cleave adjacent diols on sugar residues, forming reactive aldehyde groups (Anderson *et al.*, 1989), but this process may alter the antigenic epitopes from that of the native carbohydrate. In addition, the reducing ends of glycans can be coupled to carrier molecules after their release from glycoproteins or other glycoconjugates (Chapter 2, Section 4.6). This technique can be used to create antibodies that are specific for binding the glycosylation sites on certain proteins.

If the reducing ends of oligosaccharide or glycan molecules are used for this technique, then the time necessary to obtain good yields of hapten–carrier conjugates may be from several days to several weeks, depending upon the reaction conditions used. The extended reaction period is due to the limited time reducing sugars are in their open, aldehyde form (usually far less than 1% of the available saccharide at any given time). By contrast, if periodate-oxidized carbohydrate is used, then the reaction time is reduced to only hours. It should be noted, however, that extensive periodate oxidation could modify antigenic determinants and no longer reflect the native structure and characteristics of the carbohydrate.

Protocol

1. Dissolve the carrier protein at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 8.0.
2. Add the aldehyde-containing oligosaccharide to the carrier solution at a concentration sufficient to obtain at least a 20-fold molar excess of hapten to carrier. Adding a much greater molar excess of oligosaccharide to couple through reducing ends (i.e., up to 200-fold excess) will help to drive the conjugation reaction to completion.
3. Add sodium cyanoborohydride (Thermo Fisher) to the mixture to give a final concentration of 20 mg/ml. *Caution*: Highly toxic! Use a fume hood and avoid inhalation of dust or vapors. Seal the reaction vessel with parafilm. Do not use a rigid sealing cap, since cyanoborohydride will liberate hydrogen gas bubbles over time and may rupture the vessel.
4. React at room temperature or at 37°C with periodic mixing. Reaction times can vary significantly depending on the reactivity of the aldehyde group. For coupling of the reducing ends of polysaccharide or glycan molecules, continue the reaction for 2 to 4 days. High density derivatization through the reducing ends may take up to 2 weeks. For coupling of periodate oxidized carbohydrate, where the aldehyde residues are more accessible, the reaction is complete within 4 h. See Chapter 2, Section 4.6, for additional protocol options for working with glycans.
5. Purify the hapten–carrier conjugate to remove excess reductant by gel filtration or dialysis using a PBS, pH 7.4 buffer. Removal of unconjugated carbohydrate may be more difficult. If the oligosaccharide was of high molecular weight so that the unconjugated carbohydrate cannot be easily separated from the conjugate using typical desalting gels or small-porosity dialysis tubing, then a gel filtration matrix possessing greater exclusion limits may be used. However, often it is not necessary to remove unconjugated hapten from such preparations.

CHAPTER

20

Antibody Modification and Conjugation

The ability to conjugate an antibody to another protein or molecule is critically important for many applications in life science research, diagnostics, and therapeutics. Antibody conjugates have become one of the most important classes of biological agents associated with targeted therapy for cancer and other diseases. There literally are dozens of markers that have been identified on tumor cells to which monoclonal antibodies have been developed for targeted therapy (Carter *et al.*, 2004). The preparation of antibody conjugates to find and destroy cancer cells *in vivo* has become one of the leading strategies of research into investigational new drugs (McCarron *et al.*, 2005; Sievers and Senter, 2012). In most cases, the site-specific delivery of drugs involves the successful development of defined monoclonal antibody conjugates that can target diseased cells without affecting normal ones (see Chapter 1 for an extensive review of antibody conjugates used in the treatment of disease).

In addition, the use of antibody molecules in immunoassay or detection techniques encompasses a broad variety of applications affecting nearly every field of research. The availability of relatively inexpensive polyclonal and monoclonal antibodies of exacting specificity has made possible the design of reagent systems that can interact in high affinity with virtually any conceivable analyte. The directed specificity of purified immunoglobulins provides powerful tools for constructing immunological reagents. Using a number of conjugation and modification techniques, these specific antibodies can be modified to allow easy tracking in complex mixtures. For instance, an antibody molecule labeled with an enzyme, a fluorescent compound, or biotin provides a detectable complex able to be quantified or visualized through its tag. See Chapter 1 for an overview of how antibody conjugates are being used in a wide variety of applications in research, diagnostics, and therapeutics.

To maintain specificity in antibody conjugates derived from polyclonal antisera, only affinity-purified immunoglobulins should be used. Such purified preparations are isolated from antisera by affinity chromatography using the corresponding immobilized antigen (see Chapter 15). These preparations thus contain only that population of antibody molecules which has the desired antigenic specificity. Modification or conjugation of whole immunoglobulin fractions should be avoided, since other antibody populations will be present and cause considerable nonspecificity in the resultant activity of the reagent. Even secondary antibodies should be affinity purified and highly cross-adsorbed against immunoglobulins of other species' antibody types to prevent nonspecific interactions.

Monoclonal antibodies also should be purified by affinity chromatography prior to undergoing bioconjugation. This can be accomplished using an immobilized antigen or, if the antigen is not available in large enough quantities, an immobilized immunoglobulin binding protein (such as protein A) may be employed. Most monoclonals that can be successfully purified while maintaining activity also will be stable enough to withstand the rigors of chemical modification. Occasionally, however, a particular monoclonal will be partially or completely inactivated through the modification reaction. Sometimes this activity loss is caused by physically blocking the antigen binding sites during conjugation. In other cases, conformational changes in the complementarity-determining regions (CDRs) are the cause of the problem. If the antigen binding site is merely being blocked, then choosing an appropriate site-directed chemistry may solve the problem. On the other hand, some monoclonals are too labile to undergo modification reactions, regardless of the coupling method. Trial and error often is necessary when working with monoclonals to determine if modification will severely affect activity.

The unique structural characteristics of antibody molecules supply a number of choices for modification and conjugation schemes (Roitt, 1977; Goding, 1986; Harlow and Lane, 1988). The chemistry used to effect conjugate formation should be chosen to yield the best possible retention of antigen binding activity. A detailed

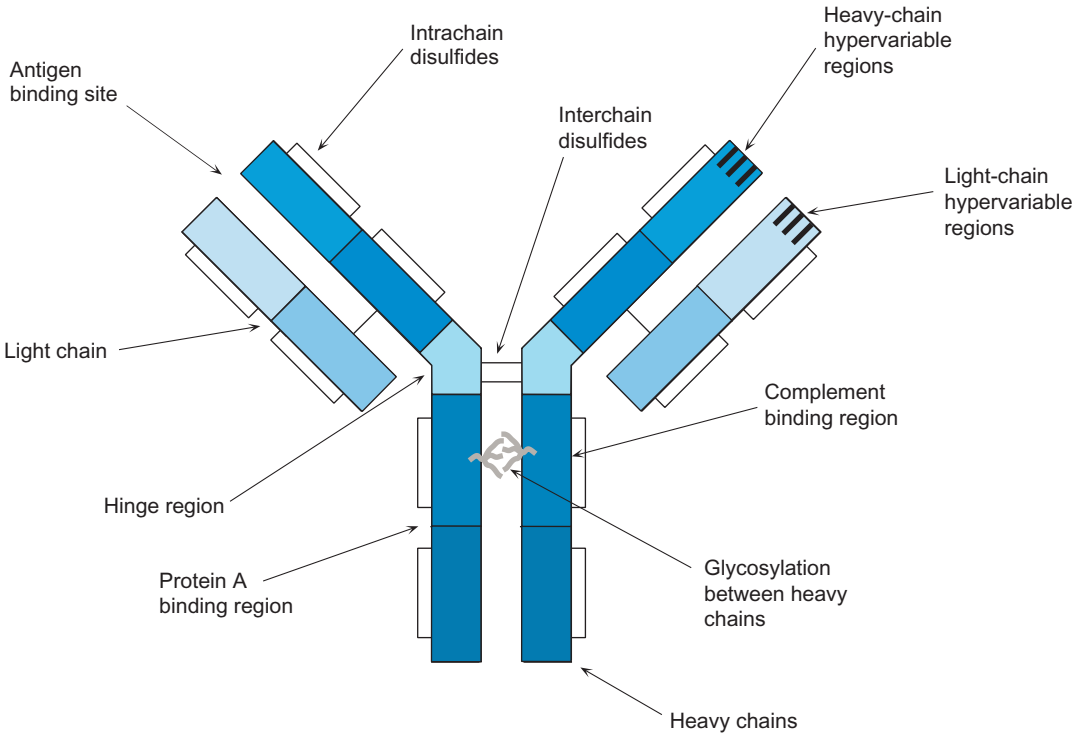

FIGURE 20.1 Detailed structure of an immunoglobulin G (IgG) antibody molecule.

illustration of antibody structure is shown in Figure 20.1. The most basic immunoglobulin G molecule is composed of two light and two heavy chains, held together by noncovalent interactions as well as a number of disulfide bonds. The light chains are disulfide-bonded to the heavy chains in the C_L and C_H^1 regions, respectively. The heavy chains are, in turn, disulfide-bonded to each other in the hinge region.

The two heavy chains in each immunoglobulin molecule are identical. Depending on the class of immunoglobulin, the molecular weight of these subunits ranges from about 50,000 to around 75,000. Similarly, the two light chains of an antibody are identical and have a molecular weight of about 25,000. For IgG molecules, the intact molecular weight representing all four subunits is in the range of 150,000 to 160,000.

There are two forms of light chains that may be found in antibodies. A single antibody will have light-chain subunits of either lambda (λ) or kappa (κ) variety, but not both types in the same molecule. The immunoglobulin class, however, is determined by an antibody's heavy-chain variety. A single antibody will also possess only one type of heavy chain (designated as γ, μ, α, ε, or δ). Thus, there are five major classes of antibody molecules, each determined from their heavy-chain type and designated as IgG, IgM, IgA, IgE, or IgD. Three of these antibody classes, IgG, IgE, and IgD, consist of the basic Ig monomeric structure containing two light and two heavy chains. By contrast, IgA molecules can exist as a singlet, doublet, or triplet of this basic Ig monomeric structure, while IgM molecules are large pentameric constructs (Figure 20.2). Both IgA and IgM contain an additional subunit, called the J chain—a very acidic polypeptide of molecular weight 15,000 that is very rich in carbohydrate. The heavy chains of immunoglobulin molecules also are glycosylated, typically in the C_H^2 domain within the Fc fragment region, but also may contain carbohydrate near the antigen binding sites.

There are two antigen binding sites on each of the basic Ig-type monomeric structures, formed by the heavy-/light-chain proximity in the N-terminal, hypervariable region at the tips of the "y" structure. The unique tertiary structure created by these subunit pairings produces the conformation necessary to interact with a complementary antigen molecule. The points of interaction on the immunoglobulin molecule with an antigen involve noncovalent forces that may encompass numerous non-sequential amino acids within the heavy and light chains. In other words, the binding site is formed not strictly from a linear sequence of amino acids on each chain, but from the unique orientation of these groups in three-dimensional space as the beta-sheet structure turns at the tips of the Fab regions. The binding site thus has affinity for a particular antigen molecule due to both structural complementarity as

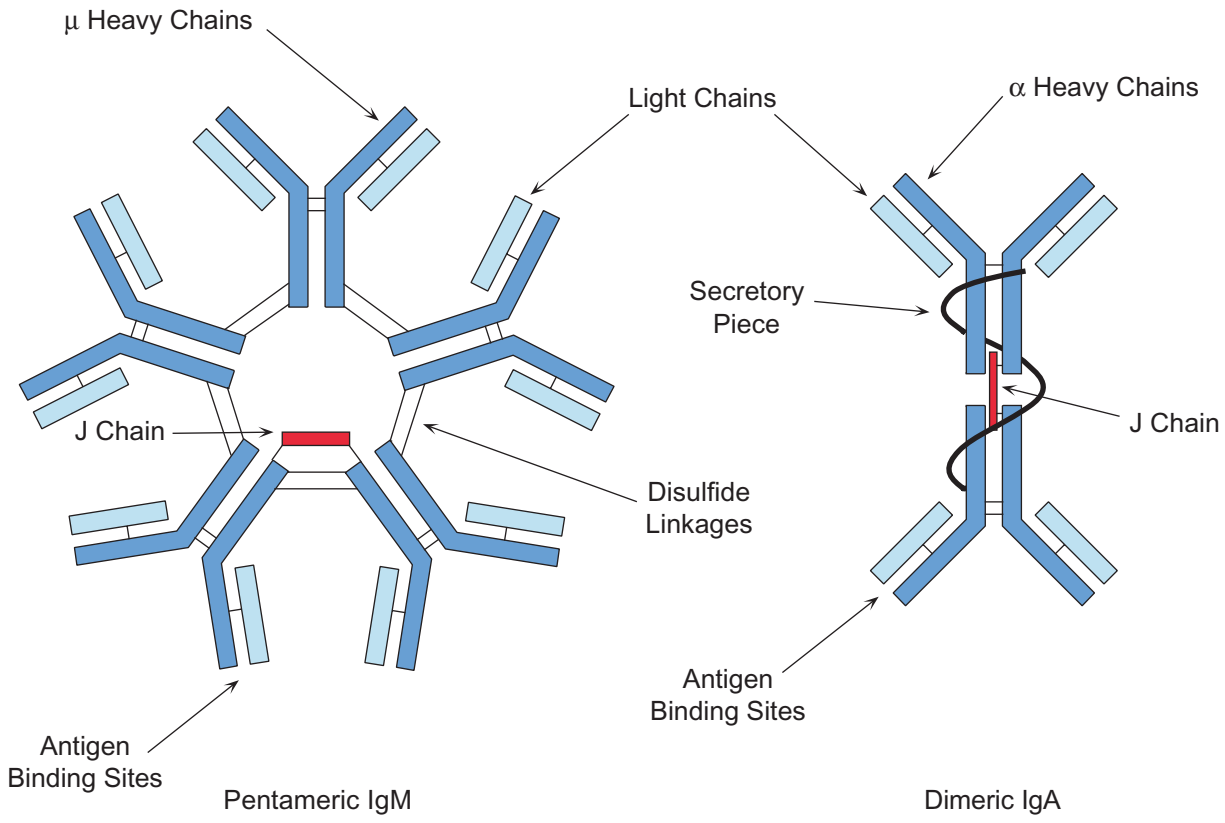

FIGURE 20.2 General structures of IgA and IgM antibodies.

well as the combination of van der Waals, ionic, hydrophobic, and hydrogen-bonding forces which may be created at each point of contact.

Useful enzymatic derivatives of antibody molecules may be prepared that still retain the antigen binding sites. Two principal digested forms of IgG antibodies are useful for creating immunological reagents. Enzymatic digestion with papain produces two small fragments of the immunoglobulin molecule, each containing an antigen binding site (called Fab fragments), and one larger fragment containing only the lower portions of the two heavy chains (called Fc, for "fragment crystallizable") (Section 1.4) (Coulter and Harris, 1983). Alternatively, pepsin cleavage produces one large fragment containing two antigen binding sites (called $F(ab')_2$) and many smaller fragments formed from extensive degradation of the Fc region (Rousseaux *et al.*, 1983). The $F(ab')_2$ fragment is held together by retention of the disulfide bonds in the hinge region. Specific reduction of these disulfides using 2-mercaptoethylamine (MEA), dithiothreitol (DTT), tris(2-carboxyethyl) phosphine (TCEP), or other reducing agents (Chapter 2, Section 4.1) produces two Fab′ fragments, each of which has one antigen binding site.

Antibody molecules possess a number of functional groups suitable for modification or conjugation purposes. Crosslinking reagents may be used to target lysine ε-amine and N-terminal α-amine groups. Carboxylate groups also may be coupled to another molecule using the C-terminal end as well as aspartic acid and glutamic acid residues. Although both amine and carboxylate groups are as plentiful in antibodies as they are in most proteins, the distribution of them within the three-dimensional structure of an immunoglobulin is nearly uniform throughout the surface topology. For this reason, conjugation procedures that utilize these functionalities will crosslink to the most accessible ones in a somewhat random fashion on nearly all parts of the antibody molecule. This, in turn, leads to a random orientation of the antibody within the conjugate structure, which may block the antigen binding sites against the surface of another coupled protein or molecule. Obscuring the binding sites in this manner results in decreased antigen binding activity in the conjugate compared to that observed for the unconjugated antibody. This effect also is dependent on how many points of modification are made on the antibody molecules. Controlling the level of modification and conjugation will typically lead to antibody conjugates having the highest possible activity in the anticipated application.

Conjugation chemistry done with antibody molecules may be more successful at preserving activity

if the functional groups that are utilized are present in limiting quantities or only at discrete sites on the molecule. Such "site-directed conjugation" schemes make use of crosslinking reagents that can specifically react with residues that are only in certain positions on the immunoglobulin surface—usually chosen to be well removed from the antigen binding sites. By proper selection of the conjugation chemistry and knowledge of antibody structure, the immunoglobulin molecule can be oriented so that its bivalent binding potential for antigen remains maximally available.

Two site-directed chemical reactions are especially useful in this regard. The disulfides in the hinge region that hold the heavy chains together can be cleaved with a reducing agent (such as MEA, DTT, or TCEP) to reveal some thiols in the intact antibody or in some cases to create two half-antibody molecules that have thiols available, each containing an antigen binding site (Palmer and Nissonoff, 1963; Sun *et al.*, 2005) (Chapter 2, Section 4.1). Alternatively, smaller antigen binding fragments may be made from pepsin digestion (which makes $F(ab')_2$ fragments lacking most of the Fc region) and similarly reduced to form monovalent Fab′ molecules containing thiols. Both of these preparations contain free sulfhydryl groups that can be targeted for conjugation using thiol-reactive probes or crosslinkers. Conjugations done using hinge-region SH groups will orient the attached protein or other molecule away from the antigen binding sites, thus preventing blockage of these regions and better preserving activity.

The second method of site-directed conjugation of antibody molecules takes advantage of the glycan carbohydrate chains typically attached to the C_H^2 domain between the heavy chains in the Fc region. Mild oxidation of the polysaccharide sugar residues with sodium periodate will generate aldehyde groups. A crosslinking or modification reagent containing a hydrazide or aminooxy functional group then can be used to specifically target these aldehydes for coupling to another molecule. Directed conjugation through antibody carbohydrate chains may avoid the antigen binding regions while allowing for use of intact antibody molecules. This method can result in the highest retention of antigen binding activity within the ensuing conjugate. However, care should be taken in using this method, because some antibody molecules can be glycosylated near the antigen binding area, thus potentially interfering with activity upon conjugate formation (Wright *et al.*, 1991).

Another limitation to the use of this strategy is the necessity for the antibody molecule to be glycosylated. Antibodies of polyclonal origin (from antisera) are usually glycosylated and work well in this procedure, but other antibody preparations may not possess polysaccharide. In particular, some monoclonals may not be post-translationally modified with carbohydrate after hybridoma synthesis. Recombinant antibodies grown in bacteria may also be devoid of carbohydrate. Before attempting to use a conjugation method that couples through polysaccharide regions, it is best to test the antibody to see if it contains carbohydrate—especially if the immunoglobulin is of hybridoma or recombinant origin.

1. PREPARATION OF ANTIBODY–ENZYME CONJUGATES

The most extensive application of antibody conjugation using crosslinking reagents is for the preparation of antibody–enzyme conjugates. Since the development of enzyme-linked immunosorbent assay (ELISA) systems, the ability to make conjugates of specific antibodies with enzymes has provided the means to quantify or detect hundreds, if not thousands, of important analytes. The use of enzymes as labels in immunoassay procedures surpassed radioactive tags as the means of detection, primarily due to the long-term stability potential of an enzyme system and the hazards and waste problems associated with radioisotopes. Designed properly, an antibody–enzyme conjugate assay system can be just as sensitive as a radiolabeled antibody system.

The development of viable methods for crosslinking antibody and enzyme molecules—methods that retain high antigen binding activity coupled with high enzymatic activity—has formed the basis for much of today's diagnostic industries, literally a multi-billion dollar enterprise with enormous impact on world health (see Chapter 1 for an extensive review). The conjugation chemistries that make this possible are designed around a knowledge of both antibody and enzyme structure. The best methods make use of definitive site-directed chemistries that target both molecules in regions removed from their respective active centers.

The major enzymes used in ELISA technology include horseradish peroxidase (HRP), alkaline phosphatase (AP), β-galactosidase (β-gal), and glucose oxidase (GO). See Chapter 22 for a detailed description of each enzyme's properties and activities. HRP is by far the most popular enzyme used in antibody–enzyme conjugates. One survey of enzyme use stated that HRP is incorporated in about 80% of all antibody conjugates, most of them utilized in diagnostic assay systems. AP is the second-most popular choice for antibody–enzyme conjugation, being used in almost 20% of all commercial enzyme-linked assays. Although β-gal and GO are used frequently in research labs and cited numerous times in the literature, their utilization for commercial ELISA applications represents less than 1% of the total assays available.

Conjugation methods for attaching these enzymes to antibody molecules vary according to the functional groups available. HRP is a glycoprotein and easily can be periodate oxidized for coupling *via* reductive amination to the amino groups on immunoglobulins. β-Gal contains abundant free sulfhydryl groups in its native state. The thiols can be utilized for coupling to the sulfhydryl-reactive end of heterobifunctional crosslinkers such as SMCC (Chapter 6, Section 1.3). Any of these enzymes can be conjugated through their amine groups using crosslinking agents such as glutaraldehyde or various heterobifunctional agents. The catalytic properties and activation methods often used with these enzymes are discussed in detail in Chapter 22.

The following sections describe the most common reagents and reactions used to create antibody–enzyme conjugates.

1.1. NHS Ester–Maleimide-Mediated Conjugation

Heterobifunctional reagents containing an amine-reactive NHS ester on one end and a sulfhydryl-reactive maleimide group on the other end generally have great utility for producing antibody–enzyme conjugates (see Chapter 6, Section 1). Crosslinking reagents possessing these reactive groups can be used in controlled, multi-step procedures that yield conjugates of defined composition and high activity. Among the most popular of these NHS ester–maleimide crosslinkers are SMCC (Chapter 6, Section 1.3), MBS (Chapter 6, Section 1.4), and GMBS (Chapter 6, Section 1.7). The use of any one of these crosslinkers in the following protocol can result in useful conjugates. However, SMCC and its water soluble analog, sulfo-SMCC, possess the most stable maleimide functionalities and are probably the most widely used crosslinkers of this type. This increased stability to hydrolysis of SMCC's hindered maleimide group allows activation of either enzyme or antibody *via* the amine-reactive NHS ester end, resulting in a maleimide-activated intermediate. The intermediate species can then be purified away from excess crosslinker and reaction byproducts before mixing with the second protein to be conjugated. The multi-step nature of this process limits polymerization of the conjugated proteins and provides control over the extent and sites of crosslinking. Antibody conjugation using SMCC or sulfo-SMCC continues to be a popular route to the formation of conjugates useful in detection and targeted therapeutic purposes (Nwe *et al.*, 2011; Lee *et al.*, 2012; Sukhanova *et al.*, 2012).

In addition, the PEG-based heterobifunctional crosslinkers described in Chapter 18, Section 1.2, provide enhanced water solubility for antibody conjugation applications. Conjugation of antibody molecules using a maleimide–PEG_n–NHS ester compound actually increases the solubility of the antibody and may help to maintain better stability for certain sensitive monoclonals than the traditional aliphatic crosslinkers. The methods described below for SMCC may be used with success for PEG-based reagents or other maleimide–NHS ester heterobifunctionals.

In protocols involving enzyme activation with SMCC and subsequent conjugation with an antibody molecule (the most common method of producing antibody–enzyme conjugates with this crosslinker), the antibody usually has to be prepared for coupling to the maleimide groups on the enzyme by introduction of sulfhydryl residues. Since antibodies typically do not contain free sulfhydryls accessible for conjugation, they must be fabricated by chemical means. Two main options are available for creating sulfhydryl functions on immunoglobulin molecules. The disulfide residues in the hinge region of the IgG structure may be reduced with DTT, TCEP, or MEA to cleave the immunoglobulin into two half-antibody molecules each possessing one antigen binding site and the requisite sulfhydryls. Alternatively, a thiolation reagent may be used to modify the intact antibody to contain sulfhydryls (Chapter 2, Section 4.1). Both options are described below. Although there are numerous thiolation reagents from which to choose, only SATA and Traut's reagent are discussed in this section, since they are the most popular.

Activation of Enzymes with NHS Ester–Maleimide Crosslinkers

The first step in conjugation of antibody molecules and enzymes using NHS ester–maleimide crosslinkers usually is modification of the enzyme with the NHS ester end of the reagent to produce a maleimide-activated derivative (Figure 20.3). The protocol described here uses sulfo-SMCC as the crosslinking agent due to the enhanced stability of its maleimide group and the water-solubility afforded by the negatively charged sulfonate on its sulfo-NHS ring. Other NHS ester–maleimide crosslinkers may be substituted without difficulty; however, water-insoluble varieties should be solubilized in DMSO or DMF prior to addition to the aqueous reaction mixture.

One note should be mentioned before proceeding: when conjugating antibody molecules with β-galactosidase, the antibody is usually activated with sulfo-SMCC first to take advantage of the indigenous sulfhydryl groups on the enzyme. Therefore, if β-gal is being used, substitute the antibody for the enzyme mentioned in this protocol, and then after the purification step add the enzyme in the desired molar excess to produce the final conjugation.

The following protocol describes the activation of horseradish peroxidase (HRP) with sulfo-SMCC.

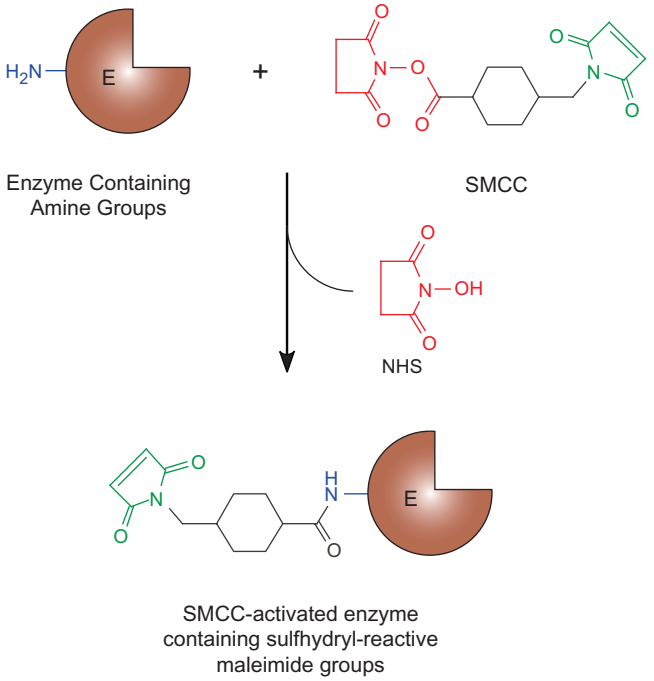

FIGURE 20.3 The reaction of SMCC with the amine groups on enzyme molecules yields a maleimide-activated derivative capable of coupling with sulfhydryl-containing antibody molecules.

Activation of other enzymes is performed similarly, with the appropriate adjustments in the mass of enzyme added to the reaction to account for differences in molecular weight.

The gel filtration column described in step 3 should be prepared and equilibrated prior to starting the modification reaction. Enzymes activated with sulfo-SMCC are available from Thermo Fisher.

Protocol

1. Dissolve 18 mg of HRP in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 20 to 30 mg/ml. The more highly concentrated the enzyme solution, the more efficient the modification reaction will be. For conjugating smaller quantities of enzyme and antibody, proportionally decrease the amount of the reagents used, while attempting to maintain the same relative concentrations in solution.
2. Add 6 mg of sulfo-SMCC (Thermo Fisher) to the HRP solution. Mix to dissolve and react for 30 min at room temperature. Alternatively, two 3-mg additions of crosslinker may be performed—the second one after 15 min of incubation—to obtain even more efficient modification.
3. Immediately purify the maleimide-activated HRP away from excess crosslinker and reaction byproducts by gel filtration using a desalting resin. Use 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, as the chromatography buffer. At this concentration, HRP can be observed visually as it flows through the column due to the color of its heme ring. Pool the fractions containing the HRP peak. After elution, adjust the HRP concentration to 10 mg/ml for the conjugation reaction. At this point, the maleimide-activated enzyme may be frozen and lyophilized to preserve its maleimide activity. The modified enzyme is stable for at least 1 year in a freeze-dried state. If kept in solution, the maleimide-activated HRP should be used immediately to conjugate with an antibody following one of the three options outlined below.

Conjugation with Reduced Antibodies

One method of introducing sulfhydryl residues into antibody molecules for conjugation with maleimide-activated enzymes is to reduce indigenous disulfide groups in the hinge region of the immunoglobulin structure. Reduction with low concentrations of DTT, TCEP, or 2-mercaptoethylamine (MEA) will principally cleave the disulfide bonds holding the heavy chains together, but the disulfides between the heavy and light chains may also be partially reduced to some extent. In a comparative study of disulfide reducing agents, it was determined that use of the relatively strong reductants DTT and TCEP required only 3.25 and 2.75 mole equivalents per mole equivalent of antibody molecule to achieve the reduction of two inter-chain disulfide bonds between the heavy chains of a monoclonal IgG (Sun *et al.*, 2005). This limited reduction strategy retains intact bispecific antibody molecules while providing discrete sites for conjugation to thiols. Using higher concentrations of DTT, TCEP, or MEA will result in complete cleavage of the disulfides between the heavy chains and formation of two half antibody molecules, each containing an antigen binding site. Under these conditions, some inter-chain cleavage also will occur and result in some smaller fragments being produced. Similar reduction can be done with $F(ab')_2$ fragments produced from pepsin digestion of IgG molecules. Either of these reduction steps creates half-antibody fragments, each containing one heavy and one light chain and one antigen binding site (Figure 20.4). The sulfhydryl groups produced by this reduction are able to couple with maleimide-activated enzymes without blocking the antigen binding area.

Antibody reduction is usually carried out in the presence of EDTA to prevent re-oxidation of the sulfhydryls by metal catalysis. In phosphate buffer at pH 6 to 7 and 4°C, one report stated that the number of available thiols decreased only by about 7% in the presence of EDTA over a 40-h time span. In the absence of EDTA, this sulfhydryl loss increased to 63 to 90% in the same period (Yoshitake *et al.*, 1979).

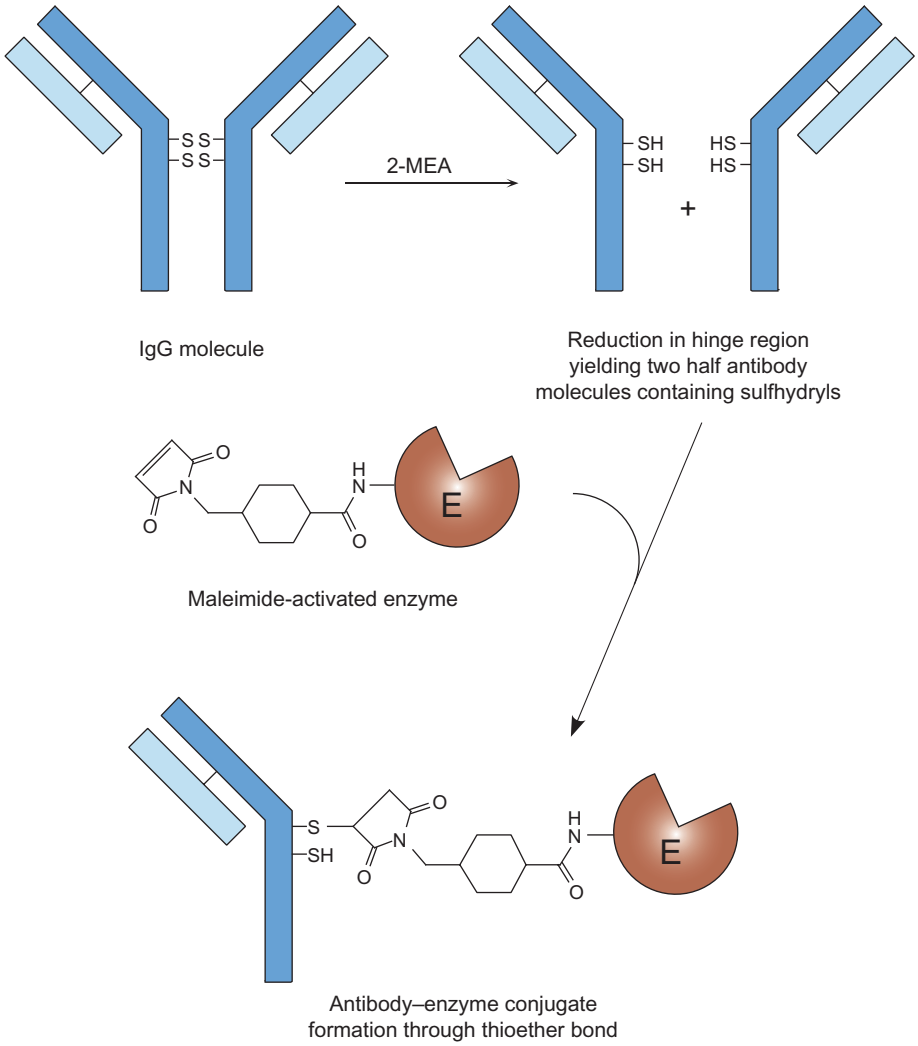

FIGURE 20.4 Reduction of the disulfide bonds within the hinge region of an IgG molecule can produce half-antibody molecules containing thiol groups. More limited reduction with low concentrations of reducing agents can be used to retain the intact antibody structure while revealing several thiols for conjugation. Reaction of these reduced antibodies with a maleimide-activated enzyme creates a conjugate through thioether bond formation.

In the following protocol, the most critical aspects are the concentration of reducing agent and EDTA in the reaction mixture. Good reduction of IgG will take place with 50- to 100-m*M* MEA and 1- to 100-m*M* EDTA. For DTT or TCEP, the concentration of reducing agent should be lowered to a 3-fold molar excess over the amount of antibody present. The pH of the reaction can vary from pH 6 to 9, with about pH 8 being optimal. The absolute concentration of antibody can vary and still yield acceptable results. With some monoclonals, however, reduction may not be completely efficient in cleaving the antibody between the heavy-chain pairs. Particularly, some subclasses of immunoglobulins contain structures with unusually high numbers of disulfides in the hinge region, and some of them may not be reduced except under much higher concentrations of reductant. Polyclonal populations typically work well in this procedure.

A final consideration is to provide adequate desalting of the reduced antibody molecule from excess reducing agent. If even a small amount of a thiol-containing reductant remains, subsequent conjugation with a maleimide-activated enzyme will be inhibited.

Protocol

1. Dissolve the IgG to be reduced at a concentration of 1 to 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA.
2. Add 6 mg of MEA to each ml of antibody solution. Alternatively, add DTT or TCEP to a final concentration equal to 3 mole equivalents per mole equivalent of antibody present. Mix to dissolve.

3. Incubate for 90 min at 37°C.
4. Purify the reduced IgG by gel filtration using a desalting resin. Perform the chromatography using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA as the buffer. To obtain efficient separation between the reduced antibody and excess reductant, the sample size applied to the column should be at a ratio of no more than 5% sample volume to column volume. Collect 0.5-ml fractions and monitor for protein at 280 nm. Since the reducing agents typically have no absorbance at 280 nm, the elution profile also may be monitored by use of the BCA Protein Assay method (Thermo Fisher). The BCA–copper reagent reacts with the reductants to produce a colored product. EDTA in the chromatography buffer will inhibit the BCA method somewhat, but a color response to the reducing agent peak will still be obtained. A micromethod for monitoring each fraction is as follows:
   a. Take 5 µl from each fraction collected and place in a separate well of a microtiter plate.
   b. Add 200 µl of BCA working reagent.
   c. Incubate at room temperature or 37°C for 15 to 30 min or until color develops. The color response may be measured visually or by absorbance at 562 nm. To ensure good separation between the antibody peak and excess MEA, at least one fraction of little or no color should separate the two peaks.
5. Pool the fractions containing antibody and immediately mix with an amount of maleimide-activated enzyme to obtain the desired molar ratio of antibody-to-enzyme in the conjugate. Use of a 4:1 (enzyme:antibody) molar ratio in the conjugation reaction usually results in high-activity conjugates suitable for use in many enzyme-linked immunoassay procedures. Higher molar ratios also have been used with success.
6. React for 30 to 60 min at 37°C or 2 h at room temperature. The conjugation reaction also may be carried out at 4°C overnight.
7. The conjugate may be further purified away from unconjugated enzyme by the procedures described in Section 1.5. For storage, the conjugate should be kept frozen, lyophilized, or sterile filtered and kept at 4°C. Stability studies may have to be carried out to determine the optimal method of long-term storage for a particular conjugate.

ETAC REAGENTS FOR DITHIOL CONJUGATION

The use of disulfide reduction within antibodies to create sites for bioconjugation has the potential deficiency of breaking down the subunit structure of an antibody. This may occur even when using limiting quantities of reducing agent, such as the method described in the previous protocol. Each time a cysteine disulfide is reduced to two thiols, the subsequent conjugation step usually involves the reaction of only one of the thiols with a reactive group, such as in the use of a maleimide, haloacetyl, vinyl sulfone, or epoxy group. Using these common reagents, one of the two sulfhydryls gets covalently linked to the crosslinker, but the other one may remain free without attachment. A broken disulfide linkage within the antibody may allow for subunit dissociation to occur even if the conjugation reaction is successful. However, this situation may be overcome if the conjugation reaction is able to link both thiols simultaneously using a single crosslinking agent.

Both thiols of a reduced disulfide within a protein can be targeted concurrently using a unique compound containing two reactive components consisting of an α,α-*bis*[(*p*-tolylsulfonyl)methyl]-*m*-aminoacetophenone group, termed an "equilibrium transfer alkylation crosslink" reagent (ETAC) (Liberatore *et al.*, 1990; Rosario *et al.*, 1990; Wilbur *et al.*, 1994). The two *p*-tolylsulfonyl groups on this compound react with neighboring thiols in a multi-step reaction sequence leading to the formation of two thioether bonds with a three-carbon bridge between the thiols (Figure 20.5). The molecular distance between the two thiols after disulfide reduction is nearly perfect for covalent conjugation with both reactive *p*-tolylsulfonyl groups, thus forming a linkage which maintains subunit association in proteins where disulfides occur between the subunits of multi-subunit proteins, such as within antibodies. The modification of hinge region disulfides with this reagent yields highly specific site-directed conjugation while maintaining the bifunctional nature of the intact antibody's antigen binding sites. Similarly, a $F(ab')_2$ fragment can be labeled with an ETAC reagent and maintain the bifunctional nature of the antibody, which normally does not occur when the reduced disulfides of the fragments are labeled using standard alkylation reagents.

ETAC derivatives have been used to biotinylate proteins and antibodies after disulfide reduction and to add PEG modifications to selected sites (Brocchini *et al.*, 2008; Choi *et al.*, 2009). At the time of writing, ETAC conjugation strategies are being applied to drug development and biotherapeutic conjugates, but no reagent systems are commercially available.

Conjugation with 2-Iminothiolane-Modified Antibodies

Traut's reagent, or 2-iminothiolane, is described in Chapter 2, Section 4.1. The reagent reacts with amine groups in proteins or other molecules in a ring-opening reaction to result in covalent modifications containing terminal sulfhydryl residues (Figure 20.6). Antibodies may be modified with Traut's reagent to create the

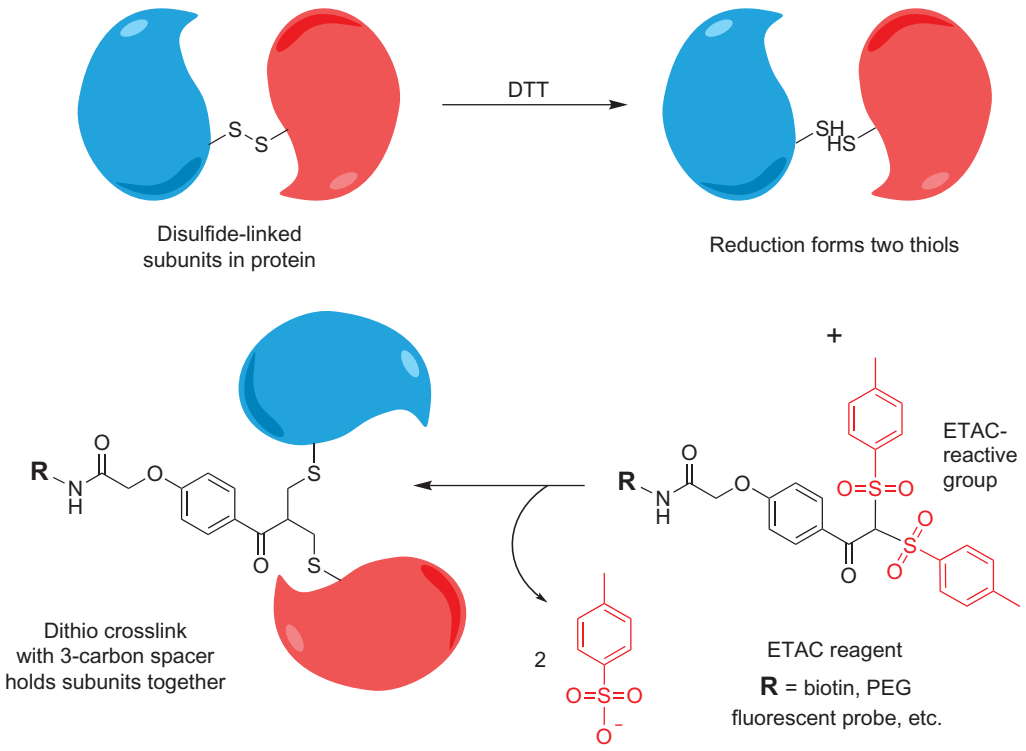

FIGURE 20.5 ETAC reagents can be used to form a covalent linkage between two thiols that were previously a part of a disulfide bond, thus retaining the subunit structure of reduced proteins or antibodies.

requisite sulfhydryls necessary for conjugation with a maleimide-activated enzyme. Unlike the disulfide reduction method described in the previous section, this protocol better retains the divalent nature of the antibody molecule. However, since amine modification of antibodies can take place at virtually any available lysine ε-amine location, the resultant sulfhydryls are distributed almost randomly over the immunoglobulin structure. Conjugation through these SH groups may result in a certain population of antibodies that have their antigen binding sites obscured or blocked by enzyme molecules. Typically, however, enough free antigen binding sites are available in the conjugate to result in high-activity complexes useful in ELISA procedures.

The number of sulfhydryls created on the immunoglobulin using thiolation procedures such as this one is more critical to the yield of conjugated enzyme molecules than the molar excess of maleimide-activated enzyme used in the conjugation reaction. Therefore, it is important to use a sufficient excess of Traut's reagent to obtain a sufficient number of available sulfhydryls. In addition, the thiolated antibody should be used immediately to prevent loss of thiols due to re-cyclization, which can tie up the available sulfhydryls in an undesired side reaction (see Chapter 2, Section 4.1).

Protocol

1. Dissolve the antibody to be modified at a concentration of 1 to 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA. High levels of EDTA often are required to completely stop metal-catalyzed oxidation of sulfhydryl groups when working with serum proteins—especially polyclonal antibodies purified from antisera. Presumably, carry-over of iron from partially hemolyzed blood is the contaminating culprit.
2. Add 2-iminothiolane (Thermo Fisher) to this solution to give a molar excess of 20 to 40 times over the amount of antibody present (MW of Traut's reagent is 137.63). Solid 2-iminothiolane may be added despite the fact that the compound is relatively insoluble in aqueous solution. As the reagent reacts, it will be completely drawn into solution. Alternatively, a stock solution of Traut's may be made in DMF and an aliquot added to the antibody solution (not to exceed 10% DMF in the final solution).
3. React for 30 min at 37°C or 1 h at room temperature.
4. Purify the thiolated antibody by gel filtration using a desalting resin. Perform the chromatography using

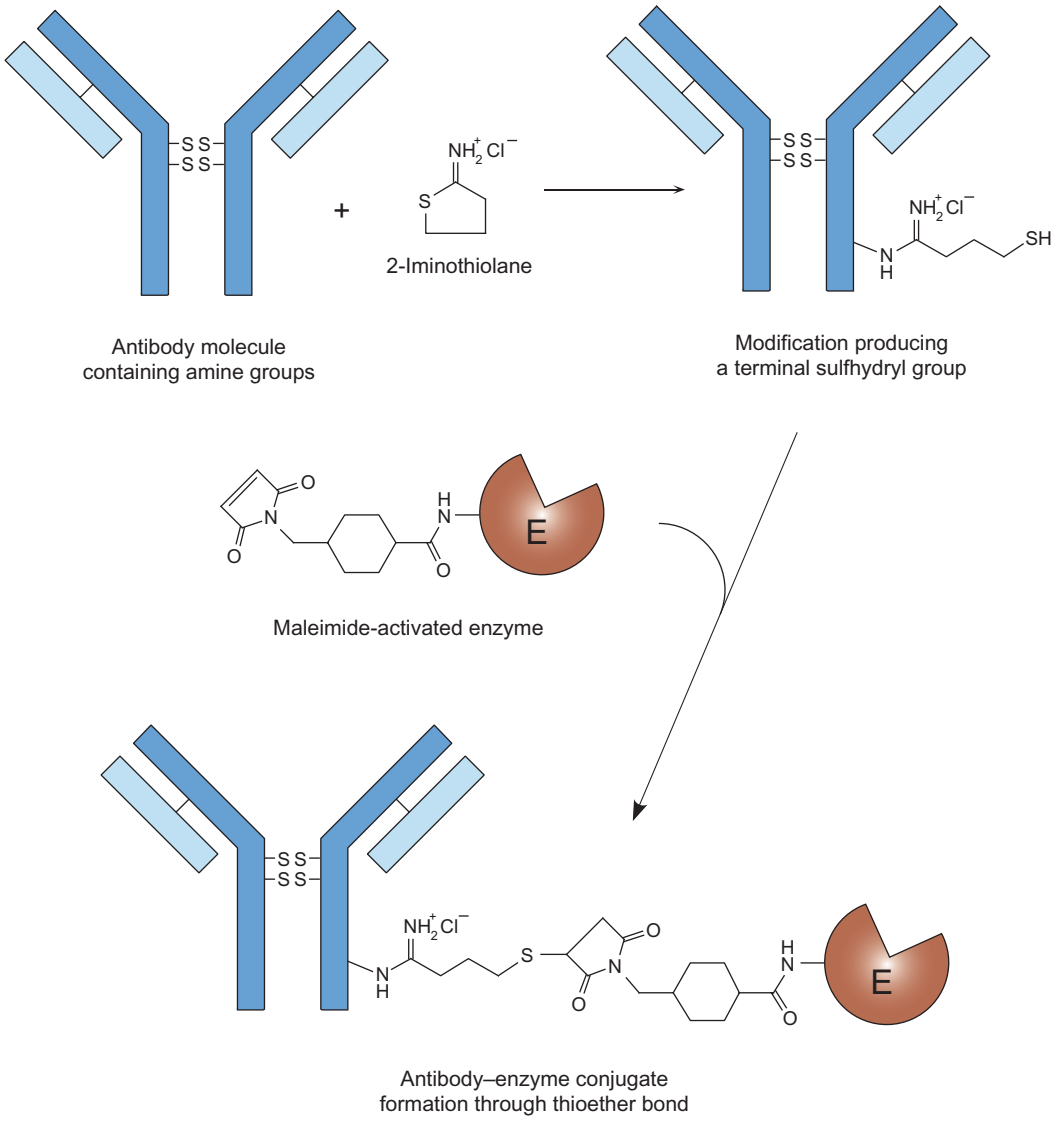

FIGURE 20.6 Antibodies may be modified with 2-iminothiolane at their amine groups to create sulfhydryls for conjugation with SMCC-activated enzymes. The maleimide groups on the derivatized enzyme react with the thiols on the antibody to form thioether bonds.

0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA as the buffer. To obtain efficient separation between the reduced antibody and excess reductant, the sample size applied to the column should be at a ratio of no more than 5% sample volume to the total column volume. Collect 0.5-ml fractions and monitor for protein at 280 nm. To monitor the separation of the second peak (excess Traut's reagent), the BCA Protein Assay reagent (Thermo Fisher) may be used according to the procedure described in the previous section, protocol step 4.

5. Pool the fractions containing antibody and immediately mix with an amount of maleimide-activated enzyme to obtain the desired molar ratio of antibody-to-enzyme in the conjugate. Use of a 4:1 to 15:1 (enzyme:antibody) molar ratio in the conjugation reaction usually results in high-activity conjugates suitable for use in many enzyme-linked immunoassay procedures.
6. React for 30 to 60 min at 37°C or 2 h at room temperature. The conjugation reaction also may be performed at 4°C overnight.
7. The conjugate may be further purified away from unconjugated enzyme by the procedures described in Section 1.5. For storage, the conjugate should be kept frozen, lyophilized, or sterile filtered and kept at 4°C. Stability studies may have to be performed to determine the optimal method of long-term storage for a particular conjugate.

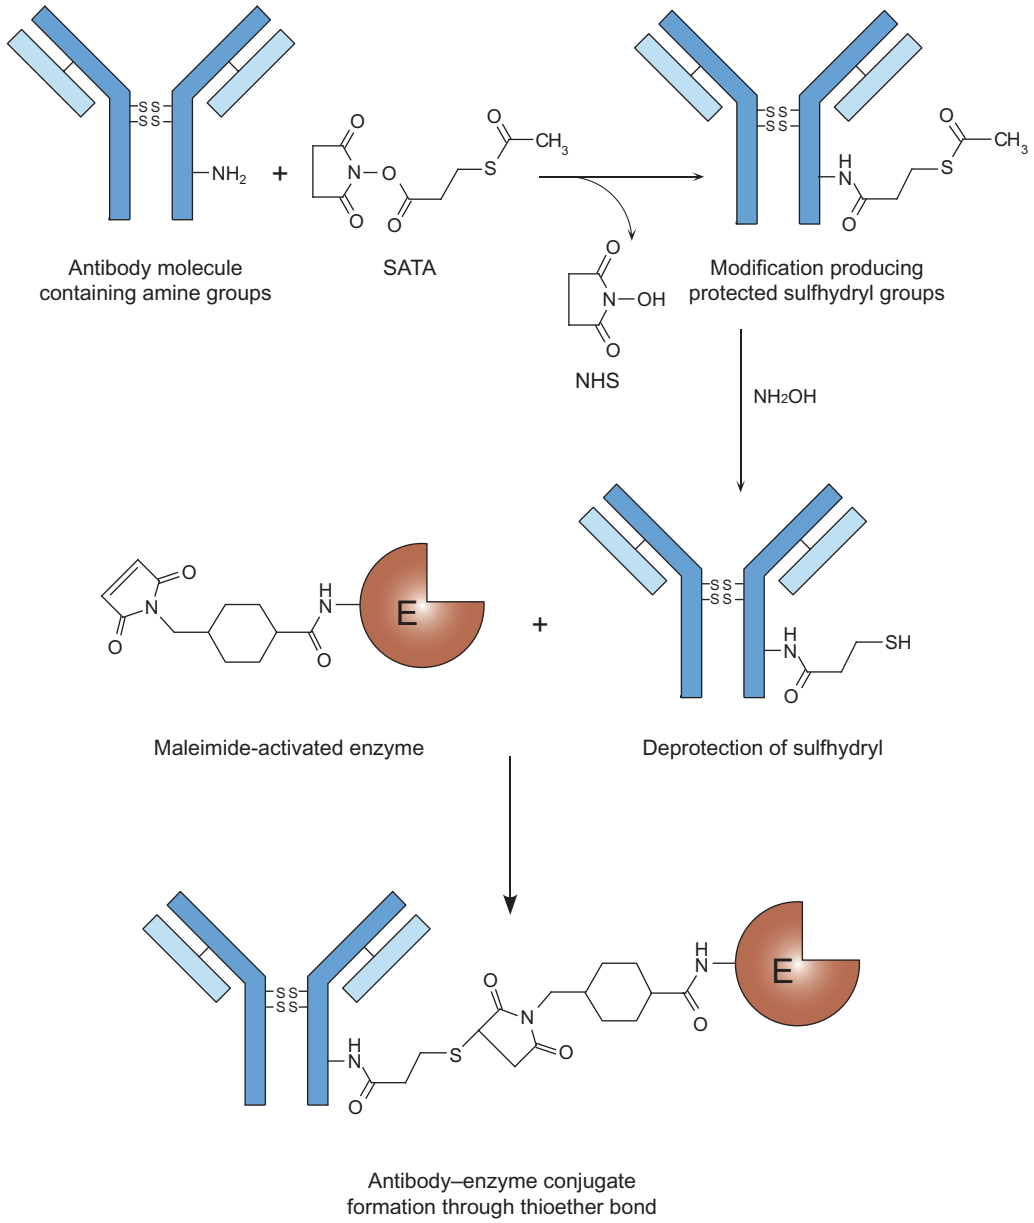

FIGURE 20.7 Available amine groups on an antibody molecule may be modified with the NHS ester end of SATA to produce amide bond derivatives containing terminal protected sulfhydryls. The acetylated thiols may be deprotected by treatment with hydroxylamine at alkaline pH. Reaction of the thiolated antibody with a maleimide-activated enzyme results in thioether crosslinks.

Conjugation with SATA-Modified Antibodies

N-Succinimidyl-*S*-acetylthioacetate (SATA) is a thiolation reagent described in detail in Chapter 2, Section 4.1. The compound reacts with primary amines *via* its NHS ester end to form stable amide linkages. The acetylated sulfhydryl group is stable until deacetylated with hydroxylamine. Thus, antibody molecules may be thiolated with SATA to create the sulfhydryl target groups necessary to couple with a maleimide-activated enzyme (Figure 20.7). Using this reagent, stock preparations of SATA-modified antibodies may be prepared and deacetylated as needed. Unlike thiolation procedures which immediately form a free sulfhydryl residue, the protected sulfhydryl group of SATA-modified proteins is stable to long-term storage without degradation.

Although amine-reactive protocols, such as SATA thiolation, result in nearly random attachment over the surface of the antibody structure, it has been shown that modification with up to six SATAs per antibody molecule typically results in no decrease in antigen binding activity (Duncan *et al.*, 1983). Even higher ratios of

SATA to antibody are possible with excellent retention of activity.

The following protocol should be compared to the method described for SATA thiolation in Chapter 2, Section 4.1. Although the procedures are slightly dissimilar, the differences indicate the flexibility inherent in the chemistry. For convenience, the buffer composition indicated here was chosen to be consistent throughout this section on enzyme–antibody conjugation using SMCC. Other buffers and alternate protocols can be found in the literature.

Protocol

1. Dissolve the antibody to be modified in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 1 to 5 mg/ml. Note: Phosphate buffers at various pH values between 7.0 and 7.6 have been used successfully with this protocol. Other mildly alkaline buffers may be substituted for phosphate in this reaction, providing they do not contain extraneous amines (e.g., Tris) or promote hydrolysis of SATA's NHS ester (e.g., imidazole).
2. Prepare a stock solution of SATA (Thermo Fisher) by dissolving it in DMF or DMSO at a concentration of 8 mg/ml. Use a fume hood to handle the organic solvents.
3. Add 10 to 40 µl of the SATA stock solution per milliliter of 1 mg/ml antibody solution. This will result in a molar excess of approximately 12- to 50-fold of SATA over the antibody concentration (for an initial antibody concentration of 1 mg/ml). A 12-fold molar excess works well, but higher levels of SATA incorporation will potentially result in more maleimide-activated enzyme molecules able to couple to each thiolated antibody molecule. For higher concentrations of antibody in the reaction medium, proportionally increase the amount of SATA addition; however, do not exceed 10% DMF in the aqueous reaction medium.
4. React for 30 min at room temperature.
5. To purify the SATA-modified antibody, perform a gel filtration separation using desalting resin or by dialysis against 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA. Purification is not absolutely required, since the following deprotection step is performed using hydroxylamine at a significant molar excess over the initial amount of SATA added. Whether a purification step is carried out or not, at this point, the derivative is stable and may be stored under conditions which favor long-term antibody activity (i.e., sterile filtered at 4°C, frozen, or lyophilized).
6. Deprotect the acetylated sulfhydryl groups on the SATA-modified antibody according to the following protocol:
   a. Prepare a 0.5-*M* hydroxylamine (Thermo Fisher) solution in 0.1-*M* sodium phosphate, pH 7.2, containing 10-m*M* EDTA.
   b. Add 100 µl of the hydroxylamine stock solution to each ml of the SATA-modified antibody. Final concentration of hydroxylamine in the antibody solution is 50-m*M*.
   c. React for 2 h at room temperature.
   d. Purify the thiolated antibody by gel filtration on a desalting resin using 0.1-*M* sodium phosphate, 0.1-*M* NaCl, pH 7.2, containing 10-m*M* EDTA as the chromatography buffer. To obtain efficient separation between the thiolated antibody and excess hydroxylamine and reaction byproducts, the sample size applied to the column should be at a ratio of no more than 5% sample volume to the total column volume. Collect 0.5-ml fractions. Pool the fractions containing protein by measuring the absorbance of each fraction at 280 nm.
7. Immediately mix the thiolated antibody with an amount of maleimide-activated enzyme to obtain the desired molar ratio of antibody-to-enzyme in the conjugate. Use of a 4:1 to 15:1 (enzyme:antibody) molar ratio in the conjugation reaction usually results in high-activity conjugates suitable for use in many enzyme-linked immunoassay procedures.
8. React for 30 to 60 min at 37°C or 2 h at room temperature. The conjugation reaction also may be performed at 4°C overnight.
9. The conjugate may be further purified away from unconjugated enzyme by the procedures described in Section 1.5. For storage, the conjugate should be kept frozen, lyophilized, or sterile filtered and kept at 4°C. Stability studies may have to be carried out to determine the optimal method of long-term storage for a particular conjugate.

1.2. Glutaraldehyde-Mediated Conjugation

Glutaraldehyde was one of the first crosslinking agents used for creating antibody–enzyme conjugates, and it is still being used today in manufacturing processes despite its shortcomings. The crosslinking process using glutaraldehyde is believed to proceed by a number of mechanisms, including Schiff base formation with possible rearrangement to a stable product, addition to hemiacetal ring structures, or through a Michael-type addition reaction that takes place at points of double-bond unsaturation created by polymerization of the reagent in solution (see Chapter 2,

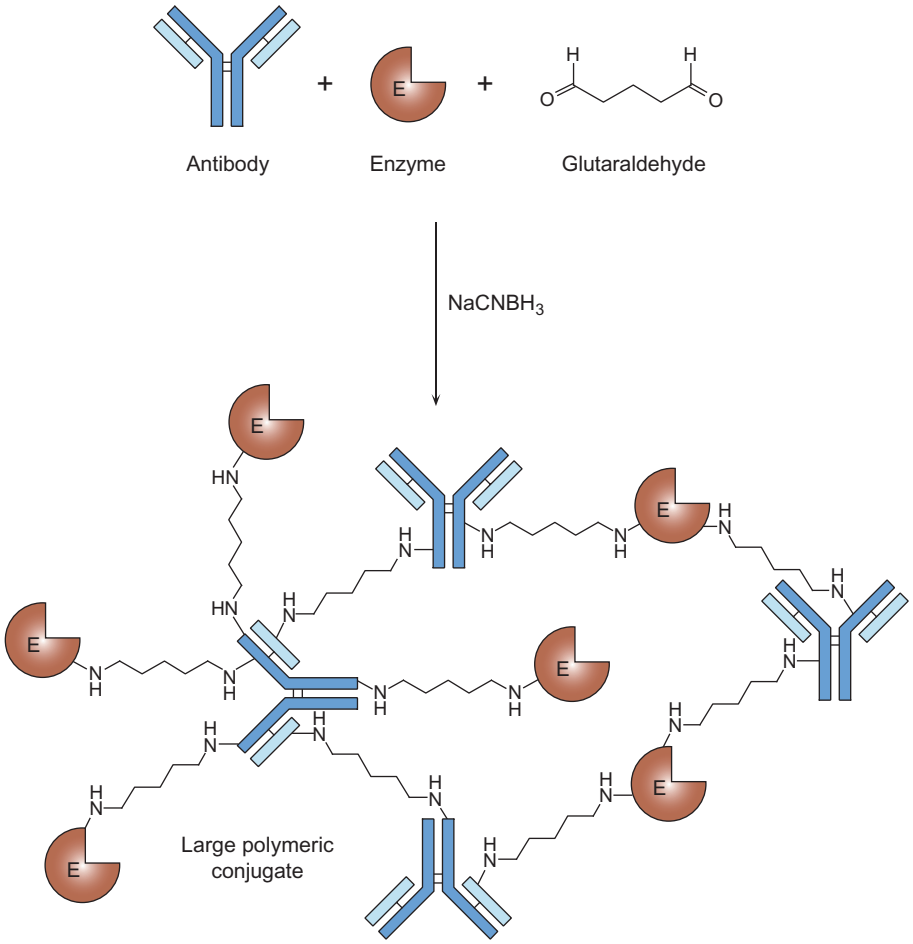

FIGURE 20.8 Glutaraldehyde antibody–enzyme crosslinking procedures usually produce a wide range of high-molecular-weight complexes, some of which may precipitate from solution. Note that there are many additional crosslinked forms that may occur upon crosslinking, including species that involve addition reactions to hemiacetal and aldol forms of glutaraldehyde which may involve high-molecular-weight polymers with multiple attachment points.

Section 4.4; Chapter 5, Section 6.2; Chapter 15, Section 2.1) (Avrameas, 1969). Reduction of Schiff base intermediates is also possible using sodium cyanoborohydride to form stable secondary amine linkages.

The problem of indeterminate reaction products is a deficiency that plagues all conjugations performed using glutaraldehyde. Part of this difficulty is due to the reagent's bifunctional nature, but a significant part of the problem is also due to the ambiguous nature of the commercial product. In aqueous solutions at alkaline pH, glutaraldehyde can undergo hemiacetal cyclization and aldol condensation reactions with itself to form a variety of structures, some of which contain α, β-unsaturated aldehydes (Hardy *et al.*, 1969, 1976). Another disadvantage of the reagent is the tendency to form high-molecular-weight conjugates due to uncontrollable polymerization during the crosslinking process. The resultant conjugates often have a significant amount of insoluble polymer which causes yield and activity losses in the preparation of antibody–enzyme conjugates. This is especially true when the conjugation is performed using the one-step method where glutaraldehyde is simply added to a solution containing the two proteins to be crosslinked (Figure 20.8). Enzymatic activity yields using this process can be as little as 10% in the final antibody–enzyme conjugate. To somewhat overcome the polymerization problem, a two-step procedure was developed which involves first activating one of the proteins with glutaraldehyde, purifying the intermediate from excess reagent, and then adding the second protein to effect the final conjugation. Unfortunately, even when using the two-step method, it results in significant formation of large-molecular-weight species that may precipitate out of solution. The only enzyme that the two-step method seems to work well with is HRP, since it only contains a limited number of available lysine amine groups.

Despite these deficiencies, antibody–enzyme conjugates are still being made using glutaraldehyde—particularly for many commercial diagnostic ELISA kits which were developed before the advent of more controllable, heterobifunctional crosslinking procedures. Today, choosing another method of producing antibody–enzyme conjugates will result in much better conjugates of higher activity and higher yield.

One-Step Glutaraldehyde Protocol

1. Prepare a solution containing 2 mg/ml antibody and 5 mg/ml enzyme in 0.02-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, chilled to 4°C.
2. In a fume hood, add 10 µl of 25% glutaraldehyde (Sigma) per milliliter of antibody/enzyme solution. Mix well.
3. React for 2 h at 4°C.
4. To reduce the resultant Schiff bases and any excess aldehydes, add sodium borohydride (Aldrich) to a final concentration of 10 mg/ml. Note: Some protocols do not call for a reduction step. As an alternative to reduction, add 50 µl of 0.2-*M* lysine in 0.5-*M* sodium carbonate, pH 9.5, to each milliliter of the conjugation reaction to block excess reactive sites. Block for 2 h at room temperature. Other amine-containing small molecules may be substituted for lysine—such as glycine, Tris buffer, or ethanolamine.
5. Reduce for 1 h at 4°C.
6. To remove any insoluble polymers that may have formed, centrifuge the conjugate or filter it through a 0.45-µm filter. Purify the conjugate by gel filtration or dialysis using PBS, pH 7.4.

Two-Step Glutaraldehyde Protocol

1. Dissolve the enzyme at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.8.
2. Add glutaraldehyde to a final concentration of 1.25%.
3. React overnight at room temperature.
4. Purify the activated enzyme from excess glutaraldehyde by gel filtration using a desalting resin or by dialysis against PBS, pH 6.8.
5. Dissolve the antibody to be conjugated at a concentration of 10 mg/ml in 0.5-*M* sodium carbonate, pH 9.5. Mix the activated enzyme with the antibody at the desired molar ratio to effect the conjugation. Mixing the equivalent of 4 mg of enzyme per milligram of antibody usually results in acceptable conjugates.
6. React overnight at 4°C.
7. To reduce any Schiff bases that may have formed as well as reduce any excess aldehydes, add sodium borohydride to a final concentration of 10 mg/ml. Note: Some protocols avoid a reduction step. As an alternative to reduction, add 50 µl of 0.2-*M* lysine in 0.5-*M* sodium carbonate, pH 9.5 to each milliliter of the conjugation reaction to block excess reactive sites. Block for 2 h at room temperature. Other amine-containing small molecules may be substituted for lysine—such as glycine, Tris buffer, or ethanolamine.
8. Reduce for 1 h at 4°C.
9. To remove any insoluble polymers that may have formed, centrifuge the conjugate or filter it through a 0.45-µm filter. Purify the conjugate by gel filtration or dialysis using PBS, pH 7.4.

1.3. Reductive Amination-Mediated Conjugation

Oxidation of polysaccharide residues in glycoproteins with sodium periodate provides an efficient way of generating reactive aldehyde groups for subsequent conjugation with amine- or hydrazide-containing molecules *via* reductive amination (Chapter 2, Section 4.4, and Chapter 4, Section 4). Some selectivity of monosaccharide oxidation may be accomplished by regulating the concentration of periodate in the reaction medium. In the presence of 1-m*M* sodium periodate at approximately 0°C, sialic acid groups will be preferentially oxidized at their adjacent hydroxyl residues on the Nos. 7, 8, and 9 carbon atoms, cleaving off two molecules of formaldehyde and leaving one aldehyde group on the No. 7 carbon. At higher concentrations of sodium periodate (10-m*M* or greater) at room temperature, other sugar residues will be oxidized at points where adjacent carbon atoms contain hydroxyl groups.

Thus, glycoproteins such as horseradish peroxidase, glucose oxidase, or most antibody molecules can be activated for conjugation by brief treatment with periodate. Crosslinking with an amine-containing protein takes place under alkaline pH conditions through the formation of Schiff base intermediates. These relatively labile intermediates can be stabilized by reduction to a secondary amine linkage with sodium cyanoborohydride (Figure 20.9).

The use of periodate coupling chemistry for HRP first was introduced by Nakane and Kawaoi (1974; see also Nakane, 1975). In the first step of their protocol, the few amine groups on HRP were initially blocked with 2,4-dinitrofluorobenzene (DNFB) before periodate oxidation. The blocking step was designed to eliminate the possibility of self-conjugation of enzyme molecules during reductive amination with an immunoglobulin. However, Boorsma and Streefkerk (1976a,b) determined that HRP can still dimerize even after DNFB blocking, perhaps by a mechanism similar to Mannich condensation (Chapter 3, Section 6.2) or through aldol formation. In fact, amine-blocked, periodate-oxidized HRP will form insoluble complexes during storage after just

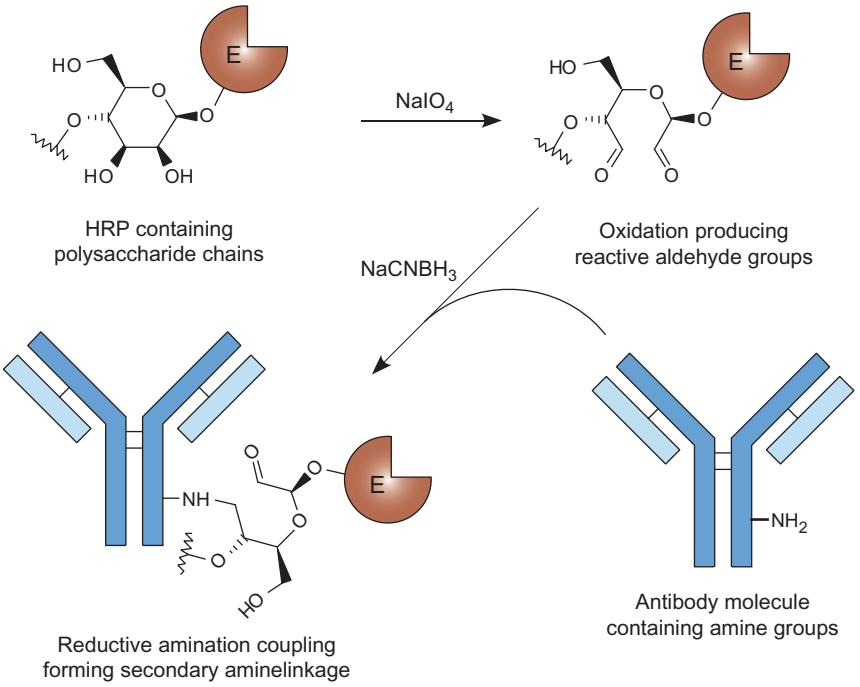

FIGURE 20.9 Enzymes that are glycoproteins like HRP may be oxidized with sodium periodate to produce reactive aldehyde residues. Conjugation with an antibody then may be done by reductive animation using sodium cyanoborohydride.

weeks in solution at room temperature or at 4°C, indicating that another route of conjugation is taking place.

Reductive amination crosslinking has been carried out using sodium borohydride or sodium cyanoborohydride; however, cyanoborohydride is the better choice since it is more specific for reducing Schiff bases and will not reduce aldehydes. Small blocking agents such as lysine, glycine, ethanolamine, or Tris can be added after conjugation to quench any unreacted aldehyde sites (Mannik and Downey, 1973; Mattiasson and Nilsson, 1977; Barbour, 1976). Ethanolamine and Tris are the best choices for blocking agents, since they contain hydrophilic hydroxyl groups with no charged functional groups.

The pH of the reductive amination reaction can be controlled to affect the efficiency of the crosslinking process and the size of the resultant antibody–enzyme complexes formed. At physiological pH, the initial Schiff base formation is less efficient and conjugates of lower molecular weight will result. At more alkaline pH values (i.e., pH 9–10), Schiff base formation occurs rapidly and with high efficiency, resulting in conjugates of higher molecular weight and greater incorporation of enzyme (when oxidized HRP is reacted in excess).

The ability to select the relative size of the antibody–enzyme complex is important depending on the assay application. Low-molecular-weight conjugates may be more optimal for immunohistochemical staining or blotting techniques where penetration of the complex through membrane barriers is an important consideration. Washing steps also more effectively remove excess reagent if the conjugate is of low molecular weight, thus maintaining a low background signal in an assay. By contrast, conjugates of high molecular weight are more appropriate for ELISA procedures in a microplate or array format, where high sensitivity is important, but washing off excess conjugate is not a problem.

The protocols appearing in the literature vary according to the amount of periodate used during polysaccharide oxidation, the type of reductant and blocking agent employed for reductive amination, and the pH at which the various reactions are done. This variability indicates considerable flexibility in the protocols, all of which yield usable antibody–enzyme conjugates. There are, however, several conclusions that can be drawn from these studies: Investigations performed using HRP indicate the optimal concentration of sodium periodate during oxidation to be approximately 4 to 8-m*M* (Tussen and Kurstak, 1984). This reaction should be performed in the dark to prevent periodate breakdown and for a limited period of time (no more than 15–30 min) to avoid loss of enzymatic activity. The conjugation reaction should be carried out at alkaline pH (7.2–9.5) in the presence of a reducing agent to stabilize the Schiff base intermediates. If sodium cyanoborohydride is used as the reductant, a blocking agent should be added at the completion of the conjugation reaction to cap excess aldehyde sites. The following

protocol follows these general guidelines and works well especially in the preparation of HRP–antibody conjugates.

Activation of Enzymes with Sodium Periodate

Enzymes that are glycosylated (i.e., HRP and glucose oxidase) may be oxidized according to the following method to produce aldehyde groups for reductive amination coupling to an antibody molecule.

Protocol

1. Dissolve the enzyme to be oxidized in water or 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 10 to 20 mg/ml.
2. Dissolve sodium periodate in water at a concentration of 0.088 *M*. Protect from light.
3. Immediately add 100 µl of the sodium periodate solution to each milliliter of the enzyme solution. This ratio of addition results in an 8-m*M* periodate concentration in the reaction mixture. Mix to dissolve. Protect from light.
4. React in the dark for 15 to 20 min at room temperature. If HRP is the enzyme being oxidized, a color change will be apparent as the reaction proceeds—changing the brownish/gold color of concentrated HRP to green. Limiting the time of oxidation will help to preserve enzyme activity.
5. Immediately quench the reaction by the addition of 0.1 ml of glycerol per milliliter of reaction solution. Instead of glycerol, *N*-acetylmethionine may be added to quench the reaction, because the thioether of the methionine side chain will react with periodate to form sulfoxide or sulfone products (Geoghegan and Stroh, 1992). In addition, sodium sulfite (Na_2SO_3) was used by Stolowitz *et al.* (2001) to quench the periodate oxidation of HRP in solution. This may be the simplest route to stopping the reaction, as sulfite is inexpensive and the reduction does not form reactive byproducts. Add quenching reagent to provide at least a 2-times molar excess over the amount of periodate initially added to the reaction. Alternatively, the reaction may be stopped by immediate gel filtration on a desalting resin. If a dextran-based resin is used for the chromatography, the support itself will react with sodium periodate to quench excess reagent. Purify the oxidized enzyme by gel filtration using 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. To obtain efficient separation between the oxidized enzyme and excess periodate (or quenching agent), the sample size applied to the column should be at a ratio of no more than 5% sample volume to the total column volume. Collect 0.5-ml fractions and monitor for protein at 280 nm. HRP also may be detected by its absorbance at 403 nm. When oxidizing large quantities of HRP, the fraction collection process may be performed visually—just pooling the main colored HRP peak as it comes off the column.
6. Pool the fractions containing protein. Adjust the enzyme concentration to 10 mg/ml for the conjugation step (see next section). The periodate-activated enzyme may be stored frozen or freeze-dried for extended periods without loss of activity. Do not store the preparation in solution at room temperature or 4°C, since precipitation will occur over time due to self-polymerization.

Activation of Antibodies with Sodium Periodate

Many immunoglobulin molecules are glycoproteins that can be periodate-oxidized to contain reactive aldehyde residues. Polyclonal IgG molecules often contain carbohydrate in the Fc portion of the molecule. This is sufficiently removed from the antigen binding sites to allow conjugation to take place through the polysaccharide chains without compromising activity. Occasionally, however, some antibodies may contain sites of glycosylation near the antigen binding regions, and in this situation conjugation through these sites may affect binding activity. Although antibody–enzyme conjugation by reductive amination is typically done by oxidation of the enzyme with subsequent crosslinking to an amine-containing antibody, oxidation of the antibody with subsequent conjugation to an amine- or hydrazide-containing molecule is also possible. It should be noted, however, that many monoclonal antibodies are not glycosylated and therefore can not be used in this protocol. Recombinant antibodies also do not contain carbohydrate. A given monoclonal should be checked to verify the presence of carbohydrate before attempting to use a periodate-mediated conjugation protocol.

Protocol

1. Dissolve the antibody to be periodate-oxidized at a concentration of 10 mg/ml in 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
2. Dissolve sodium periodate in water to a final concentration of 0.1-*M*. Protect from light.
3. Immediately add 100 µl of the sodium periodate solution to each milliliter of the antibody solution. Mix to dissolve. Protect from light.
4. React in the dark for 15 to 20 min at room temperature.
5. Immediately quench the reaction by the addition of sodium sulfite (Na_2SO_3) to provide a 2-times molar excess over the initial amount of periodate added. Purify the oxidized antibody by gel filtration using a desalting resin. The chromatography buffer is 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. To obtain efficient separation between the oxidized

antibody and excess periodate, the sample size applied to the column should be at a ratio of no more than 5% sample volume to the total column volume. Collect 0.5-ml fractions and monitor for protein at 280 nm.

6. Pool the fractions containing protein. Adjust the antibody concentration to 10 mg/ml for the conjugation step. The oxidized antibody should be used immediately.

Conjugation of Periodate-Oxidized HRP to Antibodies by Reductive Amination

The following protocol assumes that HRP has already been periodate-oxidized by the method given in Section 1.3, above.

Protocol

1. Dissolve the IgG to be conjugated at a concentration of 10 mg/ml in 0.2-*M* sodium bicarbonate, pH 9.6, at room temperature. The high pH buffer will result in very efficient conjugation with the highest possible incorporation of enzyme molecules per antibody molecule. To produce lower molecular weight conjugates, dissolve the IgG at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
2. The periodate-oxidized enzyme (HRP) prepared in Section 1.3 was finally purified using 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. For conjugation using the lower-pH-buffered environment, this HRP preparation can be used directly at 10 mg/ml concentration. For conjugation using the higher pH carbonate buffer, dialyze the HRP solution against 0.2-*M* sodium carbonate, pH 9.6 for 2 h at room temperature prior to use. A volume of HRP solution equal to the volume of antibody solution will be required.
3. Mix the antibody solution with the enzyme solution at a ratio of 1:1 (v/v). Since an equal mass of antibody and enzyme is present in the final solution, this will result in a 3.75 molar excess of HRP over the amount of IgG. For conjugates consisting of greater enzyme-to-antibody ratios, proportionally increase the amount of enzyme solution as required. Typically, molar ratios of 4:1 to 15:1 (enzyme:antibody) give acceptable conjugates useful in a variety of ELISA techniques.
4. React for 2 h at room temperature.
5. In a fume hood, add 10 µl of 5-*M* sodium cyanoborohydride (Sigma) per milliliter of reaction solution. **Caution**: Cyanoborohydride is extremely toxic. All operations should be carried out with care in a fume hood. Also, avoid any contact with the reagent, as the 5-*M* solution is prepared in 1-*N* NaOH.
6. React for 30 min at room temperature with gentle mixing (in a fume hood).
7. Block unreacted aldehyde sites by addition of 50 µl of 1-*M* ethanolamine, pH 9.6, per milliliter of conjugation solution. Approximately a 1-*M* ethanolamine solution may be prepared by addition of 300 µl ethanolamine to 5 ml of deionized water. Adjust the pH of the ethanolamine solution by addition of concentrated HCl, keeping the solution cool on ice.
8. React for 30 min at room temperature.
9. Purify the conjugate from excess reactants by dialysis or gel filtration using a desalting resin. Use 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.0, as the buffer for either operation. The conjugate may be further purified by removal of unconjugated enzyme using one of the methods described in Section 1.5.

Conjugation of Periodate-Oxidized Antibodies with Amine or Hydrazide Derivatives

The following protocol assumes that the antibody has already been periodate-oxidized by the method of Section 1.3 (above) to create reactive aldehyde groups suitable for coupling with amine-containing or hydrazide-containing molecules. This is an excellent method for directing the antibody modification reaction away from the antigen binding sites, if the antibody glycosylation points are solely in the Fc region of the molecule. For instance, biotinylation of intact antibodies can be performed after mild periodate treatment using biotin-hydrazide (Chapter 11, Section 6.4) (Figure 20.10). It should be noted, however, that periodate-oxidized antibodies can self-conjugate through their own amines if high-pH reductive amination is used. Conjugation with periodate-oxidized antibodies works best if the receiving molecule is modified to contain hydrazide groups and the reaction is carried out at more moderate pH values (e.g., slightly acidic to neutral pH).

1. For conjugation to hydrazide-containing proteins, dissolve the periodate-oxidized antibody at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.0 to 7.2. For conjugation to amine-containing molecules and proteins, dissolve the oxidized antibody at 10 mg/ml in 0.2-*M* sodium carbonate, pH 9.6.
2. Dissolve a hydrazide-containing enzyme or other protein at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.0 to 7.2. For the preparation of a hydrazide-activated enzyme, see Chapter 22, Section 2.4. For modification with a hydrazide-containing probe, such as biotin–hydrazide, use a concentration of 5-m*M* in the phosphate buffer. For conjugation through the amine groups of a secondary molecule, dissolve the

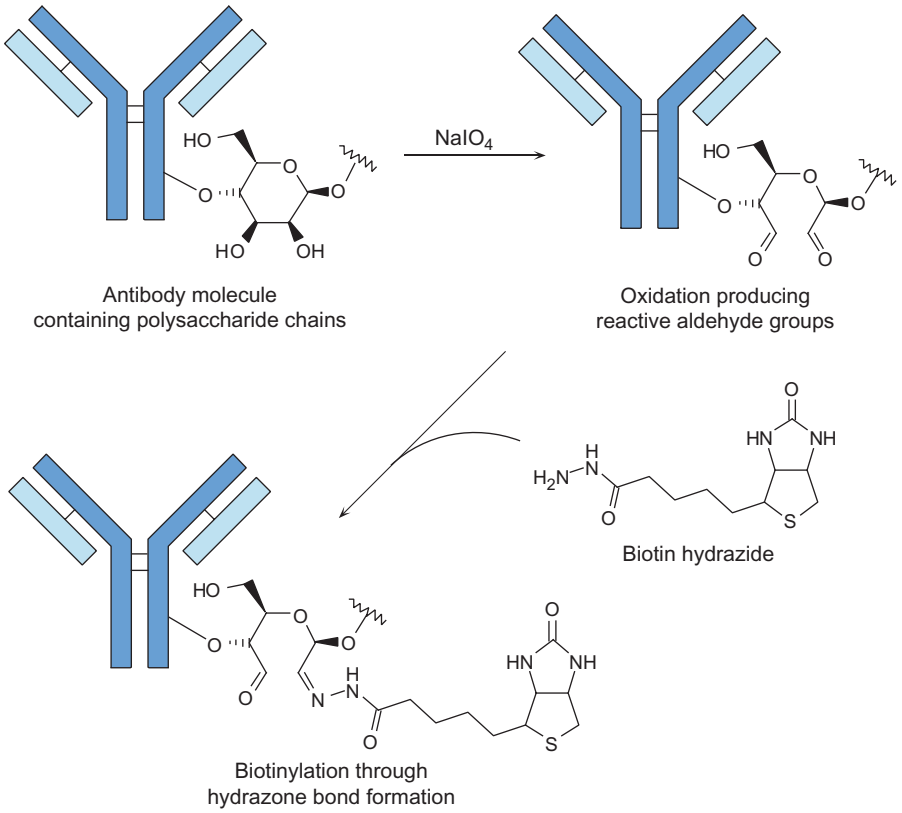

FIGURE 20.10 Polysaccharide groups on antibody molecules may be oxidized with periodate to create aldehydes. Modification with biotin–hydrazide results in hydrazone linkages. The sites of modification using this technique are often away from the antibody–antigen binding regions, thus preserving antibody activity.

amine-containing protein at 10 mg/ml in 0.2-*M* sodium carbonate, pH 9.6.

3. Mix the antibody solution from step 1 with the protein solution from step 2 in amounts necessary to obtain the desired molar ratio for conjugation. Often, the secondary molecule is reacted in approximately a 4- to 15-fold molar excess over the amount of antibody present.
4. React for 2 h at room temperature.
5. In a fume hood, add 10 µl of 5-*M* sodium cyanoborohydride (Sigma) per milliliter of reaction solution. **Caution**: Cyanoborohydride is extremely toxic. All operations should be carried out with care in a fume hood. Also, avoid any contact with the reagent, as the 5-*M* solution is prepared in 1-*N* NaOH. The addition of a reductant is necessary for stabilization of the Schiff bases formed between an amine-containing protein and the aldehydes on the antibody. For coupling to a hydrazide-activated protein, however, most protocols do not include a reduction step. Even so, hydrazone linkages may be further stabilized by cyanoborohydride reduction. The addition of a reductant during hydrazide/aldehyde reactions also increases the efficiency and yield of the reaction.
6. React for 30 min at room temperature (in a fume hood).
7. Block unreacted aldehyde sites by addition of 50 µl of 1-*M* ethanolamine, pH 9.6, per milliliter of conjugation solution. Approximately a 1-*M* ethanolamine solution may be prepared by addition of 300 µl ethanolamine to 5 ml of deionized water. Adjust the pH of the ethanolamine solution by addition of concentrated HCl, while keeping the solution cool on ice.
8. React for 30 min at room temperature.
9. Purify the conjugate from excess reactants by dialysis or gel filtration using desalting resin. Use 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.0, as the buffer for either operation. The conjugate may be further purified by removal of unconjugated enzyme by one of the methods given in Section 1.5.

1.4. Conjugation Using Antibody Fragments

It is often advantageous to use antibody fragments in the preparation of antibody–enzyme conjugates. Selected fragmentation carried out by enzymatic digestion of intact immunoglobulins can yield lower-molecular-weight molecules still able to recognize and bind

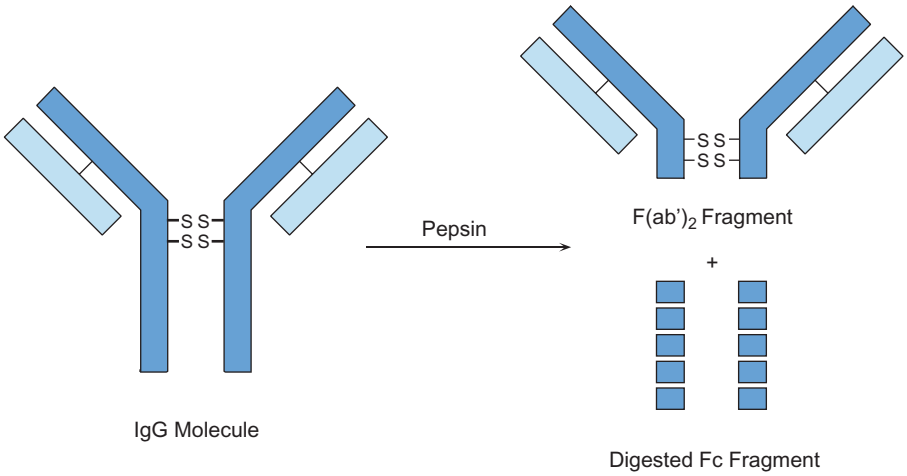

FIGURE 20.11 Digestion of IgG-class antibodies with pepsin results in heavy-chain cleavage below the disulfide groups in the hinge region. The bivalent fragments that are formed are called $F(ab')_2$. The remaining Fc region normally is severely degraded into smaller peptide fragments.

antigen. Conjugation of these fragments with enzyme molecules can result in ELISA reagents that possess better characteristics than corresponding conjugates prepared with intact antibody. Such antibody fragment conjugates display less interference with various Fc binding proteins and also less immunogenicity (due to lack of the Fc region), more facile membrane penetration for immunohistochemical staining techniques (due to lower overall conjugate molecular weight) (Wilson and Nakane, 1978; Farr and Nakane, 1981), and lower nonspecific binding to surfaces or membranes (resulting in increased signal-to-noise ratios) (Hamaguchi *et al.*, 1979; Ishikawa *et al.*, 1981a,b).

Enzymatic digests of IgG can result in two particularly useful fragments called Fab and $F(ab')_2$, prepared by the action of papain and pepsin, respectively. Most specific enzymatic cleavages of IgG occur in relatively unfolded regions between the major domains. Papain and pepsin, and similar enzymes including bromelain, ficin, and trypsin, cleave immunoglobulin molecules in the hinge region of the heavy-chain pairs. Depending on the location of cleavage, the disulfide groups holding the heavy chains together may or may not remain attached to the antigen-binding fragments that result. If the disulfide bonded region does remain with the antigen binding fragment, as in pepsin digestion, then a divalent molecule is produced ($F(ab')_2$) which differs from the intact antibody by lack of an extended Fc portion. If the disulfide region is below the point of digestion, then the two heavy-/light-chain complexes that form the two antigen binding sites of an antibody are cleaved and released, forming individual dimeric fragments (Fab) containing one antigen binding site each (see Figure 20.4, discussed previously).

Methods for producing immobilized papain or pepsin for antibody fragmentation can be found in Hermanson *et al.* (1992). The following protocol describes the use of pepsin to cleave IgG molecules at the C-terminal side of the inter-heavy-chain disulfides in the hinge region, producing a bivalent antigen binding fragment, $F(ab')_2$, with a molecular weight of about 105,000 (Figure 20.11). Using this enzyme, most of the Fc fragments undergo extensive degradation and cannot be recovered intact.

Protocol for Preparation of $F(ab')_2$ Fragments Using Pepsin

1. Equilibrate by washing 0.25 ml of immobilized pepsin (Thermo Fisher) with 4 × 1 ml of 20-m*M* sodium acetate, pH 4.5 (digestion buffer). Finally, suspend the gel in 1 ml of digestion buffer.
2. Dissolve 1 to 10 mg of IgG in 1 ml digestion buffer and add it to the gel suspension.
3. Mix the reaction slurry in a shaker at 37°C for 2 to 48 h. The optimal time for complete digestion varies depending on the IgG subclass and species of origin. Mouse IgG1 antibodies are usually digested within 24 h, human antibodies are fragmented in 12 h, whereas some minor subclasses (e.g., mouse IgG2a) require a full 48-h digestion period.
4. After the digestion is complete, add 3 ml of 10-m*M* Tris–HCl, pH 8.0, to the gel suspension. Separate the gel from the antibody solution using filtration or by centrifugation.
5. Apply the fragmented IgG solution to an immobilized protein A column containing 2 ml of gel (Thermo Fisher) that was previously equilibrated with 10-m*M* Tris–HCl, pH 8.0.
6. After the sample has entered the gel, wash the column with 10-m*M* Tris–HCl, pH 8.0, while collecting 2-ml fractions. The fractions may be monitored for protein by measuring absorbance at

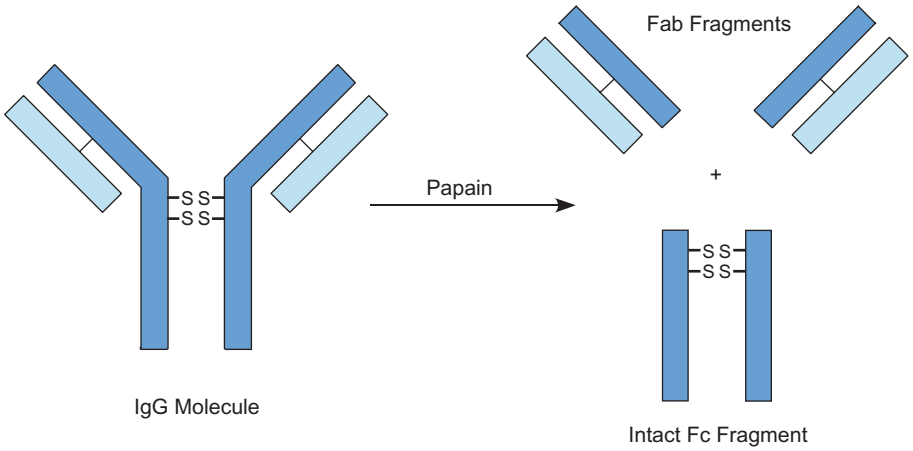

FIGURE 20.12 Papain digestion of IgG antibodies primarily results in cleavage in the hinge region above the interchain disulfides. This produces two heavy–light chain pairs, called Fab fragments, each containing one antigen binding site. The Fc region can normally be recovered intact.

280 nm. The protein peak eluting unretarded from the column is $F(ab')_2$.

7. Bound Fc or Fc fragments and any undigested IgG may be eluted from the column with 0.1-*M* glycine, pH 2.8.

Similarly, immobilized papain may be used to generate Fab fragments from immunoglobulin molecules. Papain is a sulfhydryl protease that is activated by the presence of a reducing agent. Cleavage of IgG occurs above the disulfides in the hinge region, creating two types of fragments, two identical Fab portions and one intact Fc fragment (Figure 20.12). For preparation of the immobilized papain gel used in the following protocol, see Hermanson *et al.* (1992). The gel is also commercially available from Thermo Fisher.

Protocol for Preparation of Fab Fragments using Papain

1. Wash 0.5 ml of immobilized papain (Thermo Fisher) with 4 × 2 ml of 20-m*M* sodium phosphate, 20-m*M* cysteine-HCl, 10-m*M* EDTA, pH 6.2 (digestion buffer), and finally suspend the gel in 1.0 ml of digestion buffer.
2. Dissolve 10 mg of human IgG solution in 1.0 ml of digestion buffer and add it to the immobilized papain gel suspension.
3. Mix the gel suspension in a shaker at 37°C for 4 to 48 h. Maintain the gel in suspension during mixing. The optimal time for complete digestion varies depending on the IgG subclass and species of origin. Mouse IgG_1 antibodies are usually digested within 27 h, whereas other mouse subclasses require only 4 h; human antibodies are fragmented in 4 h (IgG_1 and IgG_3), 24 h (IgG_4), or 48 h (IgG_2); and bovine, sheep, and horse antibodies are somewhat resistant to digestion and require a full 48 h.
4. After the required time of digestion, add 3.0 ml 10-m*M* Tris–HCl buffer, pH 8.0, to the gel suspension, mix, and then separate the digest solution from the gel by filtration or centrifugation at 2000 *g* for 5 min.
5. Apply the supernatant liquid to an immobilized protein A column (2 ml gel) (Thermo Fisher) which was previously equilibrated by washing with 20 ml of 10-m*M* Tris–HCl buffer, pH 8.0.
6. After the sample has entered the gel bed, wash the column with 15 ml of 10-m*M* Tris–HCl buffer, pH 8.0, while 2.0-ml fractions are collected. Monitor the fractions for protein by their absorbance at 280 nm. The protein eluted unretarded from the column is purified Fab.
7. Elute Fc and undigested IgG bound to the immobilized protein A column with 0.1-*M* glycine–HCl buffer, pH 2.8.

Conjugation of these fragments with enzymes is carried out using similar methods to those previously discussed for intact antibody molecules. $F(ab')_2$ fragments may be selectively reduced in the hinge region with DTT, TCEP, or MEA using the identical protocols outlined for whole antibody molecules (Chapter 2, Section 4.1, and Section 1.1, this chapter). Mild reduction results in cleaving the disulfides holding the heavy-chain pairs together at the central portion of the fragment, thus creating two F(ab′) fragments each containing one antigen binding site (Figure 20.13).

The amine groups on these fragments also may be modified with thiolating agents, such as SATA or 2-iminothiolane, to create sulfhydryl residues suitable for coupling to maleimide-activated enzymes (Section 1.1) (Figure 20.14). Amine groups may be further utilized in reductive amination coupling to periodate-oxidized glycoproteins, such as in the protocol outlined for HRP

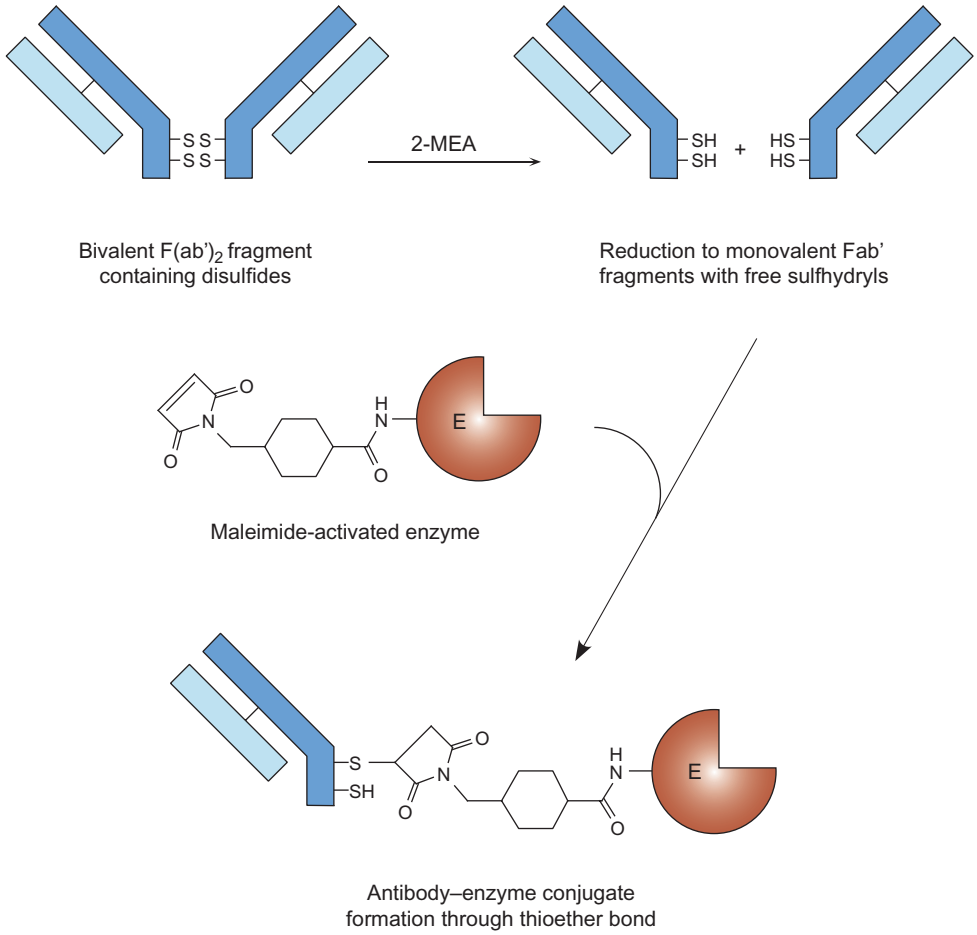

FIGURE 20.13 $F(ab')_2$ fragments produced by pepsin digestion of IgG can be reduced at their heavy-chain disulfides using a reducing agent, such as 2-mercaptoethylamine (MEA), DTT, or TCEP. Conjugation then can be carried out with a maleimide-activated enzyme to produce relatively low-molecular-weight complexes linked by thioether bonds.

conjugation, previously (Section 1.3, this chapter) (Figure 20.15). Successful periodate oxidation of the fragments themselves, however, may not be possible unless they contain carbohydrate in the antigen binding region, which is true for some polyclonal antibodies. Finally, glutaraldehyde-mediated conjugation techniques will work with antibody fragments, but are not recommended due to the reasons discussed in Section 1.2.

The primary goal of any of these conjugation strategies using antibody fragments is to maintain the activity of the antigen binding site while limiting the size of the final complex with a second molecule. The use of heterobifunctional crosslinkers such as SMCC or reductive amination techniques allows sufficient control over the process to realize these goals.

1.5. Removal of Unconjugated Enzyme from Antibody–Enzyme Conjugates

Conjugates of antibodies and enzymes are essential components in immunoassay and detection systems. In the preparation of such conjugates, a molar excess of enzyme is typically crosslinked to a specific antibody to obtain a complex of high activity. As a result of this ratio, there is typically excess enzyme left unconjugated after completion of the reaction. The unconjugated enzyme confers nothing to the utility of the final product and can be detrimental if it contributes to increased backgrounds in assay procedures. The removal of this free enzyme component may be advantageous to improving the resultant signal-to-noise ratio in some immunoassays. Commercial preparations of antibody–enzyme conjugates usually are not purified to remove unconjugated enzyme. Frequently, the major proteinaceous part of these products is not active conjugate, but leftover enzyme that contributes nothing to the immunochemical activity of what was purchased.

Boorsma and Kalsbeek (1976) state that unconjugated HRP must be removed from antibody–enzyme conjugates to obtain optimal staining in immunoassay procedures. This is especially true in blotting techniques and cytochemical staining where free enzyme

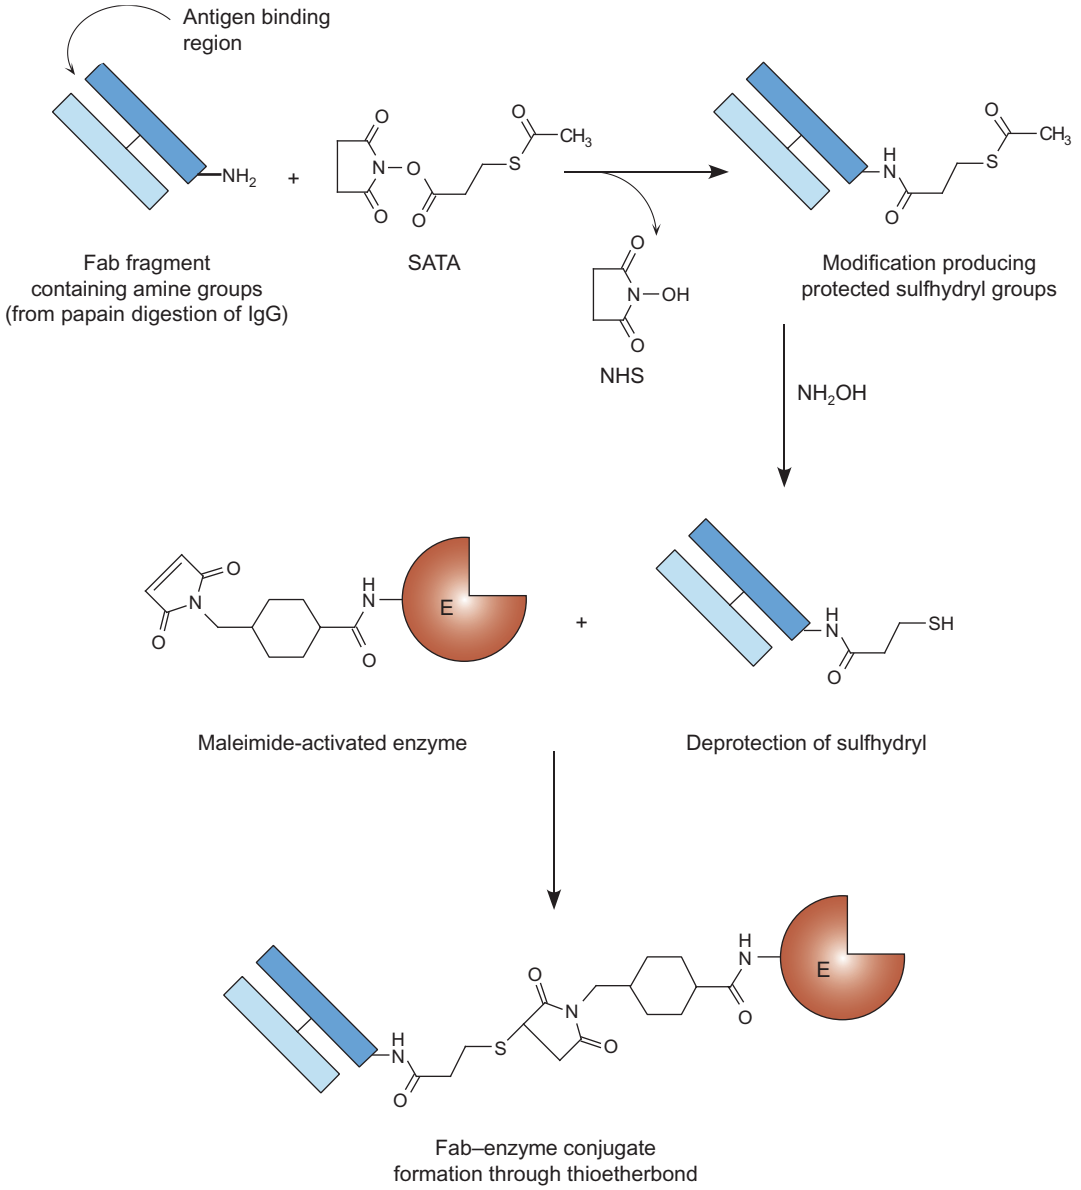

FIGURE 20.14 The thiolation reagent SATA can be used to create sulfhydryl groups on Fab fragments. After deprotection of the acetylated thiol of SATA with hydroxylamine, conjugation with a maleimide-activated enzyme can take place, producing thioether linkages.

may become entrapped nonspecifically within the membrane or cellular structures. The presence of this unconjugated enzyme leads to diffuse substrate noise that can obscure the immunospecific signal.

Several methods may be used to purify an antibody–enzyme conjugate and remove unconjugated enzyme. For instances where the enzyme molecular weight is significantly different than the conjugate molecular weight, separation may be achieved by gel filtration chromatography. Using the proper support with an exclusion limit and separation range able to accommodate all the proteins in the sample, the conjugate peak will elute before the enzyme peak, thus providing an efficient way of removing free enzyme. However, gel filtration procedures can be time consuming and of relatively low capacity for the amount of gel required. In addition, separation of higher-molecular-weight enzymes from antibody conjugates, such as in the case of AP (MW 140,000), is considerably less efficient or impossible. Gel filtration separation also becomes a problem if the conjugate itself consists of a broad range of molecular weights, as is often true when glutaraldehyde is used as the crosslinking agent.

The most effective methods of removing unconjugated enzyme all make use of affinity chromatography systems using specific ligands that can interact with the

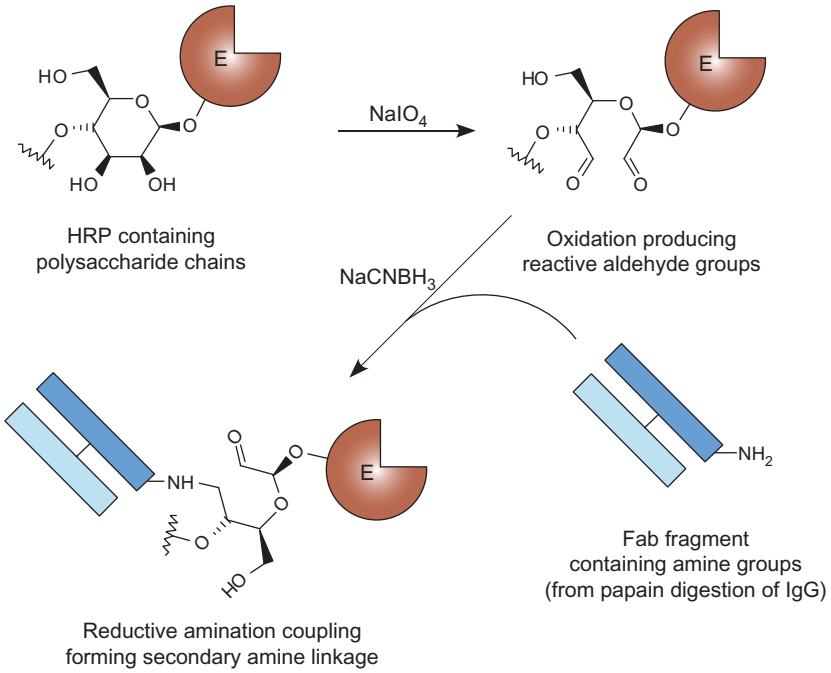

FIGURE 20.15 Periodate oxidation of HRP creates aldehyde groups on the carbohydrate chains of the enzyme. Reaction with a Fab fragment may then be done using reductive amination to produce a lower-molecular-weight complex than would be obtained using intact IgG antibodies.

antibody portion of the conjugate. Thus, the supports retain any unconjugated antibody (usually in very low percentage when the enzyme is reacted in excess) as well as the antibody–enzyme conjugate produced from the crosslinking reaction. The unconjugated enzyme, however, passes through such affinity columns unretarded. Two main methods are discussed below: (1) affinity chromatography, which makes use of immobilized immunoglobulin binding proteins or immobilized antigen molecules having specificity for the antibody used in the conjugate; and (2) nickel-chelate affinity chromatography, which binds the Fc region of antibody molecules.

The use of immunoaffinity techniques (whether antigen specific or immunoglobulin binding proteins such as protein A) allows strong binding of the antibody conjugate, but they have the significant disadvantage of requiring elution conditions that are often too severe for maintaining activity of the antibody or enzyme components. By contrast, nickel-chelate affinity techniques give excellent binding of the conjugate while allowing free enzyme to pass through the gel unretarded. It also has the significant advantage of having mild elution conditions which preserve the activity of the conjugate.

Immunoaffinity Chromatography

Immunoaffinity chromatography makes use of immobilized antigen molecules to bind and separate specific antibody from a complex mixture. After the preparation of an antibody–enzyme conjugate, the antibody binding capability of the crosslinked complex toward its complementary antigen ideally remains intact. This highly specific interaction can be used to purify the conjugate from excess enzyme if the antibody and enzyme can survive the conditions necessary for binding and elution from such a column. Binding conditions are typically mild physiological pH conditions which cause no difficulty. However, many elution conditions require acidic or basic conditions or the presence of a chaotropic agent to deform the antigen binding site. Sometimes these conditions can irreversibly damage the antigen binding recognition capability of the antibody or denature the active site of the enzyme, thus diminishing enzymatic activity. Activity losses for both the antibody and enzyme can be severe under such circumstances.

Another potential disadvantage of an immunoaffinity separation is the assumed abundance of the purified antigen in sufficient quantities to immobilize on a chromatography support (see Chapter 15 for common immobilization techniques). Protein antigens should be immobilized at densities of at least 2 to 3 mg/ml of affinity gel to produce supports of acceptable capacity for binding antibody. Often, the antigen is too expensive or scarce to obtain in the amounts needed.

However, if the antigen is abundant and inexpensive and the antibody–enzyme complex will survive the associated elution conditions, then immunoaffinity

chromatography can provide a very efficient method of purifying a conjugate from excess enzyme. This method also ensures that the recovered antibody still retains its ability to bind specific target molecules (i.e., the antigen binding site was not blocked during conjugation). The preparation of immunoaffinity supports can be found in Hermanson *et al.* (1992) and in Chapter 15. A suggested method for performing immunoaffinity chromatography follows:

Protocol

1. Equilibrate the immunoaffinity column with 50-m*M* Tris, 0.15-*M* NaCl, pH 8.0 (binding buffer). Wash with at least 5 column volumes of buffer. The amount of gel used should be based on the total binding capacity of the support. A determination of binding capacity can be achieved by overloading a small-scale column, eluting, and measuring the amount of conjugate that bound. Such an experiment may be coupled with a determination of conjugate viability for using immunoaffinity as the purification method. The final column size should represent an amount of gel capable of binding at least 1.5-times more than the amount of conjugate that will be applied.
2. Apply the conjugate to the column in the binding buffer while taking 2-ml fractions.
3. Wash with binding buffer until the absorbance at 280 nm decreases back to baseline. The unbound protein flowing through the column will consist of mainly unconjugated enzyme. Some conjugate may also flow through if some of the conjugate is inactive or the column is overloaded.
4. Elute the bound conjugate with 0.1-*M* glycine, 0.15-*M* NaCl, pH 2.8, or another suitable elution buffer. A neutral pH alternative to this buffer is the Gentle Elution Buffer from Thermo Fisher. If acid pH conditions are used, immediately neutralize the fractions eluting from the column by the addition of 0.5 ml of 1-*M* Tris, pH 8.0, per fraction.

Nickel-Chelate Affinity Chromatography

Immobilized metal-chelate affinity chromatography (IMAC) is a powerful purification technique whereby proteins or other molecules can be separated based upon their ability to form coordination complexes with immobilized metal ions (Porath *et al.*, 1975; Lonnerdal and Keen, 1982; Porath and Belew, 1983; Porath and Olin, 1983; Sulkowski, 1985; Kagedal, 1989). The metal ions are stabilized on a matrix through the use of organic chelating compounds which usually have multivalent points of interaction with the metal atoms. To form useful affinity supports, these metal ion complexes must have some free or weakly associated

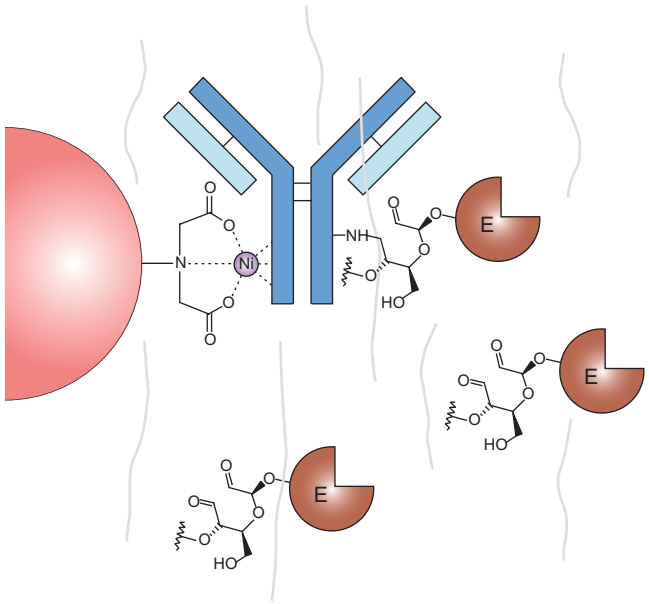

FIGURE 20.16 An affinity chromatography support containing iminodiacetic acid groups chelated with nickel may be used to remove excess enzyme after reactions to produce antibody–enzyme conjugates. The nickel chelate binds to the antibody in the Fc region, retaining the conjugate while allowing free enzyme to pass through the gel unretarded.

and exchangeable coordination sites. These exchangeable sites can then form complexes with coordination sites on proteins or other molecules. Substances that are able to interact with the immobilized metals will bind and be retained on the column. Elution is typically accomplished by one or a combination of the following options: (1) lowering the pH; (2) raising the salt strength; and/or (3) inclusion of a competing chelating agent such as EDTA or imidazole in the buffer.

Sorensen (1993) reported that a nickel-chelate affinity column will specifically bind IgG class immunoglobulins while allowing certain enzymes to pass through the gel unretarded (Thermo Fisher). This phenomenon allows the separation of antibody–enzyme complexes containing, in particular, HRP or alkaline phosphatase conjugated to common polyclonal or monoclonal antibodies. The nickel chelate column binds the conjugate through the Fc region of the associated antibody, even if enzyme molecules are covalently attached. Any unconjugated enzyme will pass through the affinity column unretarded (Figure 20.16).

Elution of the bound antibody–enzyme conjugate occurs by only a slight shift in pH to acidic conditions or through the inclusion of a metal chelating agent like EDTA or imidazole in the binding buffer. Either method of elution is mild compared to most immunoaffinity separation techniques (discussed in the previous section). Thus, purification of the antibody–enzyme complex can be performed without damage to the activity of either component.

One limitation to this method should be noted. If the antibody–enzyme conjugate is prepared using antibody fragments such as Fab or $F(ab')_2$, then nickel chelate affinity chromatography will not work, since the requisite Fc portion of the antibody necessary for complexing with the metal is not present.

The preparation of a metal-chelate affinity support containing iminodiacetic acid functionalities may be found in Hermanson *et al.* (1992), or purchased from a commercial source (see also Chapter 15 for a discussion on the preparation of immobilized affinity ligands, including metal chelate resins). Any metal chelate support that is designed to bind His-tagged fusion proteins also will work well in this procedure. The following protocol is adapted from the instructions accompanying the nickel-chelate support. Thermo Fisher offers a kit based on this technology for the purpose of removing unconjugated enzyme from antibody–enzyme conjugates (called the FreeZyme™ Conjugate Purification Kit).

Protocol

1. Pack a column containing an immobilized iminodiacetic acid support (or another chelating agent designed to bind His-tagged proteins) (Thermo Fisher). The column size should be no less than 1.5 times that required to bind the anticipated amount of conjugate to be applied. The maximal capacity of such a column for binding antibody can be up to 50 mg/ml gel; however, best results are obtained if no more than 10 to 20 mg/ml of conjugate is applied.
2. Dissolve 50 mg of nickel ammonium sulfate per ml of deionized water. Apply 1 ml of nickel solution per ml of gel to the column. Note: The metal salt and all solutions containing it should be considered hazardous waste and disposed of according to relevant environmental regulations.
3. Wash the column with 10 volumes of water, then equilibrate the support with 2 volumes of 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.0 (binding buffer).
4. Dissolve or dialyze the conjugate into binding buffer. Apply the conjugate solution to the column while collecting 2-ml fractions.
5. Continue to wash the gel with 0.15-*M* NaCl (saline solution) until the absorbance at 280 nm is down to baseline. The protein eluting from the column at this point is unconjugated enzyme.
6. Elute the bound conjugate with 0.1-*M* sodium acetate, 0.5-*M* NaCl, pH 5.0. Pool the fractions containing protein, and dialyze the conjugate into 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.0, or other suitable storage buffers.

2. PREPARATION OF LABELED ANTIBODIES

In addition to labeling immunoglobulins with enzymes to provide detectability through their catalytic action on a substrate, antibody molecules can also be labeled or tagged with small compounds that can provide detectable properties, either directly or indirectly. The specificity of the antibody component of the conjugate can then be used to bind unique antigenic determinants, while the attached tag supplies the properties necessary for detection. Such small chemical labels are typically one of several types: intense fluorescent molecules, contrast agents, affinity tags, or unstable radioactive isotopes.

Radiolabeling antibodies with ^{125}I forms the basis for most of the original radioimmunoassays (RIA) that were first developed in the early days of immunoglobulin-mediated testing. The use of radioisotopes in tagging antibodies is used less often today for *in vitro* immunoassays due to the hazards associated with handling and disposal of radioactive compounds and the better sensitivity offered by using enzyme labels. However, radioisotopes are becoming very important as monoclonal antibody labels for *in vivo* diagnostic or therapeutic conjugates for cancer therapy or detection. Radioactive isotopes either directly attached to antibodies or attached through metal-chelating groups have become a significant tactic for the targeting and detection of tumor cells *in vivo* (Chapter 1 and Chapter 12) (van Dongen *et al.*, 2012). In addition, a radiolabel may have a distinct advantage over other chemical tags, because it is not influenced by conformational changes within the antibody molecule or by changes in its chemical environment, as enzymes or labels with unique spectral characteristics are often affected. Thus, in certain circumstances, radiolabels can still provide an important means of detection that approaches the most sensitive and reliable tags now available, particularly for *in vivo* imaging purposes.

Another form of label often used to tag antibody molecules is chemical modification with a biotin group. Biotinylation (see Chapter 11, Section 6) creates an affinity handle on an immunoglobulin with the ability to bind strongly either avidin or streptavidin in two of the most tightly held noncovalent interactions known. With a dissociation constant (K_d) on the order of 1.3×10^{-15}, the avidin–biotin interaction can be used to detect biotinylated molecules with extreme sensitivity. In this type of system, instead of the antibody being directly labeled with a detectable probe, the avidin (or streptavidin) molecules are modified to contain the detection complex—consisting of an enzyme, fluorescent probe, contrast agent, or radiolabel. Interaction of the

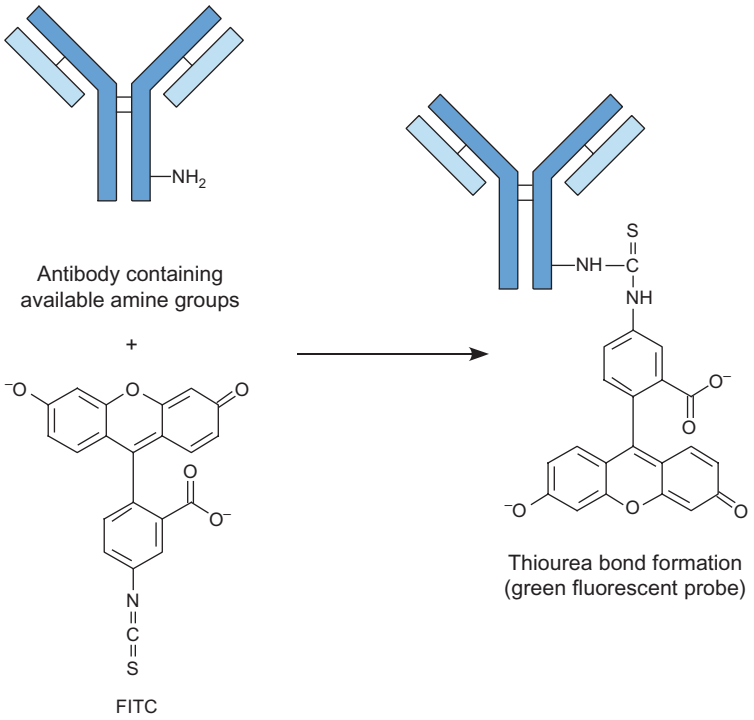

FIGURE 20.17 FITC may be used to label amine groups on antibody molecules, forming isothiourea bonds.

biotinylated antibody with its targeted antigen is then amplified and detected by the addition of such labeled avidin or streptavidin reagents.

The following three sections describe the preparation and properties of fluorescent, radiolabeled, and biotinylated antibodies. See also Chapter 1 for a review of labeled antibody reagents currently being used in a broad range of applications in research, diagnostics, and therapeutics as well as Chapters 10, 11, and 12 for discussions on the labels themselves.

2.1. Fluorescently Labeled Antibodies

Antibody molecules can be labeled with any one of more than a dozen different fluorescent probes currently available from commercial sources. Each probe option has its own characteristic spectral signals of excitation (or absorption) and emission (or fluorescence). Many derivatives of these fluorescent probes possess reactive functionalities convenient for covalently linking them to antibodies and other targeting molecules. Each of the main fluorophore families contains at least a few main choices in coupling chemistry to direct the modification reaction to selected functional groups on the molecule to be labeled. The most popular derivatives include amine-reactive, sulfhydryl-reactive, and carbonyl-reactive. Examples of some of the more useful varieties of fluorescent probes can be found in Chapter 10.

In addition to the wide range of commercial probes, many other fluorescent molecules have been synthesized and described in the literature. Only a handful, however, are generally used to label antibody molecules. Perhaps the most common fluorescent tags with application to immunoglobulin assays are reflected in the main derivatives produced by the prominent antibody manufacturing companies. These include derivatives of cyanine dyes, fluorescein, rhodamine, Texas red, aminomethylcoumarin (AMCA), and phycobiliproteins. Figure 20.17 shows the reaction of fluorescein isothiocyanate (FITC), one of the most common fluorescent probes, with an antibody molecule.

To a large degree, standardization has occurred in the use of these fluorescent probes due to the large body of published literature available on their successful application to antibody-based assays. As a result of this history, instrumentation has become widely available for measuring the fluorescence signals, including standard lasers and filter sets which match the common excitation and emission wavelengths. Such fluorescently labeled antibodies are used in immunohistochemical staining (IHC) (Osborn and Weber, 1982), in flow cytometry or cell sorting techniques (Ormerod, 1990; Watson, 1991), for tracking and localization of antigens, and in various double-staining methods (Kawamura, 1977). Extensive use of fluorescent antibodies in microscopy, pathology, and high content screening for drug discovery has made fluorescently

labeled antibodies the most common antibody derivatives used in immunochemical detection techniques (Lichtman and Conchello, 2005; Luo *et al.*, 2011).

In choosing a fluorescent tag, the most important factors to consider are good absorption (high extinction coefficient), stable excitation without photobleaching, and efficient, high quantum yield of fluorescence. Some fluorophores, such as fluorescein, exhibit rapid photobleaching and undergo fluorescent quenching due to dye–dye interactions at even moderate dye substitution levels, which lowers the quantum yield and fluorescence signal. Up to 50% of the fluorescent intensity observed on a fluorescein-stained slide can be lost within one month in storage. AMCA and some cyanine dyes have much better stability, but all fluorophores lose some intensity upon exposure to light or upon storage. Exceptions to this rule are the use of fluorescent nanoparticles, such as dye-doped silica (Chapter 14, Section 5) and quantum dots (Chapter 10, Section 10).

In some cases, the preparation of a fluorescently labeled antibody is not even necessary. Particularly, if indirect methods are used to detect antibody binding to antigens, then preparing a fluorescently labeled primary antibody is not needed. Instead, the selection from a commercial source of a labeled secondary antibody having specificity for the species and class of primary antibody to be used is all that is required. However, if the primary antibody needs to be labeled and it is not manufactured commercially, then a custom labeling procedure will have to be performed.

Generalized protocols for the attachment of these fluorophores to protein molecules, including antibodies, can be found in Chapter 10 and Chapter 14, Section 5. The main consideration for the modification of immunoglobulins is to couple these probes at an optimal level to allow good detectability without high backgrounds. Too low a substitution level and the response of the fluorophore will yield low signal strength and poor sensitivity. Too high a substitution level and the fluorophore may self-quench through energy transfer, decrease the antibody's ability to bind target molecules by blocking the antigen binding sites, or cause nonspecific interactions resulting in high background or noise levels. In some cases, trial and error will be required to optimize this process.

For other examples of antibody labeling protocols see Goding (1976) and Harlow and Lane (1988).

2.2. Radiolabeled Antibodies

The attachment of a radioactive label onto an antibody molecule provides a powerful means of detection in immunoassay procedures, tracking of analytes, for *in vivo* diagnostic procedures, and, more recently, for the detection or therapy of numerous types of cancers. Originally, radiolabeling of antibodies merely meant modifying tyrosine residues with ^{125}I. Now, a number of different radioactive elements are being attached, both covalently and through specialized chelating compounds to provide imaging capabilities for the detection of primary tumors and metastases (Order, 1989).

Radioiodination can be carried out using any one of a number of techniques. Most of the procedures utilize ^{125}I as the unstable isotope of choice for *in vitro* use due to its easy availability, comparably long 60-day half-life, and relatively low-energy photon emissions. Radioactive ^{125}I usually is supplied as its sodium salt and must be oxidized to create an electrophilic species capable of modifying molecules. Commonly used oxidizing agents include chloramine-T, Iodogen, and Iodo-beads (Chapter 12, Section 2). When used in direct labeling techniques with antibodies and other proteins, these oxidants cause an iodination reaction to occur at available tyrosine or histidine residues within the polypeptide chain. If either of these amino acids is important to antibody activity and cannot be labeled, then certain crosslinking or modification reagents containing an activated aromatic ring may be used to radiolabel the molecule at other functional sites, particularly at lysine amines. An example of this technique is to use the Bolton–Hunter reagent (Chapter 12, Section 2.5) labeled with radioactive iodine to modify the primary amines within the antibody. This reagent also can be used to add an iodinatable site to molecules containing no tyrosine residues (Figure 20.18).

Reagent options and protocols for the radioiodination of antibodies and other molecules may be found in Chapter 12.

Another method of adding a radioactive tag to antibodies is to use a chelating compound capable of complexing metal isotopes. One of the most frequently used chelating reagents is diethylenetriamine pentaacetic acid (DTPA) (Chapter 12, Section 1.1). The reagent contains 2 anhydride groups that can be used to modify primary amines in proteins and other molecules. The reaction process involves ring opening and the formation of an amide bond. Ring opening also creates up to four free carboxylate groups which, combined with the three nitrogen atoms in the chelator, are able to form strong coordination complexes with metals such as indium-111 (Figure 20.19). Monoclonal antibodies labeled with bifunctional chelating agents containing radioisotopes can be used in targeting tumor cells *in vivo*. The detection sensitivity of radiolabeled antibodies has led to effective diagnostic procedures to monitor primary and secondary cancer growths. In addition, the intensity of radioactivity at the tumor site when labeled monoclonals are used therapeutically can be great enough to cause tumor cell death and remission.

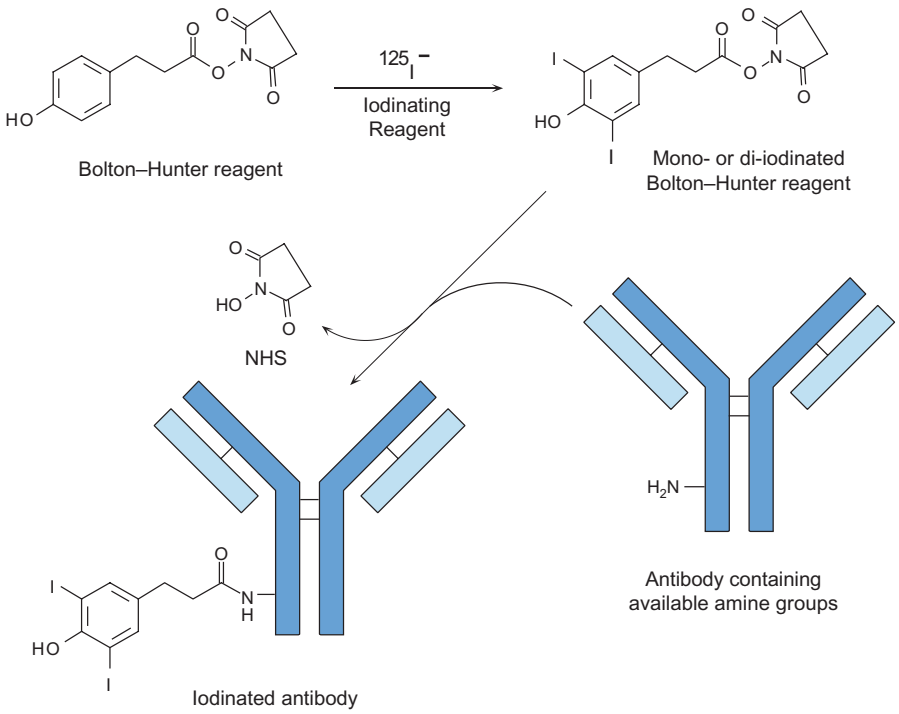

FIGURE 20.18 Bolton–Hunter reagent may be used to add radioactive iodine labels to antibody molecules by modification of amines.

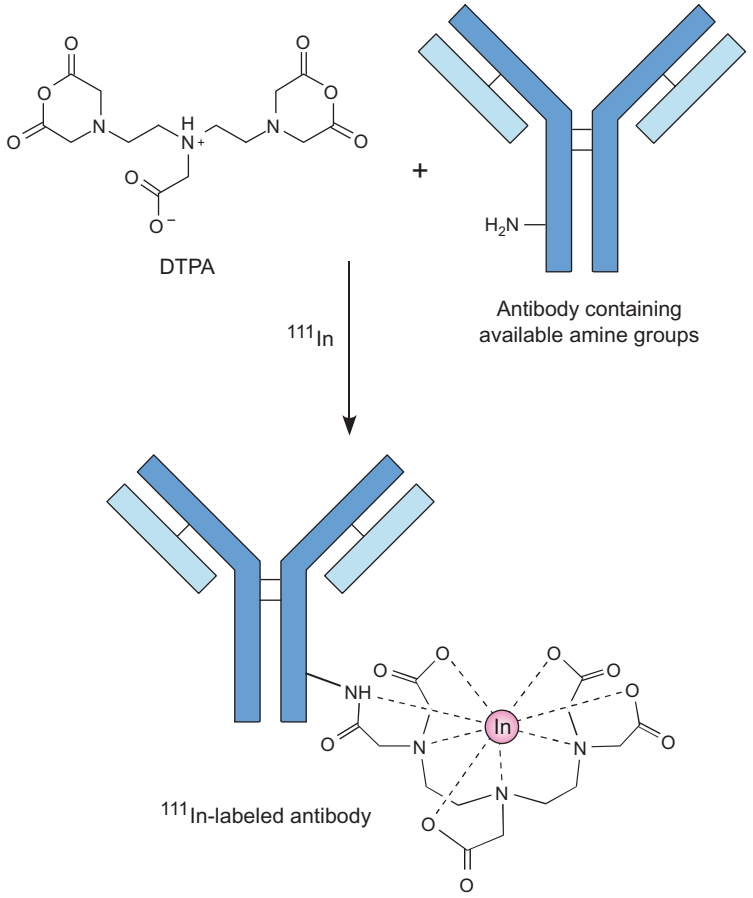

FIGURE 20.19 The bifunctional chelating reagent DTPA may be used to modify amine groups on antibody molecules, forming amide bond linkages. The isotope indium-111 may then be complexed to the chelator group to create a radiolabeled targeting reagent.

2.3. Biotinylated Antibodies

Another popular tag for use with immunoglobulins is biotin. Modification reagents that can covalently add a functional biotin group to proteins, nucleic acids, and other molecules now come in many shapes and reactivities (Chapter 11, Section 6, and Chapter 18, Section 1.3). Depending on the reactive group present on the biotinylation reagent, precise functional groups on antibodies may be modified to create an affinity tag capable of binding avidin or streptavidin derivatives. Amines, carboxylates, sulfhydryls, and carbohydrate groups can be specifically targeted for biotinylation through the appropriate choice of reactive biotin compound and modification procedure. Figure 20.20 shows the biotinylation of an antibody with NHS–LC-biotin, one of the most common biotinylation reagents.

Streptavidin conjugates are now used extensively to detect biotinylated antibodies after they have bound an antigen. A streptavidin probe labeled with an enzyme, fluorophore, high-contrast agent, or radiolabel can provide a very sensitive detection system to locate or assay antigens in many different applications. In addition, the potential for more than one labeled (strept)avidin conjugate to become attached to each biotinylated antibody through multiple biotin groups provides an increase in detectability over antibodies directly labeled with a detectable tag.

Several assay designs that use the enhanced sensitivity afforded through biotinylated antibodies have been developed. Most of these systems use conjugates of avidin or streptavidin with enzymes (such as HRP or AP), although other labels (such as fluorophores) can be used as well. In the simplest assay design, called the labeled avidin–biotin (LAB) system, a biotinylated antibody is allowed to incubate and bind with its target antigen. Next, an avidin–enzyme conjugate is introduced and allowed to interact with the available biotinylation sites on the bound antibody. Substrate development then provides the detectability necessary to quantify the antigen.

In a slightly more complex design, the bridged avidin–biotin system (BRAB) uses (strept)avidin's multiple biotin-binding sites to create an assay potentially of higher sensitivity than that of the LAB assay. Again, the biotinylated antibody is allowed to bind its target, but next unmodified (strept)avidin is introduced to bind with the biotin binding sites on the antibody. Finally, a biotinylated enzyme is added to provide a detection vehicle. Since the bound (strept)avidin still has additional biotin binding sites available, the potential exists for more than one biotinylated enzyme to interact with each bound (strept)avidin molecule. In some cases, sensitivity can be increased over that of the LAB technique by using the bridging ability of avidin or streptavidin (Chapter 11, Section 2).

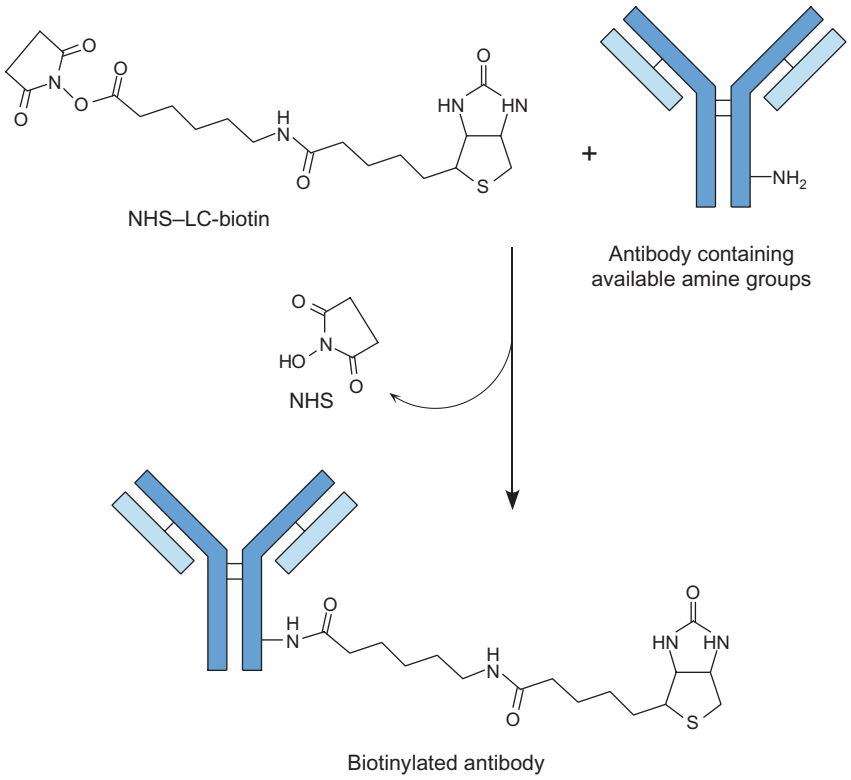

FIGURE 20.20 Biotinylated antibodies can be formed by reacting NHS–LC-biotin with available amine groups to create amide bonds.

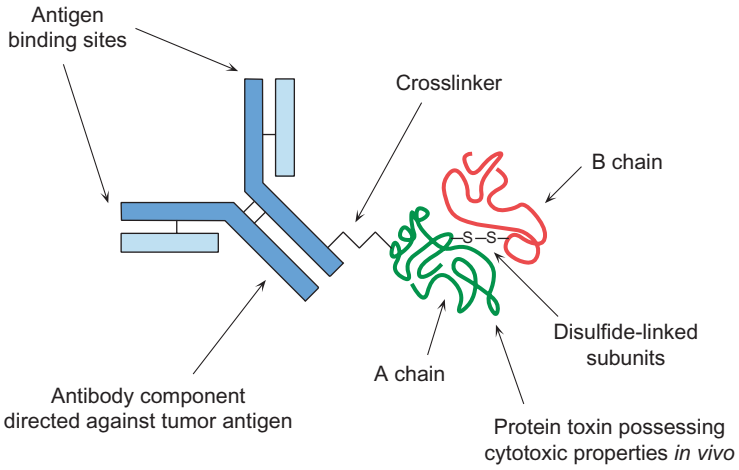

FIGURE 20.21 The basic design of an immunotoxin conjugate consists of an antibody-targeting component crosslinked to a toxin molecule. The complexation typically includes a disulfide bond between the antibody portion and the cytotoxic component of the conjugate to allow release of the toxin intracellularly. In this illustration, an intact A–B toxin protein provides the requisite disulfide, but the linkage may also be designed into the crosslinker itself.

A modification on this theme can be used to produce one of the most sensitive enzyme-linked assay systems known. The ABC system (for avidin–biotin complex) increases antigen detectability beyond that possible with either the LAB or BRAB designs by forming a polymer of biotinylated enzyme and (strept)avidin before addition to an antigen-bound, biotinylated antibody. When avidin and a biotinylated enzyme are mixed together in solution in the proper proportion, the multiple binding sites on (strept)avidin create a high-molecular-weight, multimeric complex. If the biotinylated enzyme is not in large enough excess to block the binding sites on all the (strept)avidin molecules, then additional sites will still be available on this complex to bind a biotinylated antibody bound to its complementary antigen. The large complex provides multiple enzyme molecules to dramatically enhance the sensitivity of detecting antigen. Thus, the ABC procedure is currently among the highest-sensitivity methods available for immunoassay work.

More detailed discussions of (strept)avidin–biotin systems as well as the process of adding a biotin affinity group to proteins, nucleic acids, and other biomolecules can be found in Chapter 11.

3. IMMUNOTOXIN CONJUGATES

Monoclonal antibodies directed against tumor antigens may be used as targeting agents for conducting certain cytotoxic substances to malignant cells for selective killing. Numerous cell surface markers are known to proliferate in human solid tumors (Boyer *et al.*, 1988; Carter *et al.*, 2004; Aplin *et al.*, 2011; Kelly *et al.*, 2011; Yang *et al.*, 2011). The ability to raise monospecific antibodies to these markers creates the capacity to discretely target the tumor, causing cell death while leaving healthy cells alone (Salmon, 1989; McCarron *et al.*, 2005).

The design of such cytotoxic antibodies is conceptually simple: attach a toxic substance or a mediator of toxicity to the appropriate monoclonal and you have a "magic bullet" that can find and eliminate the one-in-a-billion cells that have the requisite marker (Figure 20.21). The antibody provides the recognition and binding capacity, while the associated toxic component effects cellular alterations leading to cell death (Pastan *et al.*, 2006).

The approach to constructing antibody immunoconjugates for cancer has taken a number of forms (Vogel, 1987; Dosio *et al.*, 2011). One of the first designs used conjugates of monoclonal antibodies with toxins that were able to block protein synthesis at the ribosome level inside the cell (Lord *et al.*, 1988). Other conjugate forms used radioactive labels that killed cells by overexposure to radiation in proximity to where antibody docking occurred (Order, 1989). Drug conjugates were also constructed that combined the known benefits of chemotherapy with the targeting capability of monoclonals (Reisfeld *et al.*, 1989; Willner *et al.*, 1993; Bross *et al.*, 2001; Sievers and Senter, 2012). The expected result was the effective concentration of the chemotherapeutic agent at the location of the tumor—hopefully eliminating or minimizing the side-effects of traditional chemotherapy. In addition, conjugates of monoclonals with certain biological modulators such as lymphokines or growth factors were tried to affect malignant cell viability (Obrist *et al.*, 1988; Choudhary *et al.*, 2011).

Some immunoconjugates utilize intermediate carrier systems consisting of polymeric molecules such as polysaccharides, particularly dextran (Hurwitz *et al.*, 1978, 1980, 1983a,b, 1985; Manabe *et al.*, 1983; Sela and Hurwitz, 1987). The activated dextran is crosslinked to both the monoclonal and the cytotoxic agent, providing multivalent conjugation sites to create larger complexes (Section 2.3, this chapter, and Chapter 18, Section 2). Liposomes can be used in similar fashion by anchoring the antibody to its outer surface and charging the

vesicle with cytotoxic compounds (Gregoriadis, 1984; Ho *et al.*, 1986; Matthay *et al.*, 1986; Singhal and Gupta, 1986; Kirpotin *et al.*, 2012). See Chapter 21 for a survey of liposome conjugation techniques. Also, dendrimer conjugates with antibody targeting molecules and cytotoxic components have been used to create multivalent immunotoxin conjugates (Chapter 8).

Other systems have been designed to use a two-stage approach where an antibody is conjugated with an intermediate agent, which, when combined with another factor, could elicit cytotoxicity. For instance, enzyme conjugates with monoclonals have been used that could transform an inactive pro-drug into a chemo-cytotoxic agent *in vivo* (Senter *et al.*, 1989). Antibody-directed enzyme-prodrug therapy (ADEPT) has become an important option in the design of antibody therapeutics (Tietze and Schmuck, 2011). See Chapter 1, Section 3.5, for current applications of ADEPT conjugates.

Monoclonals can also be tagged with a biotin label and a secondary, avidin–toxin conjugate used to target the antibody once it bound the tumor cell. Two-stage radiative treatment also has been tried through the use of boron neutron capture therapy (Holmberg and Meurling, 1993). In this case, a carrier molecule is modified to contain ^{10}B. After administration *in vivo* to target tumor cells, neutron bombardment yields an unstable intermediate ^{11}B which immediately undergoes a fission reaction to yield ^{7}Li and ^{4}He. The induced radiation from this decomposition then kills the surrounding cells.

Tumor-targeting conjugates which use biospecific agents other than monoclonal antibodies have been developed as well. The targeting component in these systems consists of any molecule that can function as a ligand having specific affinity for some receptor molecule on the surface of the tumor cells. Such an affinity molecule might be a hormone (typically called hormonotoxins) (Singh *et al.*, 1989; Singh *et al.*, 1993), a growth factor, an antigen specific for binding particular antibodies projecting from B cell surfaces, transferrin, α_2-macroglobulin, or anything else able to specifically interact with the targeted tumor cells. See Chapter 1 for a review of current strategies in the use of antibody conjugates and other conjugates in the treatment of cancer.

It became apparent very early in the development of such agents that their conception and design was much easier to imagine than to successfully implement. Monoclonal antibodies used *in vitro* could easily detect antigen molecules in complex mixtures with very little nonspecificity or cross-reactivity, even in cell-based assays. Very quickly following the invention of hybridoma technology, monoclonals were employed in numerous diagnostic assays and their use in detection and assay applications continues to grow. The use of monoclonals as therapeutic agents *in vivo*, however, was complicated by the body's natural immune response designed to prevent the invasion of foreign substances.

A major problem in the use of immunotoxins is that injection of conjugates prepared from mouse (or animal-based) monoclonals usually results in antibody production against the foreign protein. Antibodies of animal origin quickly get removed from circulation by the immune system, which prevents any therapeutic benefit from the conjugate drug. Sometimes allergic reactions can further complicate the side-effects, making continued therapy infeasible. Most often, however, induced host immunoglobulins will quickly bind the immunoconjugate and remove it from the circulatory system. Instead of finding the targeted tumor cells, the immunotoxin conjugate ends up sequestered and degraded in the liver or removed by the kidneys. Since the common culprit in this scenario is often the monoclonal, the acronym HAMA, for *human anti-mouse antibody*, is given to this response.

In an attempt to overcome the HAMA problem, "humanized" mouse monoclonals were designed where large portions of the murine antibody are substituted for their human counterparts. For instance, replacing a mouse Fc portion with the corresponding human ones can significantly decrease the immune response against such conjugates. Replacing everything but the hypervariable regions that code for antigen binding has been accomplished, too. Unfortunately, regardless of how much "humanization" is done, the remaining murine part still has the potential of causing immunological reactions. However, in the intervening years since the beginning of monoclonal antibody targeting in the late 1970s, the development of fully human antibodies and antibody–drug conjugates (ADCs) of many types has dramatically changed the effectiveness of such agents *in vivo* (Jakobovits, 1995; Kucherlapati *et al.*, 2012). The advent of recombinant antibody technology and transgenic mice producing antibodies of completely human origin has essentially overcome the problem of immune system response to the antibody component. As a result, there are now hundreds of antibody therapeutic agents in development and over a dozen antibody conjugates in late-stage clinical trials with excellent prospects for approval (see *Therapeutic Monoclonal Antibodies: World Market 2010–2025*, Visiongain, 2010). ADCs employing fully human antibodies attached to many different chemotherapeutic agents are now poised to revolutionize the use of antibody conjugates for the treatment of disease (Chari, 2008). See Chapter 1 for an extensive overview of antibody bioconjugates designed for therapeutic purposes.

Modification of immunotoxin conjugates with synthetic polymers also has been used to mask the complex from the host immune response. Particularly, polyethylene glycol (PEG; see Chapter 18) has been found to be quite successful in reducing or eliminating immune system reactions to modified proteins or antibodies (Roffler and Tseng, 1994). Modification of an antibody conjugate with two to four PEG molecules increases the serum half-life and improves tumor localization of the targeted reagent.

Other innovations in preparing targeted conjugates for cancer utilize recombinant DNA techniques to create antibody molecules that are entirely of human origin (Huse *et al.*, 1989; Orlandi *et al.*, 1989; Sastry *et al.*, 1989; Ward *et al.*, 1989). A completely human antibody molecule eliminates the immunological problems associated with mouse monoclonals. Intact antibodies, Fab fragments, small Fv fragments held together by synthetically designed amino acid segments, and short peptides representing the antigen binding site have all been developed by recombinant means. Although frequently the word "antibody" is used to describe these engineered proteins, many of the molecules are far removed from the traditional picture of an antibody molecule. The terms "single-chain antibody" or "single-chain Fv protein" are commonly used and more closely describe these new targeting molecules.

With the great diversity of targeted toxic agents being developed for cancer therapy, it would be difficult to characterize this section strictly as antibody conjugation. While many, if not most, studies utilize monoclonal antibodies of one form or another as the biospecific targeting component, the complete picture involves the crosslinking of a wide variety of molecules together to create the final conjugate. This section presents some of the most common methods of immunotoxin preparation. For the preparation of other unique targeted toxin conjugates, including.

ADCs, the methods found throughout this book for linking one particular functional group to another, can be followed with an excellent probability for success. When preparing ADC conjugates, it is often important to give great consideration to the cross-bridge and linkages formed between the antibody and the drug. Bonds that are cleavable *in vivo*, such as disulfides and hydrazone linkages, have proven to be essential in the successful design of effective ADCs (McCarron *et al.*, 2005; Beck, 2010).

3.1. Properties and Use of Immunotoxin Conjugates

Conjugates of monoclonal antibodies and protein toxins have been studied extensively for their usefulness in the treatment of cancer (Chandramohan *et al.*, 2012). Toxins of many different types can be used to create effective immunotoxin conjugates, including the proteins ricin from castor beans (*Ricinus communis*), abrin from *Abrus precatorius*, modeccin, gelonin from *Gelonium multiflorum* seeds, diphtheria toxin produced by *Corynebacterium diphtheriae*, pokeweed antiviral proteins (PAPs; three types: PAP, PAP II, and PAP-S) from *Phytolacca americana* seeds, cobra venom factor (CVF), *Pseudomonas* exotoxin, restrictocin from *Aspergillus restrictus*, momordin from *Momordica charantia* seeds, saporin from *Saponaria officinalis* seeds, as well as other ribosome-inactivating proteins (RIPs).

By far the most popular choices for the toxin component of protein-based immunotoxins are ricin, abrin, modeccin, and diphtheria toxin. The three plant toxins have lectin binding activity toward terminal β-galactosyl residues and they can be inhibited by the presence of simple sugars like galactose and lactose. The toxin proteins bind to cell-surface polysaccharide receptors with high affinity (K_a in the range of 10^7–10^8/M). Ricin, abrin, and modeccin consist of two subunits with remarkably similar structures and activities. The intact proteins have molecular weights of approximately 63–65,000 with each subunit of about equal size. The subunits are joined by disulfide linkages that are important reversible bonds in the mechanism of cytotoxicity. The A chain is called the effectomer and possesses ribosomal-inactivating properties. The B chain contains the carbohydrate binding site and it is termed the haptomer. While the intact toxin molecules have potent cytotoxic effects on cells, they exhibit no ribosomal inactivating activity on ribosomes in a cell-free system. By contrast, reduction of the toxins with a disulfide reducing agent creates the opposite effects. Reduced, dissociated toxin subunits inhibit ribosomal activity in cell-free systems, but they have no affect on intact cells.

The reason for these properties is due to the toxins' mode of action. Toxin molecules bind through saccharide recognition sites on the B chain to particular β-galactosyl-containing glycoprotein or glycolipid components on the surface of cell membranes. In animals sensitive to these toxins, the necessary polysaccharide ligands are present in large quantities on virtually all cell types (Cumber *et al.*, 1985). Upon binding of the protein dimer to the cell, the A chain enters the cell either by active transport into endocytic vesicles or through some mechanism of its own. Once inside the cell membrane, the A chain enters the cytoplasmic space, binding to and enzymatically inactivating the 60S subunit of ribosomes (Olsnes and Pihl, 1976, 1982). The result is cessation of protein synthesis and eventual cell death. Because the A chain's action is through enzymatic means, as little as one active toxin molecule is enough to seriously disrupt protein synthesis operations and probably sufficient to kill a target cell (Eiklid

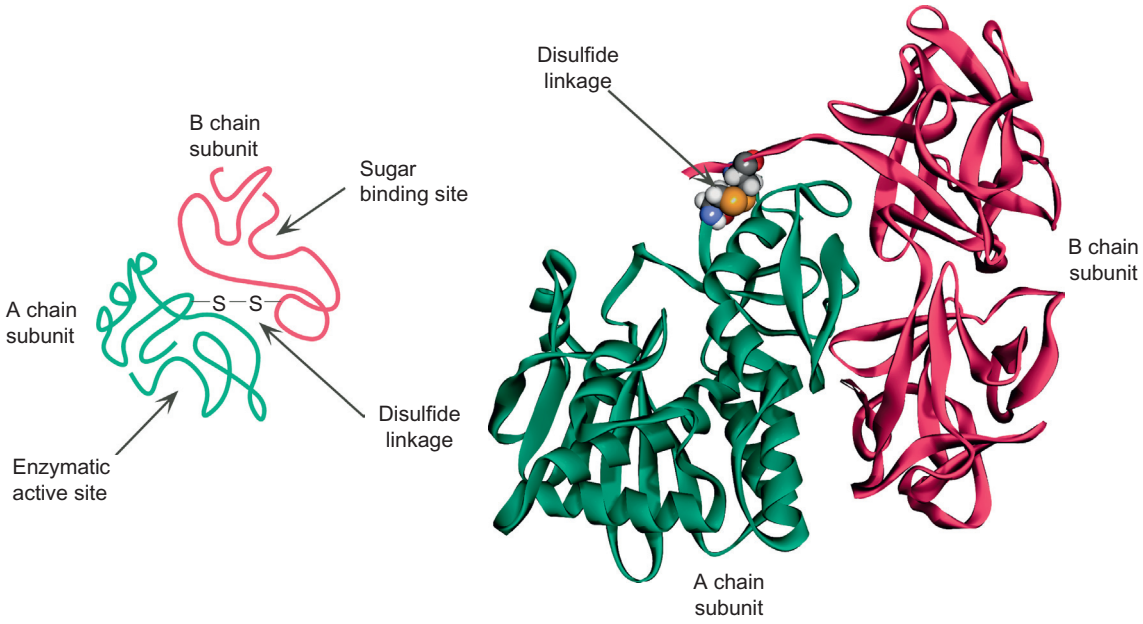

FIGURE 20.22 Conceptualized construction of an A–B subunit protein toxin (left). The B chain contains a binding region for docking onto cell surfaces, while the A chain contains a catalytic site that produces cytotoxic affects intracellularly. The two subunits are joined by a disulfide bond that is reductively cleaved at the cellular level to allow the A subunit to cause cell death. A molecular model of the protein toxin ricin is on the right.

et al., 1980). The turnover rate of one A chain molecule is about 1500 ribosomes inactivated per minute (Olsnes, 1978).

Diphtheria toxin also is a two-subunit protein, but it is initially synthesized by certain strains of *Corynebacterium diphtheriae* as a single polypeptide chain of molecular weight 63,000. Proteolytic processing results in the formation of a "nicked toxin" which is enzymatically inactive, but consists of two subunits bonded together by an interchain disulfide. Upon reduction of the disulfide, the A chain (MW 24,000) is released and manifests enzymatic activity toward ribosomal proteins (Collier and Cole, 1969; Sandvig and Olsnes, 1981). Its mode of action is different than that of the plant toxins. The A chain fragment of diphtheria toxin catalyzes the ADP-ribosylation of eukaryotic aminoacyl-transferase II (EF2) using NAD^+ (Honjo *et al.*, 1968; Gill *et al.*, 1969). The B chain, by contrast, possesses no enzymatic activity, but evidence points to the fact that a binding site on it recognizes certain cell surface receptors. As in the action of ricin, abrin, and modeccin, the B chain of diphtheria toxin is necessary for cytotoxicity (Colombatti *et al.*, 1986). There also is a role for the C-terminus cysteine residue of the B chain in cell penetration (Dell'Arciprete *et al.*, 1988).

Figure 20.22 illustrates the basic structure of these common two-subunit toxins, showing schematically their major characteristics. The molecular model of ricin is from Rutenber *et al.* (1991), RSCB structure No. 2aai.

Due to the extraordinary toxicity of intact ribosome-inactivating toxins like ricin, abrin, and modeccin, purification and handling of these proteins must be carried out with extreme care. Even dust from crude seed powders or lyophilized proteins should be considered dangerous. During the height of the Cold War days, a Soviet KGB agent killed a man from the West by injecting at most only milligram quantities of ricin into his leg using a modified umbrella tip. There even have been instances of worker deaths at companies that routinely purify these proteins. For this reason, all handling operations of intact toxin dimers and purified subunits should be performed in fume or laminar-flow hoods. Avoid, also, the use of laboratory tools that could lead to puncture wounds causing contaminating toxin injection.

Some potentially cytotoxic proteins contain only a single polypeptide chain, such as gelonin and PAPs. Such toxins manifest similar enzymatic ribosome-inactivating properties as the multi-subunit proteins like ricin, but do not possess the cell-recognition capacity that the B chain subunit contains. The result is the inability of these toxins to bind or affect intact cells. However, they do maintain the typical ribosome-inactivating properties in a cell-free system that the A chain of two-subunit toxins possess. If these proteins are conjugated with a cell-targeting agent, such as the B chain of ricin or a specific antibody that recognizes cell-surface epitopes, full cytotoxicity results.

Gelonin and PAPs are much more convenient to work with than ricin and the other two-subunit toxins. Most importantly, they are relatively nontoxic to cells unless conjugated with something that can facilitate cell binding and internalization (Stirpe *et al.*, 1980; Irvin, 1983). The pI of these toxins is in the basic range, and they each have a molecular weight of about 30,000 (Barbieri and Stirpe, 1982). These single-subunit proteins are very stable, especially to purification techniques, but also to most modification and crosslinking steps associated with preparing immunotoxins. Studies have shown (Lambert *et al.*, 1985) that modification of gelonin or PAPs can be performed with 2-iminothiolane (Traut's reagent; Chapter 2, Section 4.1) to create sulfhydryl groups without loss of activity. Previous studies, however, have determined that the use of SPDP to modify gelonin resulted in a 90% inactivation (Thorpe *et al.*, 1981). The difference in these results may be due to the retention of positive charge characteristics on the modified amine when using Traut's reagent, but neutralization of that charge when using SPDP. This is an example of how a slight difference in conjugation strategy can result in a dramatic difference in conjugate performance.

Immunotoxin conjugates consist of an antibody covalently crosslinked to a toxin molecule in a way that maintains the unique properties of both proteins. The antibody component consists of a monoclonal having specificity for an antigenic determinant on the surface of a particular cell type. Most often, the targeted cells are tumors that express a unique cell surface marker which can be recognized by the monoclonal. The role of the antibody, therefore, is to function as a passive taxi, carrying the toxin component to the targeted cells. Once at the tumor location, the toxin component effects its intended ribosome-inhibiting action, ultimately causing cell death and tumor destruction.

Since immunotoxin conjugates are destined to be used *in vivo*, their preparation involves more critical consideration of crosslinking methods than most of the other conjugation protocols described in this book. The following sections discuss the issues associated with toxin conjugates and the main crosslinking methods for preparing them.

3.2. Preparation of Immunotoxin Conjugates

It has become apparent that the method of crosslinking can dramatically affect the activity of an immunotoxin *in vivo*. This is true not only with regard to possible direct blocking by the crosslinker of the enzymatic active site which is responsible for inactivation of ribosomes, but the chemistry of conjugation is also an important factor in proper binding and entry of the conjugate into the cell. Preparation of the conjugate should maintain the antigen binding character of the attached antibody and at the same time not block the ribosome-inactivating activity of the toxin component.

Studies have been carried out to investigate the importance of using a cleavable linker between the antibody and the toxin. This configuration in the immunoconjugate would mimic the natural state of two-subunit toxins like ricin that are held together by disulfide bonds. There is evidence that disulfide reduction and cleavage of the A chain from the B chain is necessary for cytotoxicity in native toxins (Olsnes, 1978). There is similar evidence that the creation of cytotoxic immunotoxins using only A chain subunits requires that the conjugation be done with a monoclonal using a crosslinker that possesses a disulfide bond in its cross-bridge or creates a disulfide linkage upon coupling (Masuho *et al.*, 1982). Using disulfide-cleavable crosslinkers in the preparation of immunotoxins results in the antibody taking on the role of the B chain in recognizing and binding to antigenic determinants on the surface of cells. After binding, some mechanism internalizes the conjugate wherein the two components then are separated by disulfide reduction. The A chain subunit is then freed to enter the cytoplasmic space where enzymatic degradation of the ribosomal proteins occurs.

Other investigators, however, have demonstrated that conjugations of antibody with intact, two-subunit toxins can be carried out using non-cleavable crosslinkers such as NHS ester–maleimide heterobifunctionals (Chapter 6, Section 1) (Myers *et al.*, 1989). Presumably, the toxin is still able to release the A chain after the antibody has bound to the cell, since the conjugation process does not permanently attach the two toxin subunits together—only the toxin to the antibody.

Thus, two main strategies can be used in making immunotoxin conjugates (Figure 20.23). In the most often used method, the isolated A chain of two-subunit toxins (or the intact polypeptide of single-subunit toxins like gelonin) is conjugated to a monoclonal using a crosslinker that can introduce a disulfide bond. When using only purified A chain, it is common (but not absolutely required) to couple through the sulfhydryl that is freed during A–B chain cleavage by disulfide reduction. The single-chain toxins like gelonin, however, have no free sulfhydryls, so a thiolation agent such as 2-iminothiolane (Chapter 2, Section 4.1) may be used to create them (Lambert *et al.*, 1985).

When using ricin A chains, it has been found that chemical deglycosylation of the subunit prevents its nonspecific binding to receptors for mannose on certain cells of the reticuloendothelial system (Bitetta and Thorpe, 1985; Ghetie *et al.*, 1988, 1991; O'Hare *et al.*, 1988). Thus, immunotoxin conjugates consisting of deglycosylated ricin A chain (dgA) have been shown to survive longer *in vivo* and are more efficient

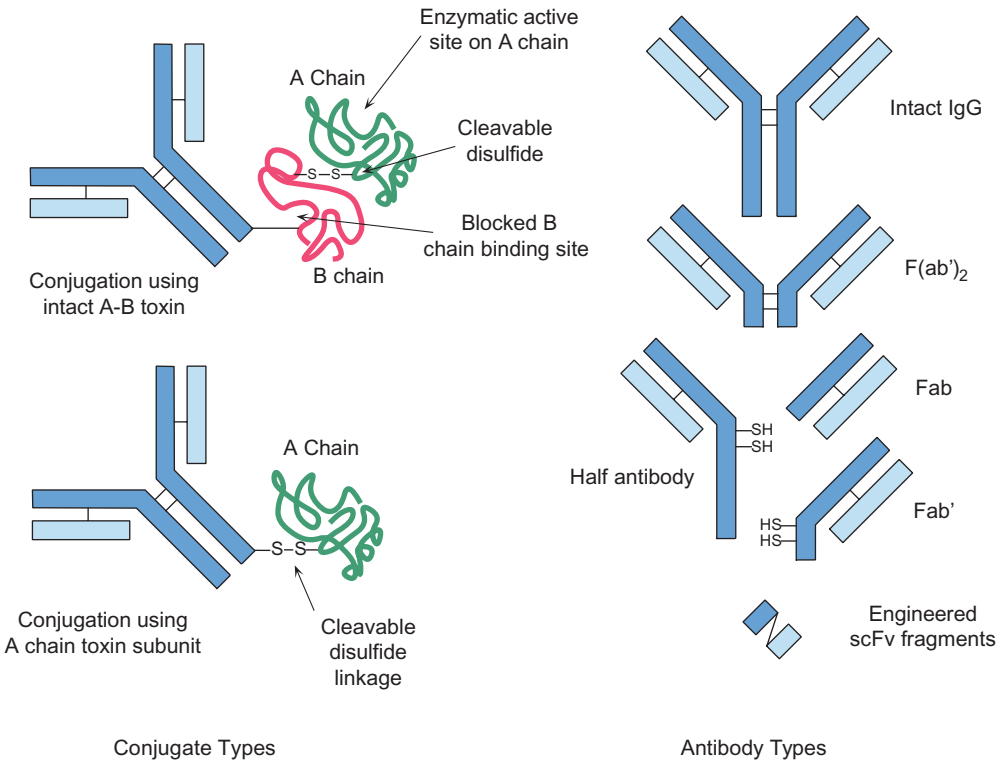

FIGURE 20.23 The strategies involved in creating an immunotoxin conjugate are numerous. Intact antibody molecules or enzymatic fragments may be used as the targeting component. Even small recombinant Fv fragments that are genetically engineered to limit host immune response can be employed. Conjugates can include two-subunit toxins or purified A chain components. If intact toxins are used, the B chain binding site must be blocked to prevent nonspecific cell death. If A chain subunits are used, to induce cytotoxic effects in the conjugate the crosslinking agent must generate a disulfide bond that can allow toxin release.

at reaching their intended target cells. In addition, if the antibody component does not contain Fc region, but consists of only $F(ab')_2$, Fab′, Fab, or smaller Fv fragments, then nonspecific binding of the immunotoxin *in vivo* will be reduced to a minimum. One study found that constructing immunotoxin conjugates with molar ratios of two dgA per antibody molecule resulted in a 7-fold increase in cytotoxicity over a 1:1 conjugate ratio (Ghetie *et al.*, 1993).

A chain immunotoxins, however, may not be quite as cytotoxic as conjugates formed from intact toxin molecules (Manske *et al.*, 1989). In an alternative approach to A chain use, the intact toxin of two-subunit proteins is directly conjugated to a monoclonal without isolation of the A chain. Conjugation of an antibody with intact A–B chain toxins can be performed without a cleavable linker, as long as the A chain can still separate from the B chain once it is internalized. Therefore, it is important to avoid intramolecular crosslinking during the conjugation process which can prevent release of the A–B complex. In addition, since the B chain possesses a recognition site for most cell surfaces, it still has the ability to nonselectively bind and kill non-tumor cells. To maintain antibody specificity in intact toxin conjugates toward only one cell type (and thus prevent nonspecific cell death), all cell binding capability within the toxin itself must be removed. Fortunately, a large proportion of the binding sites on the B chains are usually blocked during the conjugation process, and the galactose binding potential is significantly impaired. Further purification to remove conjugates that have remaining galactose binding potential can be carried out on an acid-treated agarose chromatography column (which contains galactose residues) or on a column of asialofetuin bound to agarose (Cumber *et al.*, 1985). Conjugate fractions which do not bind to both affinity gels contain no nonspecific binding potential toward non-targeted cells.

More elaborate methods of blocking or eliminating the B chain galactose binding site can also be done to prevent nonspecific cytotoxicity. For instance, the crosslinking agent may have a lactose molecule designed into it that can block B chain activity. The lactose portion possesses natural affinity for the B chain binding site, and thus it occupies that area while a nearby reactive group covalently attaches the crosslinker to neighboring functional groups on the protein.

Moroney *et al.* (1987) used this approach in creating a ricin conjugate. Lactose was modified at its reducing

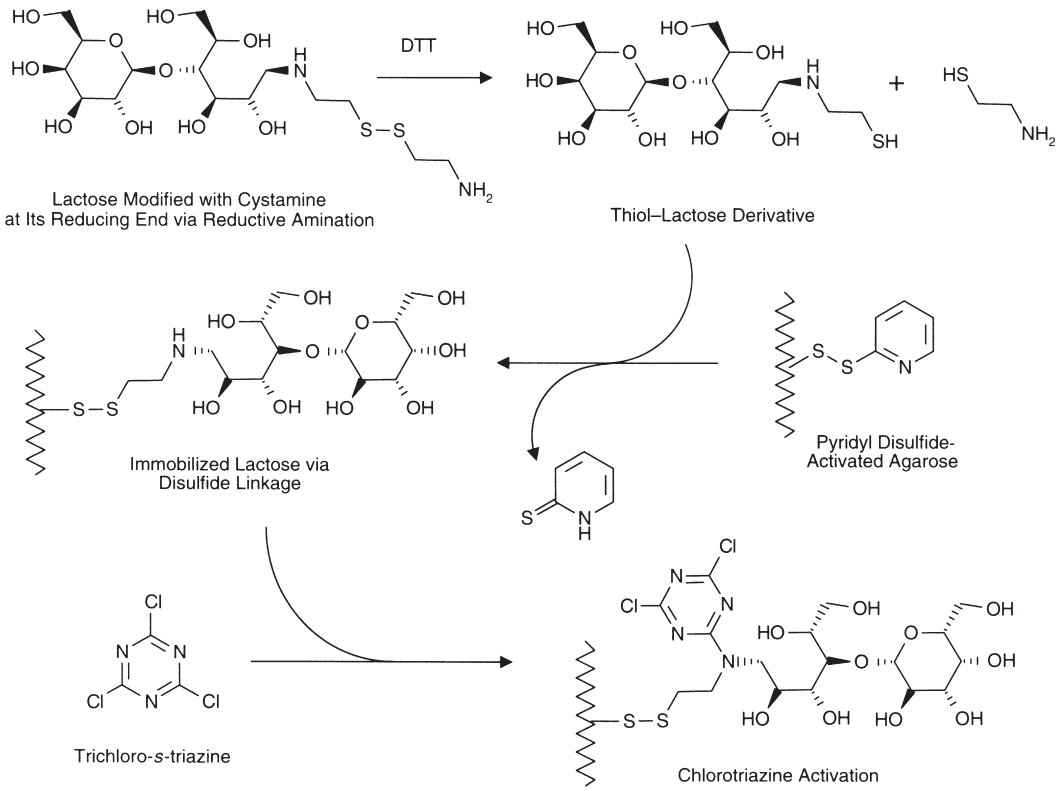

FIGURE 20.24 In an elaborate strategy to block the B chain binding site in the construction of immunotoxins using intact A–B subunit toxins, cystamine was first coupled to the reducing end of lactose by reductive amination. DTT was then used to reduce the cystamine disulfide group, revealing the free thiol. A pyridyl disulfide-activated agarose gel then was used to couple the lactose derivative through its sulfhydryl. Next, trichloro-*s*-triazine was reacted with the support to modify the secondary amine on the cystamine component, forming a reactive gel. Finally, addition of an intact toxin to the affinity support caused binding with the lactose group at the B chain binding site. Since the B chain was now in proximity to the chlorotriazine ring, covalent coupling occurred with available amines on the protein toxin, thus permanently blocking the binding pocket. After removal of the modified toxin from the gel using a disulfide reducing agent, the free thiol of the cystamine group was used to conjugate with an SMCC-activated immunoglobulin.

end with cystamine *via* reductive amination (Chapter 2, Section 5.3). The cystamine was reduced with dithiothreitol (DTT) and immobilized on an affinity gel which was activated with a pyridyl dithiol group (Chapter 3, Section 2.6). The coupled lactose was then modified with a chlorotriazine derivative through the secondary amine that was created by the reductive amination process. Next, the ricin molecule was immobilized by the additional reactive group on the chlorotriazine ring. Since this reactive group was immediately adjacent to the lactose residue, the ricin bound the sugar at its B chain binding site and it was covalently coupled through a nearby amine. This process effectively blocked and eliminated all nonspecific binding potential in the ricin dimer. After removal of the blocked ricin from the support by DTT, the free sulfhydryl group on the protein was conjugated to an SMCC-modified antibody, forming the final conjugate (Figure 20.24). Although this process worked in preparing an effective immunotoxin conjugate, most conjugation schemes are less elaborate.

Regardless of their method of preparation, the required and ideal characteristics of immunotoxin conjugates can be summarized in the following points:

1. The conjugation process must leave the antigen binding sites on the antibody component free to interact with its intended target. Crosslinker modification or blockage of these binding sites by the attached toxin must be kept to a minimum.
2. The toxin component of the conjugate must be able to elicit cytotoxicity by ribosomal damage as it could in its native state. This means that the cell penetration and enzymatic properties of the toxin remain unaltered, although an antibody molecule is conjugated to it.
3. The activity of toxin binding to cells through the B chain must be eliminated in the conjugate to prevent nonspecific binding and nonselective cell death. This may be accomplished by using only the A chain subunit or by blocking the B chain binding site in the intact toxin conjugate.

4. Avoid covalently linking the A and B chains together during the crosslinking process. This can be done by using heterobifunctional crosslinkers that are more controllable in their reactivity than homobifunctional reagents.
5. The crosslinking process must minimize polymerization of either the antibody or the toxin. Low-molecular-weight, 1:1 or 1:2 conjugates of antibody-to-toxin are best.
6. The crosslinker used to form the bond between the antibody and toxin must be able to survive *in vivo* and not be cleaved by enzymatic or reductive means before reaching the targeted cells.
7. The conjugate must reach its intended target without being intercepted, bound and destroyed by the host immune system.
8. Administration of the immunotoxin should result in cell death and complete elimination of all target cells.

The last two points are the most difficult to realize. The following methods describing the conjugation strategies used to prepare immunotoxins work well in creating complexes containing active antibody and toxin. The majority of research today is not so much concerned with further optimization of the crosslinking process, but primarily is directed at overcoming the host immune system and making the conjugates more effective in accomplishing complete targeted tumor destruction.

Preparation of Immunotoxin Conjugates via Disulfide Exchange Reactions

Since the cytotoxic potential of most common toxins relies on their subunit disulfide cleavability with subsequent release of associated A chains, most successful conjugation techniques for preparing immunotoxins involve the use of disulfide exchange reactions. Heterobifunctional crosslinking agents containing an amine-reactive group at one end and a disulfide bond with a good leaving group on the other end are common choices for making these conjugates (Chapter 6, Section 1, and Chapter 18, Section 1.2). The leaving group on the disulfide portion of the crosslinker permits efficient disulfide interchange with a free sulfhydryl on the antibody or toxin. The resultant covalent bond thus is a cleavable disulfide which mimics the native cleavability inherent in the toxin dimer.

PYRIDYL DISULFIDE REAGENTS

The most common reactive group for initiating disulfide interchange reactions is a pyridyl disulfide. Attack of a nucleophilic thiolate anion dissociates the pyridine-2-thione leaving group and forms a new disulfide bond with the incoming sulfhydryl compound. Several crosslinking reagents containing these groups are popular choices for producing antibody–toxin conjugates.

SPDP

SPDP, N-succinimidyl 3-(2-pyridyldithio)propionate, is by far the most popular heterobifunctional crosslinking agent used for immunotoxin conjugation (Chapter 6, Section 1.1). The activated NHS ester end of SPDP reacts with amine groups in one of the two proteins to form an amide linkage. The 2-pyridyldithiol group at the other end reacts with sulfhydryl groups in the other protein to form a disulfide linkage (Carlsson *et al.*, 1978). The result is a crosslinked antibody–toxin conjugate containing cleavable disulfide bonds that can emulate the activity of native two-subunit toxin molecules.

LC–SPDP (Chapter 6, Section 1.1) is an analog of SPDP containing a hexanoate spacer arm within its internal cross-bridge. The increased length of the extended crosslinker is important in some conjugations to avoid steric problems associated with closely linked macromolecules. However, for the preparation of immunotoxins, no advantages were observed for LC–SPDP over SPDP (Singh *et al.*, 1993).

SPDP is also useful in creating sulfhydryls in one of the two proteins being conjugated (Chapter 2, Section 4.1). Once modified with SPDP, the protein can be treated with DTT (or another disulfide reducing agent) to release the pyridine-2-thione leaving group and form the free sulfhydryl. The terminal SH group then can be used to conjugate with any crosslinking agents containing sulfhydryl-reactive groups, such as maleimide or iodoacetyl (for covalent conjugation) or 2-pyridyldithiol groups (for reversible conjugation).

In the preparation of immunotoxins, some procedures call for the modification of the antibody with SPDP to introduce reactive thiols (Cumber *et al.*, 1985). The NHS ester end of the crosslinker is reacted at slightly alkaline pH with the primary amines on the antibody. After removal of excess reagent by gel filtration, the pyridyl disulfide groups are reduced by DTT. The reductant causes the removal of pyridine-2-thione groups and the creation of sulfhydryl groups on the immunoglobulin. The reason the antibody is thiolated in this manner and not the toxin is to avoid exposing the intact toxin to reducing conditions that could disassociate the A and B subunits.

To activate the toxin, SPDP again can be used to modify the intact A–B component. After purification of the modified toxin from excess crosslinker, the SPDP–toxin is mixed with the thiolated antibody to effect the final conjugate (Figure 20.25).

This multi-step crosslinking method employing SPDP on both molecules has been used to prepare a number of immunotoxin conjugates (Edwards *et al.*, 1982; Thorpe *et al.*, 1982; Colombatti *et al.*, 1983; Wiels *et al.*, 1983; Vogel, 1987; Reiter and Fishelson, 1989).

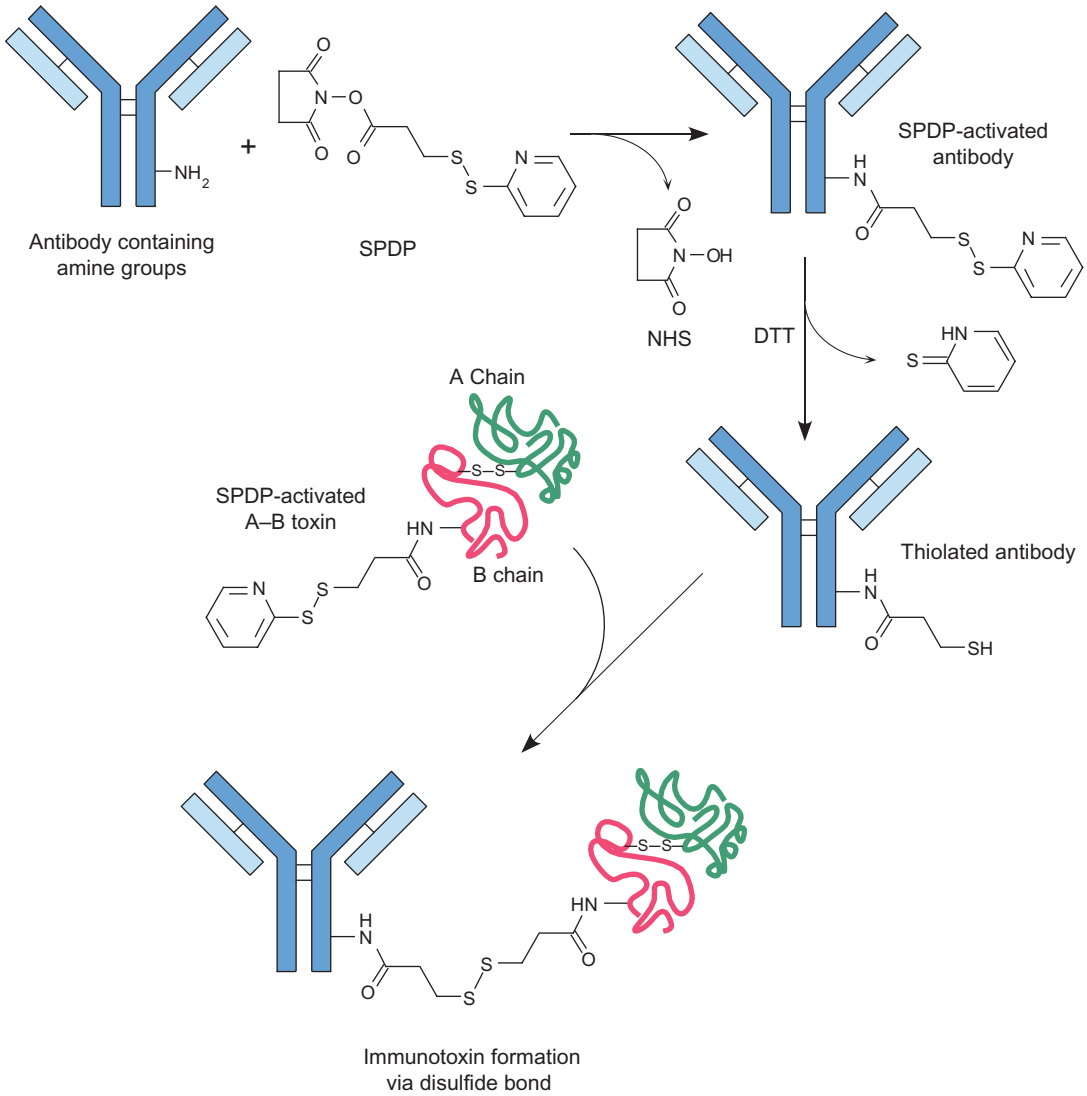

FIGURE 20.25 SPDP can be used to modify both an antibody and a toxin molecule for conjugation purposes. In this case, the antibody is thiolated to contain a sulfhydryl group by modification with SPDP followed by reduction with DTT. A toxin molecule is then activated with SPDP and reacted with the thiolated antibody to form the final conjugate through a disulfide bond.

While this method has worked well for many different toxins, its main potential disadvantage is exposure of the antibody to reducing conditions that potentially could cleave the disulfide bonds holding its heavy and light chains together. Alternative methods using SPDP in a non-reducing environment may result in better conjugates.

For instance, if toxin A chain–antibody conjugates are to be prepared, the antibody can be similarly activated with SPDP, but in this case not treated with reductant. After removal of excess crosslinker, the activated antibody can be directly mixed with isolated A chain to create the conjugate (Figure 20.26). This procedure makes use of the indigenous sulfhydryl residues produced during reductive separation of the A and B chains and therefore does not require crosslinker thiolation of one of the proteins.

Another way of utilizing SPDP is to again activate the antibody to create the pyridyl disulfide derivative, but this time thiolate the toxin component using 2-iminothiolane (Chapter 2, Section 4.1). 2-Iminothiolane reacts with primary amines in a ring-opening reaction that creates a terminal sulfhydryl group without reduction. Intact A–B toxins and toxins containing only one subunit, like gelonin, PAPs, and *Pseudomonas* toxin A, can be coupled to antibodies using this procedure (Lambert *et al.*, 1985; Bjorn *et al.*, 1986; Scott *et al.*, 1987; Lambert *et al.*, 1988; Ozawa *et al.*, 1989). Mixing the SPDP-activated antibody with the thiolated toxin effectively forms the final conjugation (Figure 20.27).

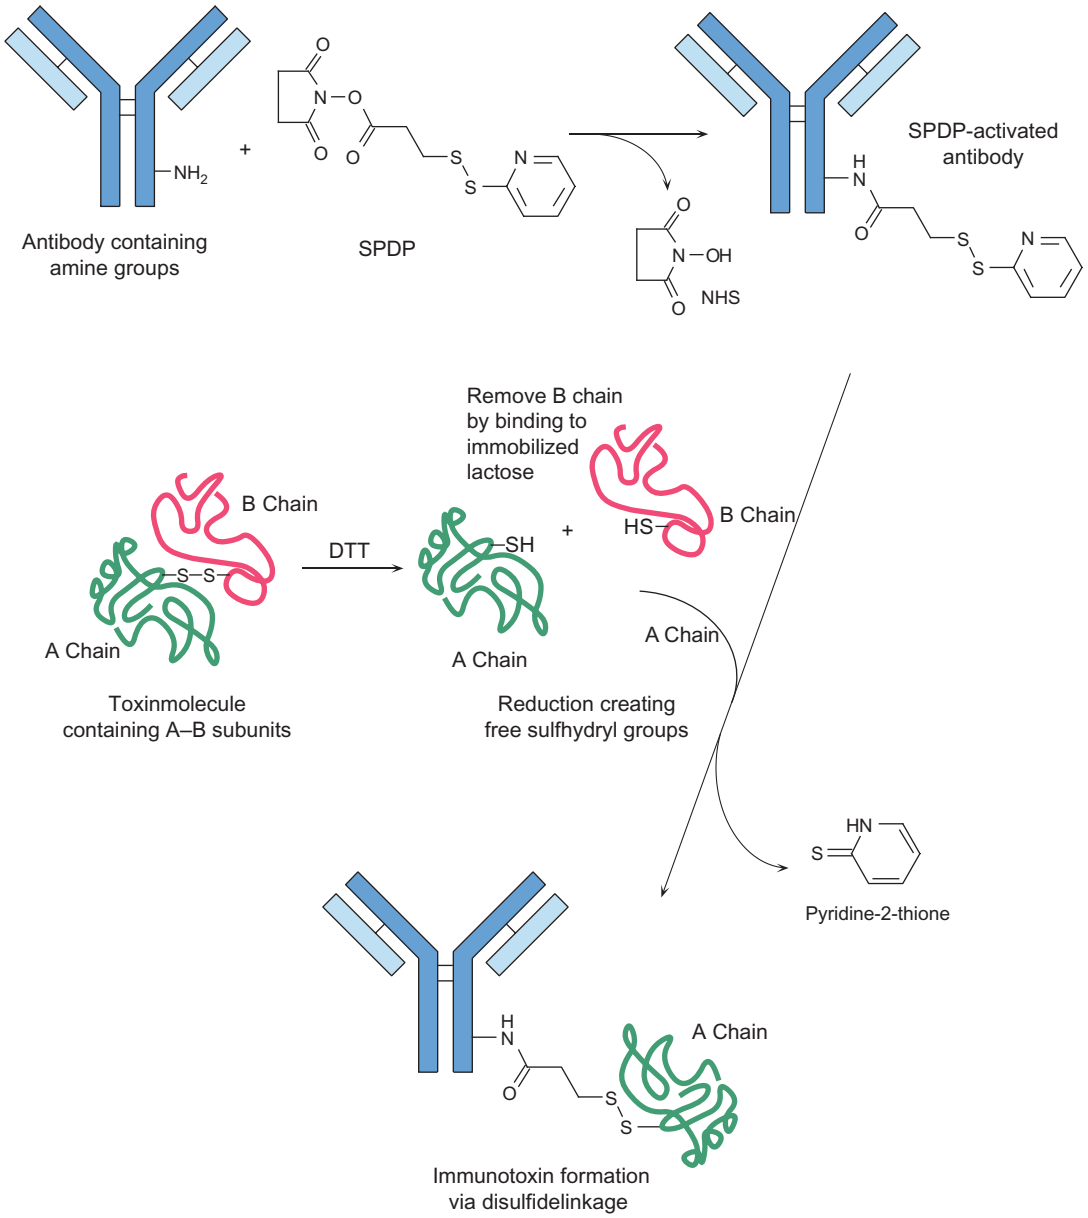

FIGURE 20.26 SPDP can be used to activate an antibody molecule through its available amine groups to form a sulfhydryl-reactive derivative. Toxin molecules containing disulfide-linked A–B chains may be reduced with DTT to isolate the A chain component containing a free thiol. The SPDP-activated antibody is then mixed with the reduced A chain to effect the final conjugate by disulfide bond formation.

SPDP can also be used to conjugate other targeting molecules to toxins, such as transferrin, epidermal growth factor, α_2-macroglobulin, and human chorionic gonadotropin (Fizgerald *et al.*, 1980; Helenius *et al.*, 1980; Keen *et al.*, 1982; Oeltmann, 1985). To create these conjugates, one of the two components must be activated with SPDP to generate the sulfhydryl-reactive pyridyl disulfide groups, while the other component must be modified to contain the SH functionality. Mixing these modified molecules together forms the toxin conjugate.

The following methods are generalized to provide an overview of how SPDP can be used in these conjugation techniques. The appropriate optimization for a particular toxin conjugate should be done.

Caution! Toxins are highly toxic even in very low amounts. Handle all toxin molecules and their isolated subunits with extreme care.

Protocol for Thiolation of Antibody with SPDP and Conjugation to an SPDP-Activated Toxin

Caution: Toxin molecules are dangerously toxic even in small amounts. Use extreme care in handling.

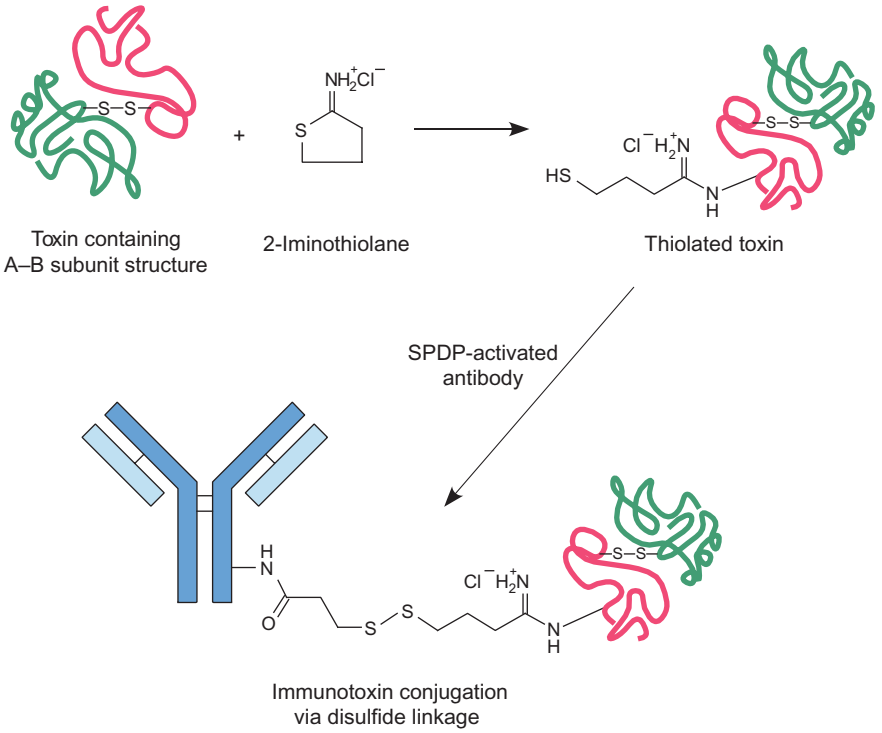

FIGURE 20.27 An intact A–B subunit toxin molecule may be activated with 2-iminothiolane with good retention of cytotoxic activity. The thiolated toxin may then be conjugated with SPDP-activated antibody to generate the immunotoxin conjugate through a disulfide bond.

Note: In this protocol, for every milligram of toxin employed, 2.5 mg of antibody are required to obtain the correct molar ratios in the final conjugate.

(A) ACTIVATION OF TOXIN WITH SPDP

1. Dissolve the toxin to be conjugated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of 10 mg/ml. Some protocols use as an SPDP reaction buffer, 50-m*M* sodium borate, 0.3-*M* NaCl, 0.5% *n*-butanol, pH 9.0. Both buffer systems work well for the NHS ester modification reaction, although the pH 9 buffer is at the higher end of effective derivatization with active esters, since the hydrolysis rate is dramatically increased at this level of alkalinity.
2. Dissolve SPDP (Thermo Fisher) in DMF at a concentration of 3 mg/ml. Add 20 µl of this solution to each milliliter of the toxin solution. Gently mix to effect dissolution. Retain the SPDP stock solution for use in the antibody modification step, below.
3. React for 30 min at room temperature.
4. Purify the SPDP-activated toxin from excess reagents and reaction byproducts by gel filtration using a desalting resin. For the chromatography separation, use as a buffer 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, containing 10-m*M* EDTA.
5. Concentrate the toxin to 10 mg/ml using a centrifugal concentrator with a molecular weight cutoff of 10,000. Retain this solution for the conjugation reaction.

(B) THIOLATION OF ANTIBODY WITH SPDP

1. Dissolve the antibody to be conjugated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration 10 mg/ml. Note: Some protocols use the borate buffer system described in step A. Use 2.5 mg of antibody per mg of toxin to be conjugated.
2. Dissolve SPDP in DMF at a concentration of 3 mg/ml. Add 24 µl of this solution to each milliliter of the antibody solution with gentle mixing to effect complete dissolution.
3. React for 30 min at room temperature.
4. Remove excess crosslinker by gel filtration using a desalting resin. Perform the chromatography using as the buffer 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5. The solution should be degassed under vacuum and nitrogen bubbled through it to remove oxygen. The presence of EDTA stabilizes the free sulfhydryls formed in the following steps against metal-catalyzed oxidation.
5. Concentrate the fractions containing protein from the gel filtration step to 10 mg/ml using a centrifugal concentrator (MW cutoff of 10,000).
6. To reduce the pyridyl dithiol groups and create reactive sulfhydryls, dissolve DTT in water at a

concentration of 17.2 mg/ml and immediately add 500 µl of this solution to each ml of concentrated antibody solution. Mix to dissolve and react for 30 min at room temperature.
7. Remove excess DTT by gel filtration using the same buffer as in step 4. Pool the fractions containing protein and concentrate to 10 mg/ml.

(C) CONJUGATION OF SPDP-ACTIVATED TOXIN WITH THIOLATED ANTIBODY

1. Immediately mix the concentrated, thiolated antibody solution from part B with the SPDP-activated toxin from part A.
2. React for 18 h at room temperature to form the final conjugate. Isolation of the ideal 1:1 or 1:2 antibody–toxin conjugate can be achieved through gel filtration separation using a column of Sephacryl S-300 or the equivalent.

(D) ACTIVATION OF ANTIBODY WITH SPDP AND CONJUGATION TO A TOXIN A CHAIN *Caution: Toxin molecules are dangerously toxic even in small amounts. Use extreme care in handling*.

Since the A chain of toxin molecules contains a free sulfhydryl group, there is no need in this conjugation strategy to thiolate one of the molecules. The following protocol calls for 1.73 mg of antibody per milligram of toxin A chain to produce a conjugate possessing the correct molar ratio of components. Best results for creating a highly cytotoxic immunotoxin will be obtained if deglycosylated ricin A chain is used.

1. Dissolve the antibody to be conjugated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration 10 mg/ml.
2. Dissolve SPDP (Thermo Fisher) in DMF at a concentration of 3.0 mg/ml. Add 30 µl of this solution to each milliliter of the antibody solution with gentle mixing to effect complete dissolution.
3. React for 30 min at room temperature.
4. Remove excess crosslinker by gel filtration using a desalting resin. Perform the chromatography using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5.
5. Concentrate the fractions containing SPDP-activated antibody from the gel filtration step to 10 mg/ml using a centrifugal concentrator (MW cutoff of 10,000).
6. Mix the activated antibody solution with a solution of deglycosylated toxin A chain (dgA) dissolved in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, containing 10-m*M* EDTA. The ratio of mixing should equal 1.73 mg of antibody per milligram of A chain or 580 µl of A chain solution at 10 mg/ml per milliliter of activated antibody solution at 10 mg/ml. The A chain solution must not contain any reducing agents left over from the disassociation of the toxin subunits during the A subunit isolation. Reductants will compete for the SPDP activation sites on the antibody molecule.
7. React for 18 h at room temperature. Isolation of the 1:1 or 1:2 antibody–toxin conjugate can be achieved through a gel filtration separation using a column of Sephacryl S-200. Isolation of conjugates containing molar ratios of 1:2 antibody:dgA have resulted in greater cytotoxicity behavior *in vivo* (Ghetie *et al.*, 1993).

(E) CONJUGATION OF SPDP-ACTIVATED ANTIBODIES WITH 2-IMINOTHIOLANE-MODIFIED TOXINS *Caution: Toxin molecules are dangerously toxic even in small amounts. Use extreme care in handling*.

A third option for immunotoxin preparation is to again activate the antibody with SPDP, while this time thiolating a single-chain toxin molecule to conjugate with it. This method works especially well using 2-iminothiolane (Chapter 2, Section 4.1) to create sulfhydryls on gelonin or PAPs. Gelonin is a single-polypeptide toxin containing no free sulfhydryls. A number of options are available for thiolation; however, the use of SPDP to add sulfhydryl groups inactivates the toxin, while 2-iminothiolane preserves its activity, perhaps by maintaining the positive charge on the amines that are being modified (Lambert *et al.*, 1985).

(F) ACTIVATION OF ANTIBODY WITH SPDP

1. Dissolve the antibody to be conjugated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of 10 mg/ml.
2. Dissolve SPDP (Thermo Fisher) in DMF at a concentration of 3.0 mg/ml. Add 30 µl of this solution to each milliliter of the antibody solution with gentle mixing to effect dissolution.
3. React for 30 min at room temperature.
4. Remove excess crosslinker by gel filtration using a desalting resin. Perform the chromatography using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5.
5. Concentrate the fractions containing SPDP-activated antibody from the gel filtration step to 10 mg/ml using a centrifugal concentrator (MW cutoff of 10,000).

(G) THIOLATION OF GELONIN (OR OTHER SINGLE-POLYPEPTIDE TOXINS) WITH 2-IMINOTHIOLANE (TRAUT'S REAGENT)

1. Dissolve gelonin at a concentration of 10 mg/ml in 50-m*M* triethanolamine hydrochloride, pH 8.0, containing 10-m*M* EDTA. The buffer should be de-gassed under vacuum and bubbled with nitrogen to remove oxygen that may cause sulfhydryl oxidation after thiolation.

2. Dissolve 2-iminothiolane (Thermo Fisher) in degassed, nitrogen-bubbled deionized water at a concentration of 20 mg/ml (makes a 0.14-*M* stock solution). The solution should be used immediately. Add 70 µl of the 2-iminothiolane solution to each ml of the gelonin solution (final concentration is about 10-m*M*).
3. React for 1 h at 0°C (or on ice) under a nitrogen blanket.
4. Purify the thiolated protein from unreacted Traut's reagent by gel filtration on a desalting resin using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, containing 10-m*M* EDTA. The presence of EDTA in this buffer helps to prevent oxidation of the sulfhydryl groups and resultant disulfide formation. The degree of SH modification in the purified protein may be determined using the Ellman's assay (Chapter 2, Section 4.1).
5. Concentrate the thiolated toxin to 10 mg/ml using centrifugal concentrators. Immediately use the modified protein in the conjugation reaction to prevent inactivation of 2-iminothiolane-modified molecules by recyclization (Chapter 2, Section 4.1).

(H) CONJUGATION OF SPDP-ACTIVATED ANTIBODY WITH THIOLATED GELONIN

1. Mix the SPDP-activated antibody with the thiolated gelonin in equal mass quantities (or equal volumes if they are at the same concentration). This ratio results in about a 5-fold molar excess of toxin over the amount of antibody.
2. React for 20 h at 4°C under a nitrogen blanket.
3. To block unreacted sulfhydryl groups, add iodoacetamide to the solution to a final concentration of 2-m*M*.
4. React for an additional 1 h at room temperature.
5. Remove unconjugated gelonin by passage of the conjugate solution over a column of immobilized protein A (Thermo Fisher). Use 2 ml of the protein A column for each 10 mg of conjugate to be purified. Equilibrate the column with 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5. Apply the conjugate sample and allow it to enter the gel. Continue to wash the column with equilibration buffer while taking 2-ml fractions until baseline is reached (monitored at an absorbance of 280 nm). Unconjugated gelonin will pass through the column unretarded. Elute bound conjugate with 0.1-*M* acetic acid, 0.15-*M* NaCl. Immediately add 0.1 ml of 1-*M* potassium phosphate, pH 7.5 to each bound fraction for neutralization. Alternatively, gel filtration may be used to isolate the conjugate from lower-molecular-weight antibody and gelonin. A column of Sephacryl S-200 works well for this purpose.

SMPT

Succinimidyloxycarbonyl-α-methyl-α-(2-pyridyldithio)toluene (SMPT) is a heterobifunctional crosslinking agent similar to SPDP that contains an amine-reactive NHS ester on one end and a sulfhydryl-reactive pyridyl disulfide group on the other (Chapter 6, Section 1.2). Reaction with a sulfhydryl-containing protein results in a cleavable disulfide linkage, important for immunotoxin activity. SMPT is an analog of SPDP that differs only in its cross-bridge, which contains an aromatic ring and a hindered disulfide group (Thorpe *et al.*, 1987; Ghetie *et al.*, 1990). The spacer arm of SMPT is slightly longer than SPDP, but the presence of the benzene ring and α-methyl group adjacent to the disulfide sterically hinders the structure sufficiently to provide increased half-life of immunotoxin conjugates *in vivo*.

SMPT is often used in place of SPDP for the preparation of immunotoxin conjugates. The hindered disulfide of SMPT has distinct advantages in this regard. Thorpe *et al.* (1987) showed that SMPT conjugates had approximately twice the half-life *in vivo* as SPDP conjugates. Antibody–toxin conjugates prepared with SMPT possess a half-life *in vivo* of up to 22 h, presumably due to the decreased susceptibility of the hindered disulfide toward reductive cleavage.

Ghetie *et al.* (1991) developed a large-scale preparation procedure for antibody-deglycosylated ricin A chain (dgA) conjugates utilizing this crosslinker. The following procedure describes a generalized method for using SMPT to prepare dgA–antibody conjugates. It is based on the Ghetie protocol, but using smaller quantities of reagents. Figure 20.28 illustrates the reactions involved in using SMPT.

Protocol

Caution: Toxin molecules are dangerously toxic even in small amounts. Use extreme care in handling.

The following method calls for mixing activated antibody with ricin A chain at a ratio of 2 mg antibody per milligram of A chain. Adjustments to the amount of antibody and A chain initially dissolved in the reaction buffers should be done to anticipate this ratio.

1. Dissolve the antibody to be conjugated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of 10 mg/ml. If the antibody contains oligomers (as evidenced by nondenaturing electrophoresis or HPLC gel filtration analysis), then the monomeric IgG form should be isolated by gel filtration using a column of Sephacryl S-200HR. If no oligomers are present, then omit the chromatographic purification.
2. Dissolve SMPT (Thermo Fisher) in DMF at a concentration of 4.8 mg/ml. Add 27 µl of this solution

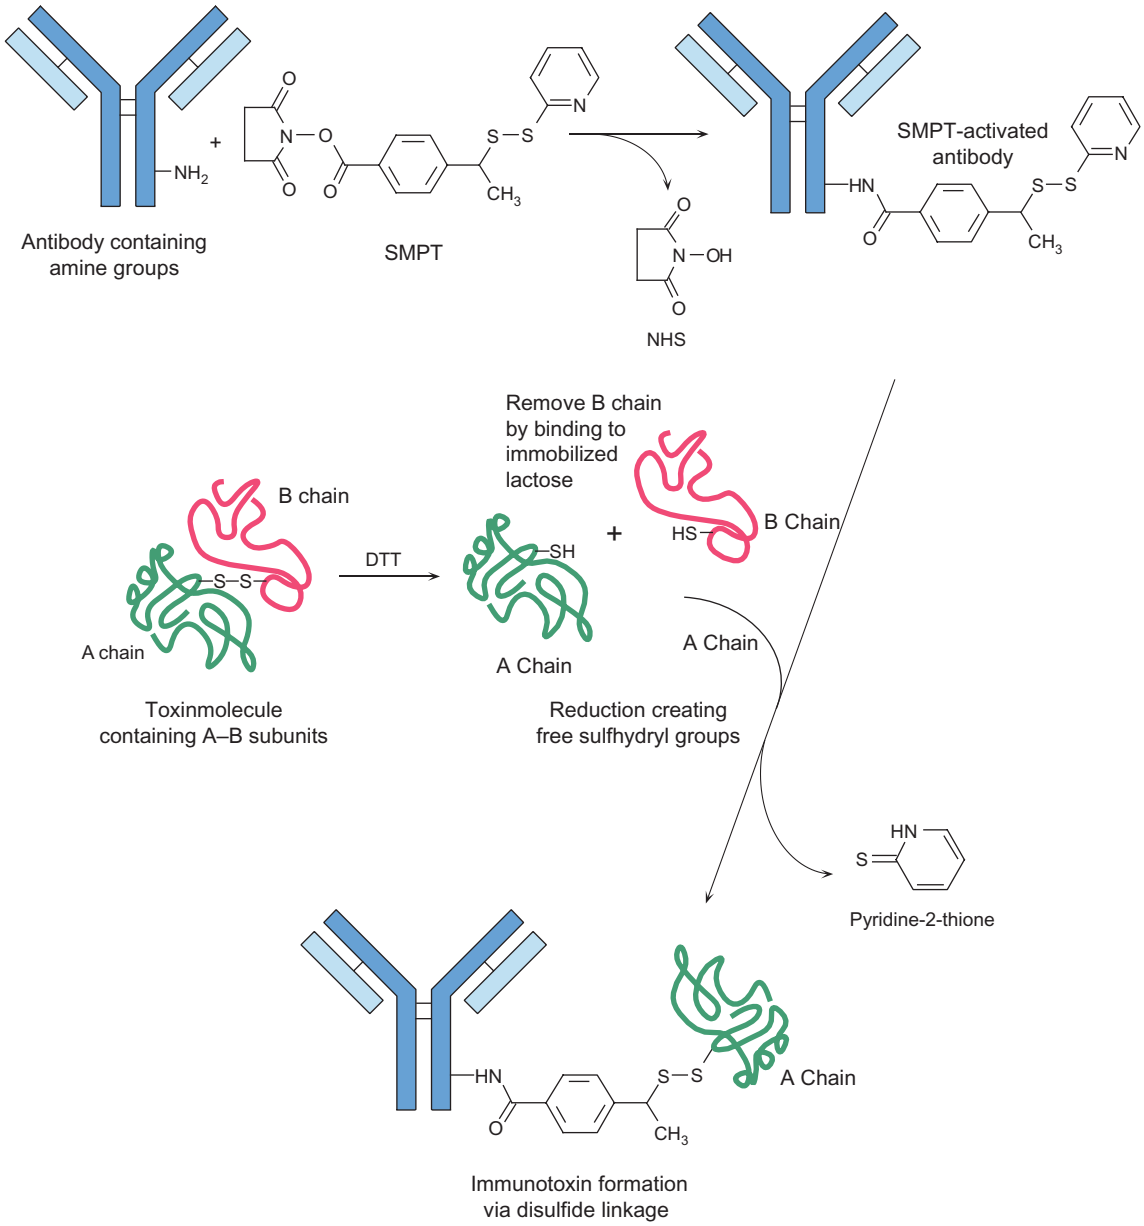

FIGURE 20.28 SMPT may be used to form immunotoxin conjugates by activation of the antibody component to form a thiol-reactive derivative. Reduction of an A–B toxin molecule with DTT can facilitate subsequent isolation of the A chain containing a free thiol. Mixing the A chain containing a sulfhydryl group with the SMPT-activated antibody causes immunotoxin formation through disulfide bond linkage. The hindered disulfide of an SMPT crosslink has been found to survive *in vivo* for longer periods than conjugates formed with SPDP.

to each ml of the antibody solution. Mix gently. The final concentration of SMPT in the reaction mixture is 0.13 mg/ml, which translates into about a 4.8-fold molar excess of crosslinker over the amount of antibody present.

3. React for 1 h at room temperature.
4. Remove unreacted SMPT and reaction byproducts by gel filtration on a desalting resin. Pool fractions containing SMPT-activated antibody (the first peak eluting from the column) and concentrate them to 10 mg/ml using centrifugal concentrators with a molecular weight cut-off of 10,000.
5. Dissolve deglycosylated ricin A chain (dgA) in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5, at a concentration of 10 mg/ml. The buffer should be degassed under vacuum and nitrogen bubbled through it to remove oxygen. Prepare half the amount of A chain solution as the amount of antibody prepared in step 1. If the A chain preparation is done in bulk quantities or if the

protein has been stored for lengthy periods, it may be necessary to reduce the sulfhydryls with DTT prior to proceeding with the crosslinking reaction. If A chain sulfhydryl oxidation is suspected, add 2.5 mg of DTT per milliliter of A chain solution. React for 1 h at room temperature. Purify the reduced ricin A chain by gel filtration on a desalting resin using the PBS–EDTA buffer. Apply no greater volume of sample to the gel than is represented by 5% of the column volume to ensure good removal of excess DTT. Collect the protein and concentrate to 10 mg/ml using centrifugal concentrators.

6. Mix the reduced A chain solution with activated antibody solution at a ratio of 2 mg of antibody per milligram of A chain. Sterile filter the solution through a 0.22-μm membrane, and react at room temperature under nitrogen for 18 h.
7. To block excess pyridyl disulfide active sites on the antibody, add cysteine to a final concentration of 25 μg/ml. React for an additional 6 h at room temperature.
8. To isolate the conjugate, apply the immunotoxin solution to a column of Sephacryl S-200HR. Collect the peaks with molecular weights between 150,000 and 210,000. Further purification to remove excess unconjugated antibody can be done on a column of immobilized Cibacron Blue (available commercially from Thermo Fisher or for column preparation, see Hermanson *et al.*, 1992). Equilibration of the column with 50-m*M* sodium borate, 1-m*M* EDTA, pH 9.0, will cause binding of the conjugate, but not the free antibody. Elution of purified immunotoxin conjugate can be done with 50-m*M* sodium borate, 1-m*M* EDTA, 0.5-*M* NaCl, pH 9.0 (see Ghetie *et al.*, 1991).

3-(2-PYRIDYLDITHIO)PROPIONATE

A lesser-used reagent to introduce sulfhydryl-reactive pyridyl disulfide groups is 3-(2-pyridyldithio) propionate (PDTP), the acid precursor of SPDP containing no NHS ester group on the carboxylate. Sulfhydryl interchange reaction at the pyridyl dithiol end results in the formation of a disulfide linkage with SH containing molecules. The carboxylate end is not further derivatized to contain a reactive species, but may be coupled to amines by the carbodiimide reaction (Chapter 4, Section 1). Reaction of PDTP with an antibody molecule in the presence of 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) results in the formation of amide linkages with the active pyridyl disulfide groups still available for coupling to sulfhydryl-containing toxins (Figure 20.29). Mixing the PDTP–antibody with purified ricin A chain results in disulfide crosslinks identical to those obtained using SPDP as the crosslinker (Jansen *et al.*, 1980; Gros *et al.*, 1985). PDTP also has been used to activate transferrin to contain reactive pyridyl dithiol groups for conjugation to ricin A chain molecules (Raso and Basala, 1984, 1985).

Since activated molecules and crosslinks formed between two species are identical to those formed using SPDP, it is of little advantage to use PDTP. Furthermore, an EDC-mediated reaction of the carboxylate end of the crosslinker with amine groups on proteins can cause concomitant zero-length crosslinking and polymerization of protein molecules. For these reasons, SPDP is the better choice for preparing immunotoxin conjugates.

USE OF CYSTAMINE, ELLMAN'S REAGENT, OR S-SULFONATES

Other reagent systems can be used to form disulfide linkages between antibody and toxin molecules in immunotoxin conjugates. Cystamine can be incorporated into proteins by reaction of its terminal amines with the carboxylates on the proteins *via* the carbodiimide reaction (Chapter 4, Section 1). The resultant modifications contain disulfide linkages that can undergo disulfide interchange reactions with other sulfhydryl-containing molecules (Chapter 2, Section

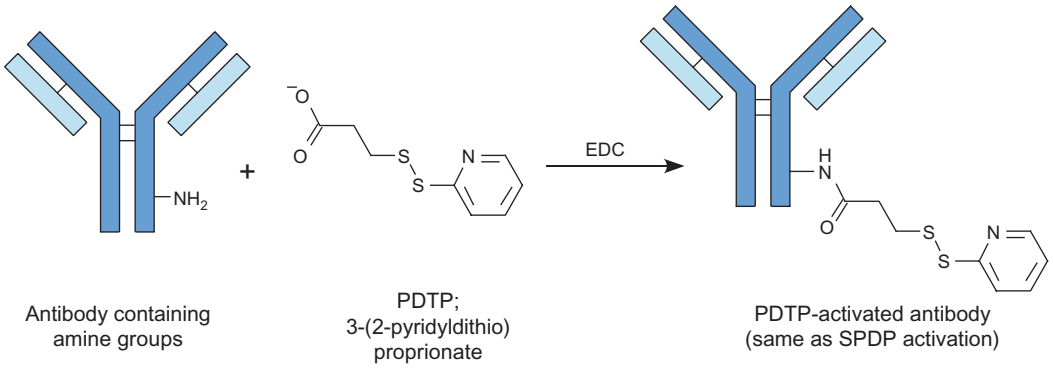

FIGURE 20.29 PDTP may be used to modify antibody molecules using a carbodiimide reaction with EDC. The derivative is the same as that obtained using SPDP activation and is highly reactive toward sulfhydryls.

4.1). For instance, a cystamine-modified targeting component, such as an antibody, can be mixed with the reduced A chain of a toxin molecule to cause conjugate formation through the creation of a disulfide bond (Figure 20.30) (Oeltmann and Forbes, 1981). Epidermal growth factor was modified with cystamine and coupled with reduced diphtheria toxin using this approach (Shimisu *et al.*, 1980).

Similarly, Ellman's reagent [5,5′-dithiobis(2-nitrobenzoic acid)] can be used to activate one thiol-containing molecule by disulfide exchange and subsequently used to couple to a second sulfhydryl-containing molecule by the same mechanism (Chapter 2, Section 5.2) (Figure 20.31). The disulfide of Elman's reagent readily undergoes disulfide exchange with a free sulfhydryl to form a mixed disulfide with simultaneous release of one molecule of the highly chromogenic 5-sulfido-2-nitrobenzoate, also called 5-thio-2-nitrobenzoic acid (TNB). The intense yellow color produced by the TNB anion can be measured by its absorbance at 412 nm. Thus, the efficiency of conjugation can be determined spectrophotometrically using this procedure (Pirker *et al.*, 1986; Fitzgerald *et al.*, 1988). A method for the large-scale conjugation of Fab′ fragments containing an available sulfhydryl group and deglycosylated ricin A chain (also containing an SH group) were developed using Ellman's reagent as the crosslinker (Ghetie *et al.*, 1988).

A final method of forming disulfide crosslinks between toxins and targeting molecules is the use of *S*-sulfonate formation using sodium sulfite (Na_2SO_3) in the presence of sodium tetrathionate ($Na_2S_4O_6$). Tetrathionate reacts with sulfhydryls to form

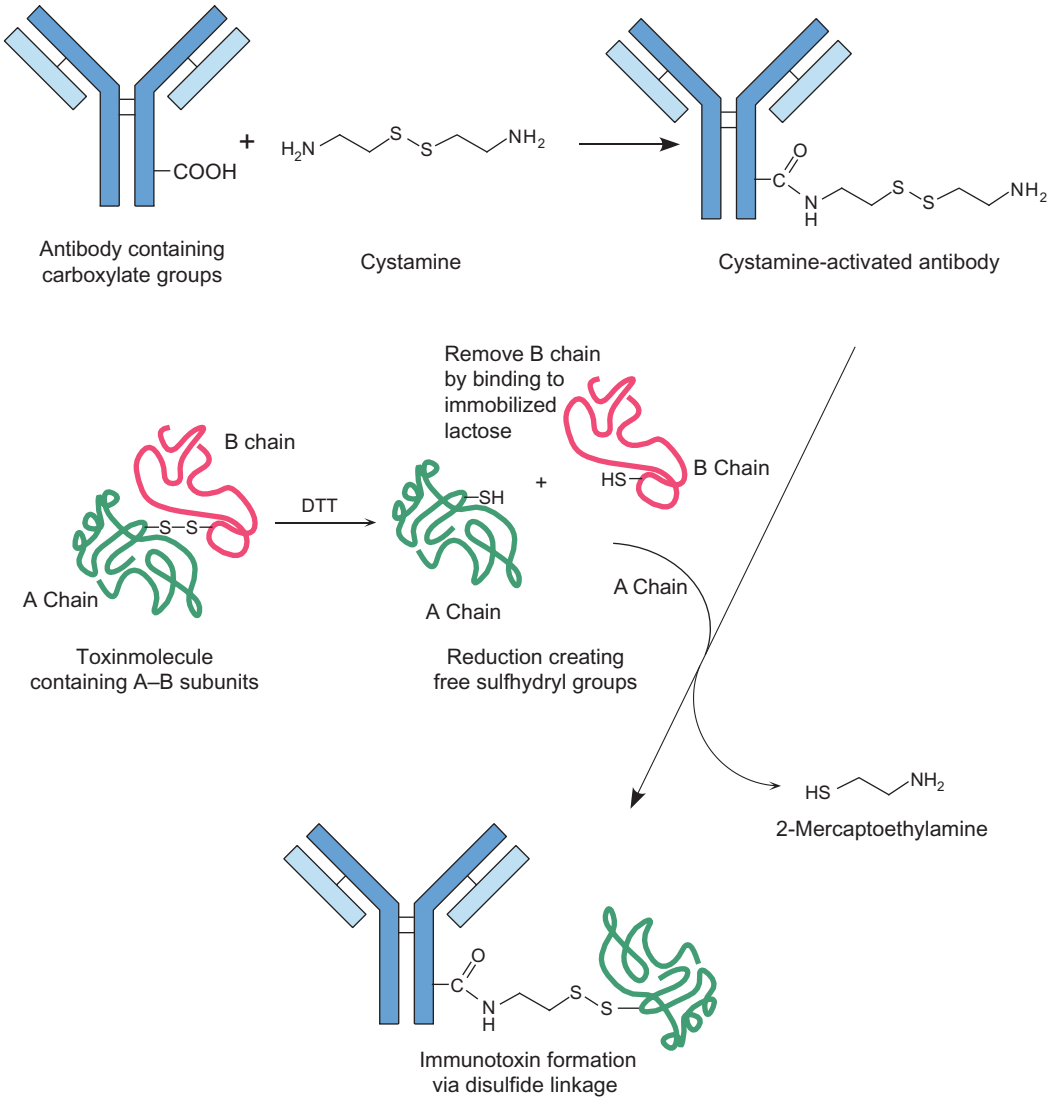

FIGURE 20.30 Cystamine may be used to make immunotoxin conjugates by a disulfide interchange reaction. Modification of antibody molecules using an EDC-mediated reaction creates a sulfhydryl-reactive derivative. A chain toxin subunits containing a free thiol can be coupled to the cystamine-modified antibody to form disulfide crosslinks.

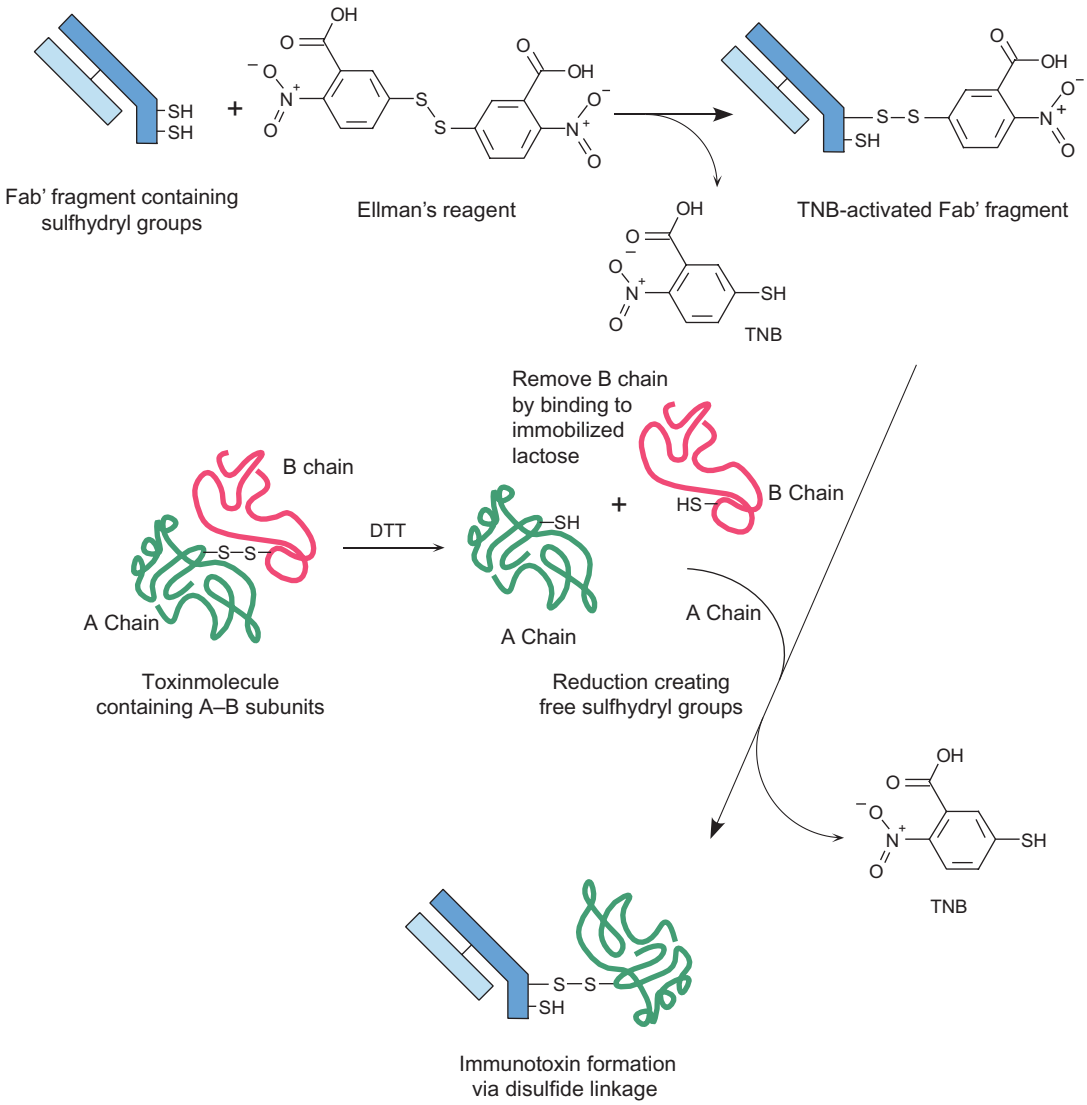

FIGURE 20.31 Fab′ antibody fragments containing free thiols can be activated with Ellman's reagent to form a sulfhydryl-reactive derivative. A chain toxin subunits that contain a free thiol group may be coupled to the activated Fab′ molecule to produce an immunotoxin complex.

sulfenylthiosulfate intermediates (Section 1.1). These derivatives are reactive toward other thiols to create disulfide linkages rapidly. Sulfite ions react with disulfides to form *S*-substituted thiosulfates, also known as *S*-sulfonates, and a thiol. The combination of these reagents results in the transformation of available thiols and disulfides into reactive *S*-sulfonates that can be used to crosslink with sulfhydryl-containing molecules. *S*-sulfonate conjugation can be used to conjugate the A chain of toxin molecules with sulfhydryl-containing Fab′ fragments with good efficiency (Masuho *et al.*, 1979).

Although the use of these alternative disulfide-generating agents has proven successful in some applications, pyridyl disulfide-containing crosslinkers, as discussed previously, are more common for producing immunotoxin conjugates.

Preparation of Immunotoxin Conjugates via Amine- and Sulfhydryl-Reactive Heterobifunctional Crosslinkers

Other forms of heterobifunctional crosslinkers that can be used for this purpose are the amine- and sulfhydryl-reactive agents that produce a thioether bond with SH containing molecules (Chapter 6, Section 1). The amine-reactive end of these crosslinkers is usually an NHS ester group that can form a stable amide bond with amine-containing proteins. One of two main reactive groups are usually used on the sulfhydryl-reactive end: an iodoacetyl group which couples to sulfhydryls with loss of HI or a maleimide group which undergoes a double-bond addition reaction with SH groups (see Chapter 3, Sections 2.1 and 2.2).

Since this type of crosslinker forms non-cleavable thioether bonds between toxin molecules and the targeting component of the conjugates, they are not appropriate for use with A chain or single-chain toxins. This is because the crosslinker will not allow the conjugated A chain to break free of the antibody by disulfide reduction after docking at the cellular target. Since release of the A chain is a prerequisite to ribosomal inactivation, such conjugates will prove to be ineffective cytotoxic agents. One report found a 1000-fold increase in cytotoxicity when an immunotoxin containing PAP or gelonin was prepared using a cleavable disulfide linker as opposed to a non-cleavable thioether linkage (Lambert *et al.*, 1985).

To make effective immunotoxin conjugates using the following crosslinkers, it is necessary to crosslink intact A–B toxins to antibodies, not single-chain or A chain toxins. Using intact two-subunit toxins allows the A chain to break free of the complex and perform its cytotoxic duties upon entering the target cell. Two main criteria are especially important when using A–B toxin conjugates: the B chain binding site must be blocked or inoperative in the final immunotoxin complex to prevent nonspecific cell death, and, second, the two subunits of the toxin must not be covalently crosslinked by the conjugation procedure, precluding them from being separated *in vivo*.

Fortunately, satisfying these criteria is not difficult. The heterobifunctional crosslinkers described in this section are sufficiently controllable as to prevent A–B chain crosslinking. In addition, during the conjugation process, the B chain binding site often becomes inactivated or physically blocked by the attached antibody molecule. Subsequent cleanup of the conjugate using affinity chromatography over a column containing an immobilized sugar can completely eliminate any potential nonspecificity contributed by the B chain in the final preparation.

It should be noted that the use of the following crosslinkers to create other forms of toxic conjugates for cancer therapy is not restricted by the disulfide bridge requirement (Trail *et al.*, 1993; Willner *et al.*, 1993). Drug–toxin conjugates, hormono-toxins, lymphokine– or growth factor–toxin conjugates all can be made using nonreversible thioether linkages without difficulty.

SIAB

N-Succinimidyl(4-iodoacetyl)aminobenzoate (SIAB) is a heterobifunctional crosslinker containing amine-reactive and sulfhydryl-reactive ends (Chapter 6, Section 1.5). The NHS ester on one end of the reagent can be used to couple with primary amine-containing molecules, forming stable amide linkages (Chapter 3, Section 1.4). The other end contains an iodoacetyl group that is specific for coupling to sulfhydryl residues, potentially creating stable thioether bonds (Chapter 3, Section 2.1).

Conjugations using SIAB to create immunotoxins can be performed by first reacting the NHS ester end of the crosslinker with available amine groups on the antibody and then coupling to a thiolated toxin dimer—or by first reacting it with the toxin and coupling to a thiolated antibody (Figure 20.32). Thiolation of the secondary component is usually done with SPDP or 2-iminothiolane. Other crosslinkers containing an iodoacetyl group can be used in a similar fashion.

Conjugations with iodoacetyl crosslinkers have been done using ricin and cobra venom factor (Thorpe *et al.*, 1984; Vogel, 1987; Myers *et al.*, 1989). The following generalized protocol for using SIAB is based on the method of Cumber *et al.* (1985).

Protocol

Caution: Toxin molecules are dangerously toxic even in small amounts. Use extreme care in handling.

To prepare an antibody–ricin conjugate using this protocol, 2.25 mg of antibody is needed for every milligram of toxin.

(A) ACTIVATION OF TOXIN WITH SIAB

1. Dissolve intact ricin in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of 10 mg/ml.
2. Dissolve SIAB (Thermo Fisher) in DMSO at a concentration of 1.4 mg/ml. Prepare fresh and protect from light to avoid breakdown of the active halogen group.
3. Add 160 µl (225 µg) of the SIAB solution to each milliliter of the ricin solution.
4. React for 30 min at room temperature in the dark.
5. Remove excess crosslinker from the activated ricin by gel filtration using a desalting resin.
6. Concentrate the purified, SIAB-activated toxin to 10 mg/ml using centrifugal concentrators with a molecular weight cut-off of 10,000. Protect the activated toxin from light to prevent degradation of the iodoacetyl reactive group.

(B) THIOLATION OF SPECIFIC ANTIBODY MOLECULE WITH SPDP

1. Dissolve the antibody to be conjugated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration 10 mg/ml. Use 2.25 mg of antibody per milligram of toxin to be conjugated.
2. Dissolve SPDP (Thermo Fisher) in DMF at a concentration of 3 mg/ml. Add 24 µl of this solution to each milliliter of the antibody solution with gentle mixing to effect complete dissolution.
3. React for 30 min at room temperature.
4. Remove excess crosslinker by gel filtration using a column of desalting resin. Perform the

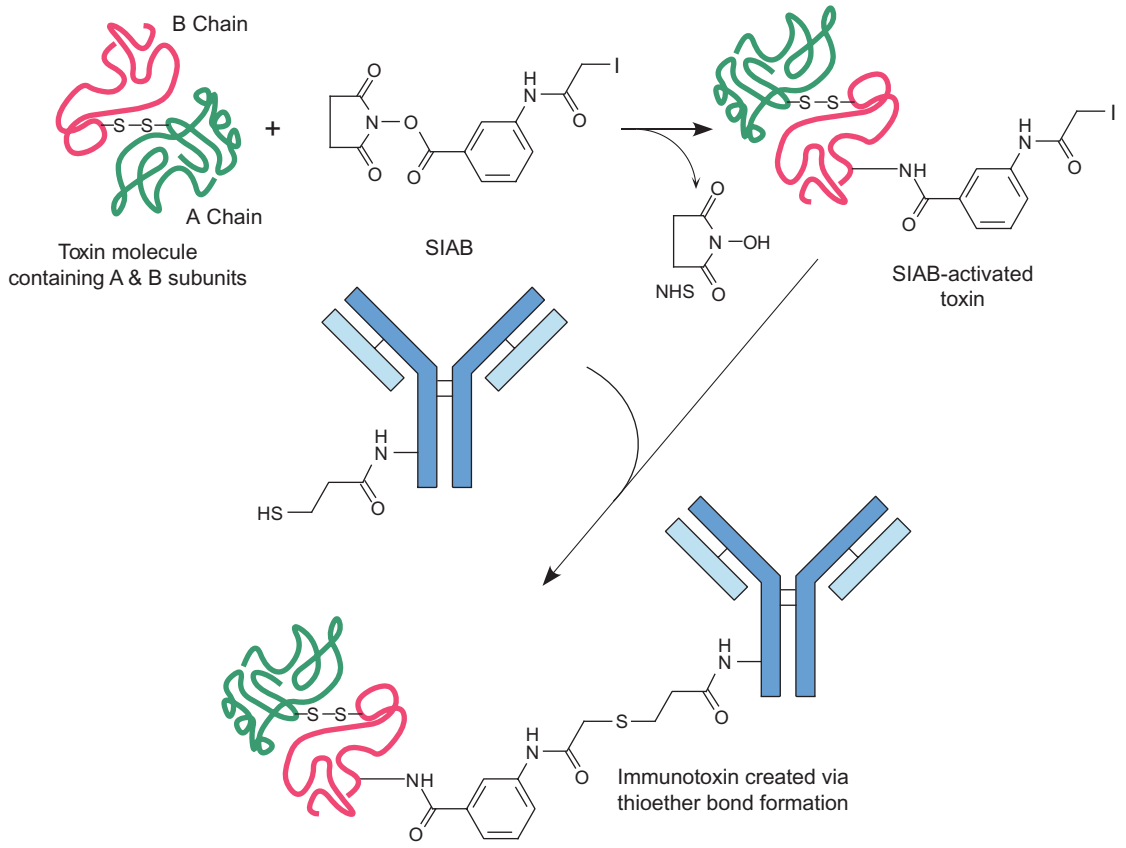

FIGURE 20.32 SIAB can be used to activate toxin molecules for coupling with sulfhydryl-containing antibodies. In this case, the antibody molecule is thiolated using SATA and deprotected to reveal the free sulfhydryl. Reaction with the SIAB-activated toxin forms the final conjugate by thioether bond formation.

chromatography using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5. The buffer should be degassed under vacuum and nitrogen bubbled through it to remove oxygen. The presence of EDTA stabilizes the free sulfhydryls formed in the following steps against metal-catalyzed oxidation.

5. Concentrate the fractions containing protein from the gel filtration step to 10 mg/ml using a centrifugal concentrator (MW cut-off of 10,000).
6. To reduce the pyridyl dithiol groups and create reactive sulfhydryls, dissolve DTT (Thermo Fisher) in water at a concentration of 17.2 mg/ml and immediately add 500 µl of this solution to each milliliter of concentrated antibody solution. Mix to dissolve and react for 30 min at room temperature.
7. Remove excess DTT by gel filtration using the same buffer as in step 4. Pool the fractions containing protein and concentrate to 10 mg/ml.

(C) CONJUGATION OF SIAB-ACTIVATED TOXIN WITH THIOLATED ANTIBODY

1. Mix activated toxin from part A with thiolated antibody from part B at a ratio of 2.25 mg of antibody per milligram of toxin. Protect the solution from light.
2. React for 18 h at room temperature in the dark.
3. To block unreacted sulfhydryl groups, add iodoacetamide to the solution to a final concentration of 2 m*M*. React for an additional 1 h at room temperature.
4. Isolation of the ideal 1:1 or 1:2 antibody–toxin conjugate can be done by gel filtration separation using a column of Sephacryl S-300.

SMCC

Succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) is a crosslinker with significant utility in protein conjugation (Chapter 6, Section 1.3). It is a popular choice among heterobifunctional reagents, especially for the preparation of antibody–enzyme and hapten–carrier conjugates (Hashida and Ishikawa, 1985; Dewey *et al.*, 1987). The NHS ester end of the reagent can react with primary amine groups on proteins to form stable amide bonds. The maleimide end of SMCC is specific for coupling to sulfhydryls when the reaction pH is in the range of 6.5 to 7.5 (Smyth *et al.*, 1964). The

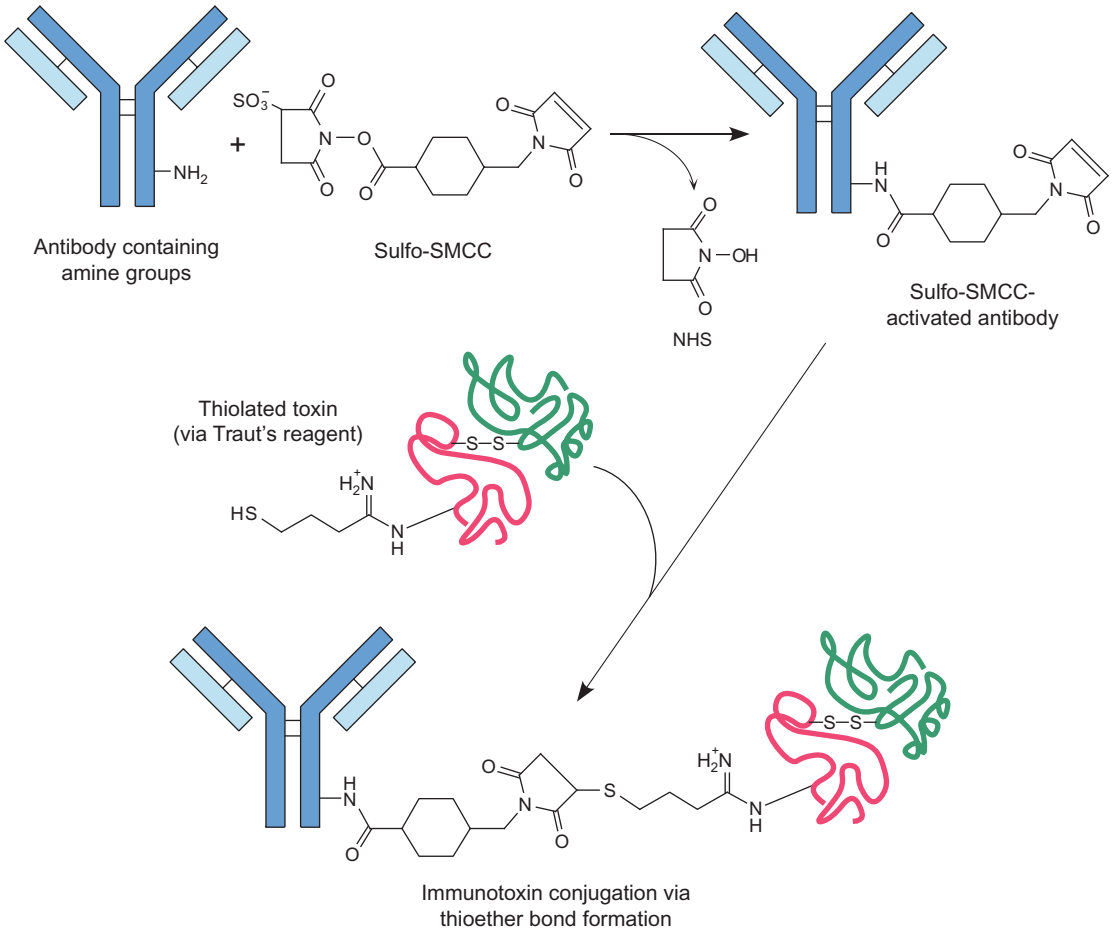

FIGURE 20.33 Sulfo-SMCC may be used to activate antibody molecules for coupling to thiolated toxin components. An intact A–B toxin molecule can be modified to contain sulfhydryls by treatment with 2-iminothiolane. Thiolation with this reagent retains the cytotoxic properties of the toxin while generating a sulfhydryl for conjugation. Reaction of the thiolated toxin with the maleimide-activated antibody creates the immunotoxin through thioether bond formation.

nature of the reactive groups of SMCC allow for highly controlled crosslinking procedures to be performed wherein the resulting products can be closely limited to a 1:1 ratio in the final complex. Thus, low-molecular-weight conjugates can be made which make ideal reagents for *in vivo* purposes.

However, since SMCC forms nonreversible thioether linkages with sulfhydryl groups, it can only be used in the preparation of immunotoxins if intact A–B toxins are employed in the conjugate. In such conjugates, the A chain still has the potential for reductive release from the B chain subunit after cellular docking and internalization. Immunotoxins prepared with A chain or single-subunit toxins will not display cytotoxicity if crosslinked with SMCC, since the crosslinker does not create cleavable disulfide bonds upon conjugation.

SMCC has been used to prepare immunotoxins with cobra venom factor (Vogel, 1987) and was compared to other crosslinkers in the preparation of gelonin and PAP conjugates (Lambert *et al.*, 1985).

The following protocol is a suggested method for the conjugation of SMCC-activated antibodies with 2-iminothiolane-modified, intact toxin molecules (Figure 20.33). It utilizes the water soluble analog of SMCC, sulfo-SMCC, which contains a negatively charged sulfonate group on its NHS ring.

Protocol

Caution: Toxin molecules are dangerously toxic even in small amounts. Use extreme care in handling.

Note: This protocol requires mixing activated antibody with thiolated toxin at a ratio of 2.25 mg of antibody per milligram of toxin. This ratio should be taken into account before starting the reactions.

(A) ACTIVATION OF ANTIBODY WITH SULFO-SMCC

1. Dissolve 10 mg of specific antibody in 1 ml of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
2. Weigh out 2 mg of sulfo-SMCC (Thermo Fisher) and add it to the above solution. Mix gently to dissolve.

To aid in measuring the exact quantity of crosslinker, a concentrated stock solution may be made in water and an aliquot equal to 2 mg transferred to the reaction solution. If a stock solution is made, it should be dissolved rapidly and used immediately to prevent extensive hydrolysis of the active ester. Alternatively, a stock solution of sulfo-SMCC may be prepared in DMSO and an aliquot added to the aqueous reaction.

3. React for 1 h at room temperature.
4. Immediately purify the maleimide-activated protein by applying the reaction mixture to a desalting column. Do not dialyze the solution, since the maleimide activity will be lost over the time course required to complete the operation. To obtain good separation between the protein peak (eluting first) and the peak representing excess reagent and reaction byproducts (eluting second), the applied sample size should be no more than 5 to 8% of the column bed volume.
5. Collect the peak containing the activated antibody (eluting first) and concentrate to 10 mg/ml using centrifugal concentrators. Use immediately for conjugating to a thiolated toxin.

(B) THIOLATION OF INTACT A–B TOXIN

1. Dissolve the toxin (e.g., intact ricin) at a concentration of 10 mg/ml in 50-m*M* triethanolamine hydrochloride, pH 8.0, containing 10-m*M* EDTA. The buffer should be degassed under vacuum and bubbled with nitrogen to remove oxygen that may cause sulfhydryl oxidation after thiolation.
2. Dissolve 2-iminothiolane in degassed, nitrogen-bubbled deionized water at a concentration of 20 mg/ml (makes a 0.14-*M* stock solution). The solution should be used immediately. Add 70 µl of the 2-iminothiolane solution to each milliliter of the toxin solution (final concentration is about 10-m*M*).
3. React for 1 h at 0°C (on ice) under a nitrogen blanket.
4. Purify the thiolated toxin from unreacted Traut's reagent by gel filtration using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, containing 10-m*M* EDTA. The presence of EDTA in this buffer helps to prevent oxidation of the sulfhydryl groups with resultant disulfide formation. The degree of SH modification in the purified protein may be determined using the Ellman's assay (Chapter 2, Section 4.1).
5. Concentrate the thiolated toxin to 10 mg/ml using centrifugal concentrators.

(C) CONJUGATION OF SMCC-ACTIVATED ANTIBODY WITH THIOLATED TOXIN

1. Mix the thiolated toxin with SMCC-activated antibody at a ratio of 2.25 mg of antibody per milligram of toxin. Protect the solution from light.
2. React for 18 h at room temperature.
3. To block unreacted sulfhydryl groups, add iodoacetamide to the solution to a final concentration of 2 mM. React for an additional 1 h at room temperature.
4. Isolation of the ideal 1:1 antibody–toxin conjugate can be done by gel filtration separation using a column of Sephacryl S-300.
5. Removal of nonspecific binding potential in the B chain must be done before using an A–B intact toxin conjugate *in vivo*. A large proportion of the binding sites on the B chains are usually blocked during the above conjugation process, and the galactose binding potential is significantly impaired. Further purification to remove conjugates that have galactose binding potential can be performed on an acid-treated agarose chromatography column (which contains galactose residues) or on a column of asialofetuin bound to agarose (Cumber *et al.*, 1985). Conjugate fractions that do not bind to both affinity gels contain no nonspecific binding potential toward non-targeted cells.

MBS

m-Maleimidobenzoyl-*N*-hydroxysuccinimide ester (MBS) is a heterobifunctional crosslinking agent containing an NHS ester and a maleimide group. The NHS ester can react with primary amines in proteins and other molecules to form stable amide bonds, while the maleimide end reacts with sulfhydryl groups to create stable thioether linkages (Chapter 6, Section 1.4). The reagent can be used in many different conjugation protocols to crosslink amine-containing proteins with sulfhydryl-containing proteins. Since the thioether bond formed at the maleimide end is nonreversible, MBS can be used for immunotoxin preparation only if the conjugate involves crosslinking intact A–B toxins with antibody molecules. Using intact toxins (as opposed to single-chain or A chain isolates), the A chain still is able to release from the complex after cellular docking and inactivate ribosomal activity (Youle and Nevelle, 1980; Dell'Arciprete *et al.*, 1988; Myers *et al.*, 1989).

MBS contains a benzoic acid derivative as its cross-bridge. In many applications involving NHS–maleimide crosslinkers, non-aromatic cross-bridges are considered superior to aromatic ones. This is reflected in the stability of the maleimide group to hydrolysis prior to conjugating with a sulfhydryl group. For immunotoxin preparation, however, aromatic maleimides resulted in better conjugate yield and more potent cytotoxic effects when compared to aliphatic ones (Myers *et al.*, 1989). MBS, therefore, may be

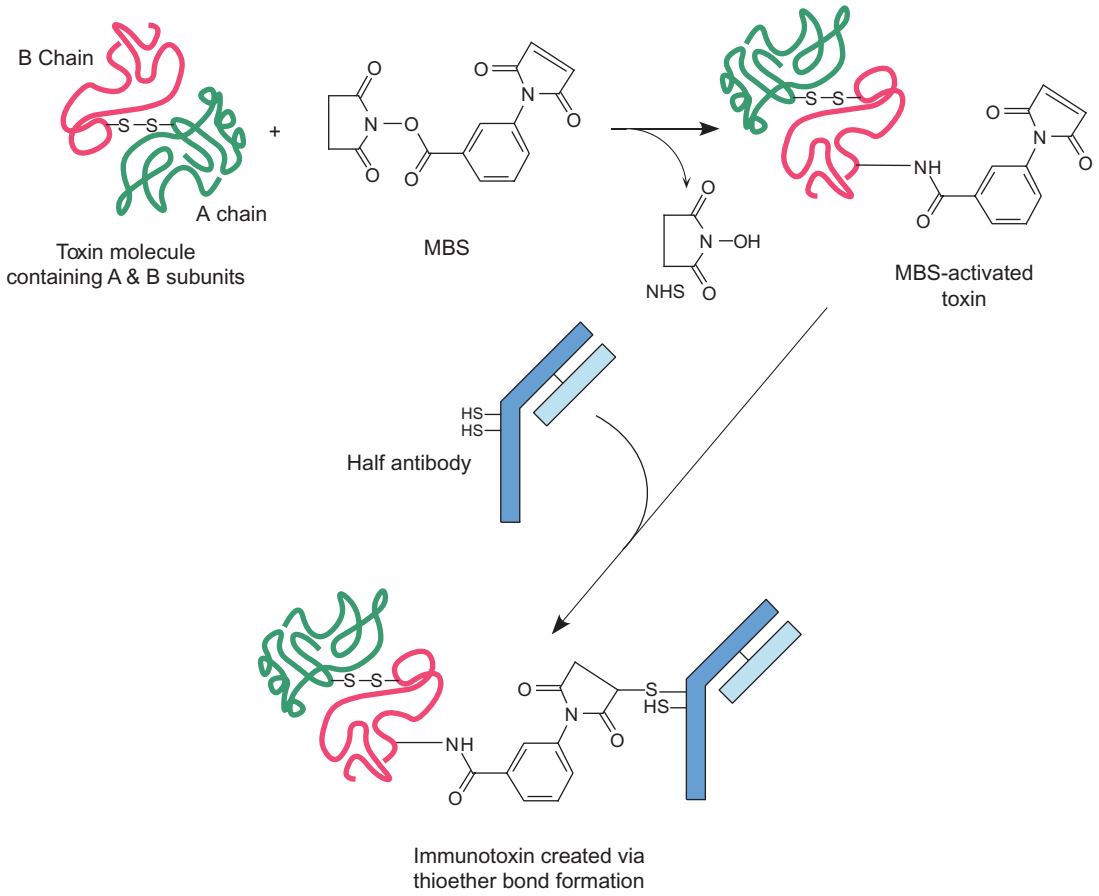

FIGURE 20.34 Activation of an intact A–B toxin molecule with MBS with subsequent conjugation with a reduced antibody fragment to produce an immunotoxin.

a crosslinker of choice when making conjugates with intact toxin molecules.

The following protocol is adapted from Myers *et al.* (1989). It involves activation of ricin with MBS and conjugation with a partially reduced antibody (Figure 20.34).

Protocol

Caution: Ricin molecules are dangerously toxic even in small amounts. Use extreme care in handling.

This method uses a molar ratio of 15:1 for ricin:antibody. This requires 6.24 mg of ricin per milligram of antibody. This ratio should be considered when determining how much starting materials to use for each step.

(A) ACTIVATION OF RICIN WITH MBS

1. Dissolve ricin at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5.
2. Dissolve MBS (Thermo Fisher) in DMF at a concentration of 2 mg/ml.
3. Add 76 µl of the MBS solution to each ml of the ricin solution. This represents a 3:1 molar ratio of crosslinker to protein.
4. React for 30 min at room temperature.
5. Immediately purify the MBS-activated toxin by gel filtration using a column of desalting resin. Apply no more sample than represents 5 to 8% of the gel volume. Isolate the protein peak by its absorbance at 280 nm and concentrate to 10 mg/ml using centrifugal concentrators with a molecular weight cut-off of 10,000.

(B) PARTIAL REDUCTION OF ANTIBODY WITH DTT

1. Dissolve the antibody in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5, at a concentration of 10 mg/ml.
2. Add DTT to a final concentration of 50 m*M*. Note: Lower concentrations of DTT may be used to avoid extensive reduction that may dissociate the antibody subunits. Concentrations in the range of 3- to 5-m*M* DTT have been shown to be appropriate for the reduction of just a few disulfides within the antibody structure (Sun *et al.*, 2005). Some optimization of the reductant concentration may have to be performed to obtain the best results for a particular antibody molecule.

3. Reduce for 30 min at room temperature.
4. Purify the reduced antibody using gel filtration on a column of Sephadex G-25. Concentrate the protein to 10 mg/ml using centrifugal concentrators.

(C) CONJUGATION OF MBS-ACTIVATED RICIN WITH PARTIALLY REDUCED ANTIBODY

1. Mix the MBS-activated ricin with the partially reduced antibody in a molar ratio of 15:1 (or 6.24 mg activated ricin per mg of reduced antibody). This represents a volume ratio (at 10 mg/ml for both proteins) of 1 ml ricin solution mixed with 160 µl antibody solution.
2. React for 18 h at room temperature.
3. Purification of the immunotoxin conjugate from unconjugated ricin can be performed using a column of TSK3000 SW (Toya Soda, Japan) according to the method of Myers *et al.* (1989).
4. Removal of nonspecific binding potential in the B chain must be done before using an A–B intact toxin conjugate *in vivo*. See step 5 of the MBS conjugation protocol discussed previous to this section.

SMPB

Succinimidyl-4-(*p*-maleimidophenyl)butyrate (SMPB) is a heterobifunctional analog of MBS containing an extended cross-bridge (Chapter 6, Section 1.6). The crosslinker has an amine-reactive NHS ester on one end and a sulfhydryl-reactive maleimide group on the other. Conjugates formed using SMPB thus are linked by stable amide and thioether bonds.

As in the case of MBS, discussed previously, SMPB was found to be more effective than aliphatic crosslinkers in producing immunotoxin conjugates with ricin that have high yields of cytotoxicity (Myers *et al.*, 1989). This was attributed to the reagent's aromatic ring structure. A comparison with SPDP produced immunotoxin conjugates concluded that SMPB formed more stable complexes that survive in serum for longer periods (Martin and Papahadjopoulos, 1982).

The method for the preparation of immunotoxins with SMPB is identical to that used for MBS (above). Since the thioether bonds formed with sulfhydryl-containing molecules are non-cleavable, A chain isolated fractions or single-chain toxin molecules cannot be conjugated with antibodies with retention of cytotoxicity. Only intact A–B toxin molecules may be used with this crosslinker, since the A chain is still capable of being reductively released from the complex.

3.3. Preparation of Immunotoxin Conjugates *via* Reductive Amination

Conjugations involving aldehyde groups and amine-containing molecules can be performed through Schiff base formation with subsequent reduction using sodium cyanoborohydride to form stable secondary amine linkages (Chapter 3, Section 5.3). Carbohydrates, glycoproteins, and other polysaccharide-containing molecules can be oxidized to contain aldehyde residues by sodium periodate or specific oxidases (Chapter 2, Section 4.4). Some antibodies and toxin molecules are glycoproteins and contain sufficient carbohydrate to be utilized for reductive amination crosslinking.

A second method of immunotoxin preparation by reductive amination involves the use of a polysaccharide spacer. Soluble dextran may be oxidized with periodate to form a multifunctional crosslinking polymer. Reaction with antibodies and cytotoxic molecules in the presence of a reducing agent forms multivalent immunotoxin conjugates. The following sections discuss these options.

Periodate Oxidation of Glycoproteins Followed by Reductive Conjugation

Antibody molecules usually contain carbohydrate in their Fc regions. Similarly, many toxins, such as ricin and abrin, are glycoproteins that contain abundant polysaccharide. These carbohydrate residues can be oxidized with 10-m*M* sodium periodate to form reactive aldehyde groups capable of being conjugated with primary amines (Chapter 2, Section 4.4). Mixing an aldehyde-containing glycoprotein with another amine-containing molecule in the presence of sodium borohydride or sodium cyanoborohydride reduces the intermediate Schiff bases that are formed to stable secondary amine bonds. Since functional groups on the antibody and the toxin components are the only ones necessary for this type of conjugation strategy, it is often referred to as a zero-length crosslinking procedure (Chapter 4). In other words, no additional crosslinking reagents are introduced into the site of the crosslink. This method of conjugation is used with great success in the formation of antibody–enzyme conjugates, especially using the glycosylated enzyme, horseradish peroxidase (HRP) (Chapter 22, Section 1.1).

The disadvantage of this type of conjugation approach for producing immunotoxins is that many of the monoclonal antibodies or antibody fragments used for immunotoxin conjugation are devoid of carbohydrate. Especially when using small Fv fragments or single-chain antibodies produced by recombinant techniques, there are typically no polysaccharide portions attached to them. In this case, creation of aldehydes on the targeting component is not possible. In addition, not all toxin molecules contain carbohydrate. Ricin, abrin, and cobra venom factor are glycoproteins and can be oxidized and coupled to antibodies without difficulty (Olsnes and Pihl, 1982a,b; Vogel and Muller-Eberhard, 1984). However, it is not well known whether

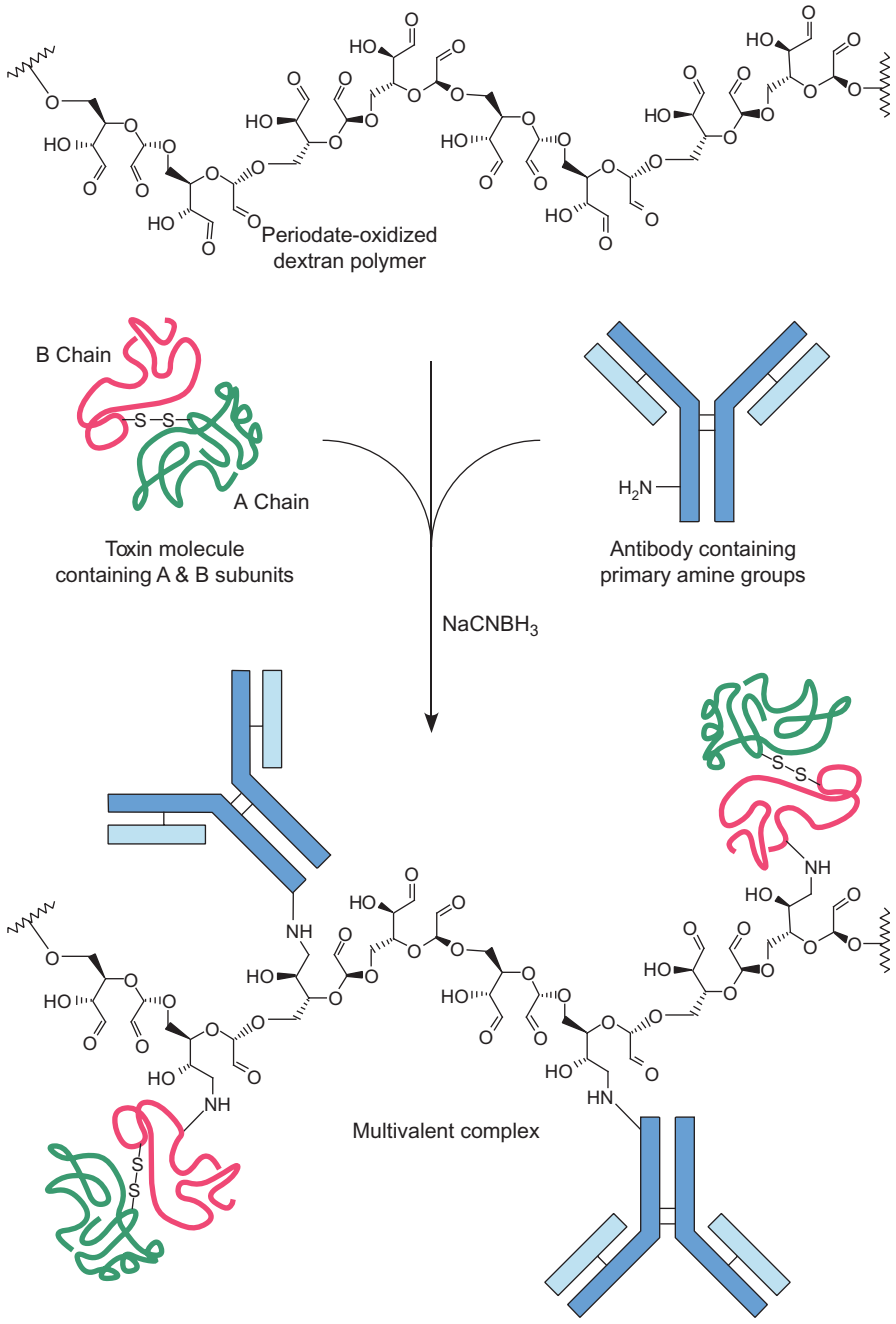

FIGURE 20.35 A periodate-oxidized dextran polymer may be reacted with both an antibody and an intact toxin component using reductive amination to form a multivalent immunotoxin complex.

immunotoxin conjugates formed by this procedure retain their ability to inhibit ribosomal activity.

Suggested procedures for using reductive amination techniques may be found in Chapter 2, Section 4.4 and Chapter 4, Section 4.

Periodate Oxidized Dextran as Crosslinking Agent

Dextran polymers consist of glucose residues bound together predominantly in α-1,6 linkages. The main repeating unit is an isomaltose group. Most preparations of dextran contain some branching, mainly incorporating 1,2, 1,3, and 1,4 linkages. The degree of branching is characteristic of its source—the strain and species of yeast or bacteria from which the dextran originated. The terminating monosaccharide in a dextran polymer is often a fructose group. Dextran polymers of molecular weight 10,000 to 40,000 provide long, hydrophilic arms that can accommodate multiple attachment

points for macromolecules along their length. Soluble dextrans can be oxidized in aqueous solution to create numerous aldehyde residues suitable for use in reductive amination techniques (Hurwitz *et al.*, 1978, 1985; Manabe *et al.*, 1983; Sela and Hurwitz, 1987). Periodate oxidation results in the cleavage of the carbon–carbon bonds between the Nos. 2 and 3 carbons within each monosaccharide unit of the chain, transforming the associated hydroxyl groups into aldehydes (Chapter 2, Section 4.4).

Periodate oxidized dextran can be used as a protein modification or crosslinking agent (Chapter 18, Section 2.2). Conjugation of antibody molecules to toxins can be performed with dextran to produce immunotoxins suitable for *in vivo* administration. Mixing of the antibody and toxin together with the oxidized dextran under alkaline conditions will result in the formation of Schiff base interactions with the amines on both proteins. Reduction of these Schiff base linkages with sodium borohydride or sodium cyanoborohydride results in stable secondary amine bonds, covalently attaching multiple antibody and toxin molecules along the length of the polysaccharide chain (Figure 20.35).

Chemoimmunoconjugates or antibody–drug conjugates (ADCs) consisting of anticancer agents attached to antibody targeting molecules also can be formed using oxidized dextran carriers. Cancer therapeutic agents such as adriamycin, bleomycin, and daunomycin can be coupled to the oxidized dextran through their amine groups (also see Chapter 1, Section 3.5). After formation of Schiff base linkages between these drugs and the carrier, the antibody is added along with a reducing agent to create the final secondary amine linkages (Sela and Hurwitz, 1987). The dextran backbone provides the ability to couple many more drug molecules associated with each antibody than could be accomplished by direct conjugation to the antibody itself.

Although dextran can be a versatile crosslinking agent for the preparation of many forms of macromolecular conjugates, immunotoxin conjugation may be impeded by the non-reversibility of the multiple amide bond linkages formed during reductive amination. Certainly, only intact A–B toxins have a chance of succeeding with this method, since A chain or single-subunit toxins would not be capable of release from the complex after cellular docking. Even intact two-subunit toxins, however, may not be capable of releasing an A chain unit, due to the multivalent nature of the oxidized dextran linker. For this reason, activated dextran may be more useful for constructing antibody conjugates consisting of cytotoxic organic compounds, not protein toxins—for example, chemotherapeutic drugs, hormones, or radioactive complexes.

Methods for using oxidized dextran and reductive amination techniques can be found in Chapter 3, Section 4.4; Chapter 3; Section 5; and especially Chapter 18, Section 2.2. Reference should also be made to the use of dendrimers as carriers for making cytotoxic targeting complexes (Chapter 8) as well as Chapter 1, Section 3.5, which provides a broad overview of the types and applications of therapeutic bioconjugates used today.

CHAPTER

21

Liposome Conjugates and Derivatives

A fast growing field that heavily depends on bioconjugate technology involves the use of liposomes. At one time, liposomes were studied only for their interesting structural characteristics in solution. Their physicochemical properties were investigated extensively as models of membrane morphology. Now they are being put to use as macromolecular carriers for nearly every application of bioconjugate chemistry. They are used as delivery devices to encapsulate cosmetics, drugs, fluorescent detection reagents, and as vehicles to transport nucleic acids, peptides, and proteins to cellular sites *in vivo* (Sawant and Torchilin, 2011; Karchemiski *et al.*, 2012; Lu and Low, 2012). Targeting components such as antibodies can be attached to liposomal surfaces and used to create large antigen-specific complexes (Smith *et al.*, 2011; Kirpotin *et al.*, 2012). In this sense, liposomal derivatives are being used to target cancer cells *in vivo*, to enhance detectability in immunoassay systems, and as multivalent scaffolds in avidin–biotin-based assays. Covalent attachment of antigens to the surface of liposomes provides excellent immunogen complexes for the generation of specific antibodies or as vaccine carriers to elicit protective immunity (Amidi *et al.*, 2011).

The end-products of liposome technology are used in retail markets, for the diagnosis of disease, as therapeutic agents, as vaccines, and as important components in assays designed to either detect or quantify certain analytes.

The following sections discuss the properties and applications of liposome technology as well as the most common methods of preparing conjugates of them with proteins and other molecules.

1. PROPERTIES AND USE OF LIPOSOMES

1.1. Liposome Morphology

Liposomes are artificial structures primarily composed of phospholipid bilayers exhibiting amphiphilic properties. Other molecules, such as cholesterol or fatty acids may also be included in the bilayer construction. In complex liposome morphologies, concentric spheres or sheets of lipid bilayers are usually separated by aqueous regions that are sequestered or compartmentalized from the surrounding solution. The phospholipid constituents of liposomes consist of hydrophobic lipid "tails" connected to a "head" constructed of various glycerylphosphate derivatives. The hydrophobic interaction between the fatty acid tails to the exclusion of the aqueous phase is the primary driving force for creating liposomal bilayers in aqueous solution.

However, the organization of liposomes in aqueous solution may be highly complicated. The nature of the lipid constituents, the composition of the medium, and the temperature of the solution all affect the association and morphology of liposomal construction. Small "monomers" or groupings of lipid molecules may assemble to create larger structures having several main forms (Figure 21.1). Aggregation of these monomers may fuse them into spherical micelles, wherein the polar head groups are all facing outward toward the surrounding aqueous medium and the hydrophobic tails are all pointing inward, thus excluding water from the core. In addition, aggregation may result in bilayer construction. In this case, sheets of lipid molecules, all with their head groups facing one direction and their tails facing the other way, are fused with another lipid sheet having their tails and heads facing the opposite direction. Thus, the inside of the bilayer contains only hydrophobic tails from both sheets, while the outside contains the hydrophilic heads facing the outer aqueous environment.

The various configurations that the bilayers can assume can also be complex. A bilayer may be in a spherical form, having one layer of hydrophilic head groups pointing outward toward the surrounding solution and the second hydrophilic layer pointing inward toward a compartment of aqueous solution sequestered within the sphere. The morphology of a liposome may be classified according to the compartmentalization of aqueous regions between bilayer shells. If the

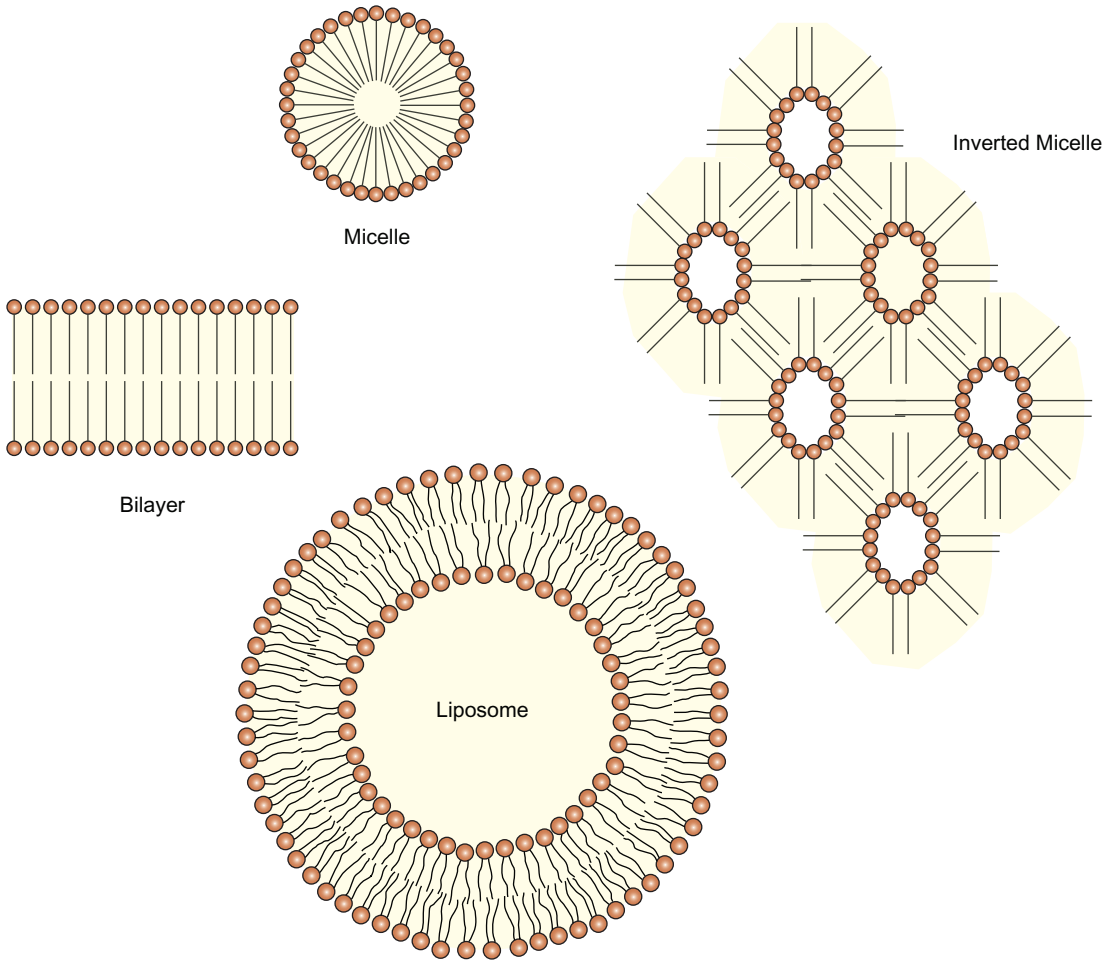

FIGURE 21.1 The amphiphilic nature of phospholipids in solution drives the formation of complex structures. Spherical micelles may form in aqueous solution, wherein the hydrophilic head groups all point out toward the surrounding water environment and the hydrophobic tails point inward to the exclusion of water. Larger lipid bilayers may form by similar forces, creating sheets, spheres, and other highly complex morphologies. Contiguous bilayer constructions, especially spheres, are called liposomes. In nonaqueous solution, inverted micelles may form, wherein the tails all point toward the outer hydrophobic region and the heads point inward forming hexagonal shapes. The yellow shaded areas represent the hydrophobic regions that are occupied by the aliphatic tails of the lipid molecules.

aqueous regions are segregated by only one bilayer each, the liposomes are called unilamellar vesicles (ULV) (Figure 21.2). If there is more than one bilayer surrounding each aqueous compartment, the liposomes are termed multilamellar vesicles (MLV). ULV forms are further classified as to their relative size, although rather crudely. Thus, there can be small unilamellar vesicles (SUV; usually thought of as less than 100 nm in diameter, with a minimum of about 25 nm) and large unilamellar vesicles (LUV; usually greater than 100 nm in diameter, with a maximal size of about 2500 nm). With regard to MLV, however, the bilayer structures cannot be as easily classified due to the almost infinite number of ways each bilayer sheet can be associated and interconnected with the next one. MLVs typically form large complex honeycomb structures that are difficult to categorize or exactly reproduce. However MLVs are the simplest to prepare, most stable, and easiest to scale up to large production levels.

Small lipid groupings or monomers may also fuse into bigger, inverted micelles, wherein their hydrophobic tails point outward toward other inverted micelle lipid tails. The individual structures are usually hexagonal in shape, but typically they exist as large groupings of inverted micelles, the outer edge of which contains partial inverted micelles, exposing their inner hydrophilic heads to the surrounding aqueous environment.

The most useful form of liposomes for bioconjugate applications consists of small, spherical ULVs that possess layers of hydrophilic head groups on their inner and outer surfaces. The inside of each vesicle can contain hydrophilic molecules that are protected from the outer environment by the lipid shell. The outside surface can be derivatized to contain covalently attached

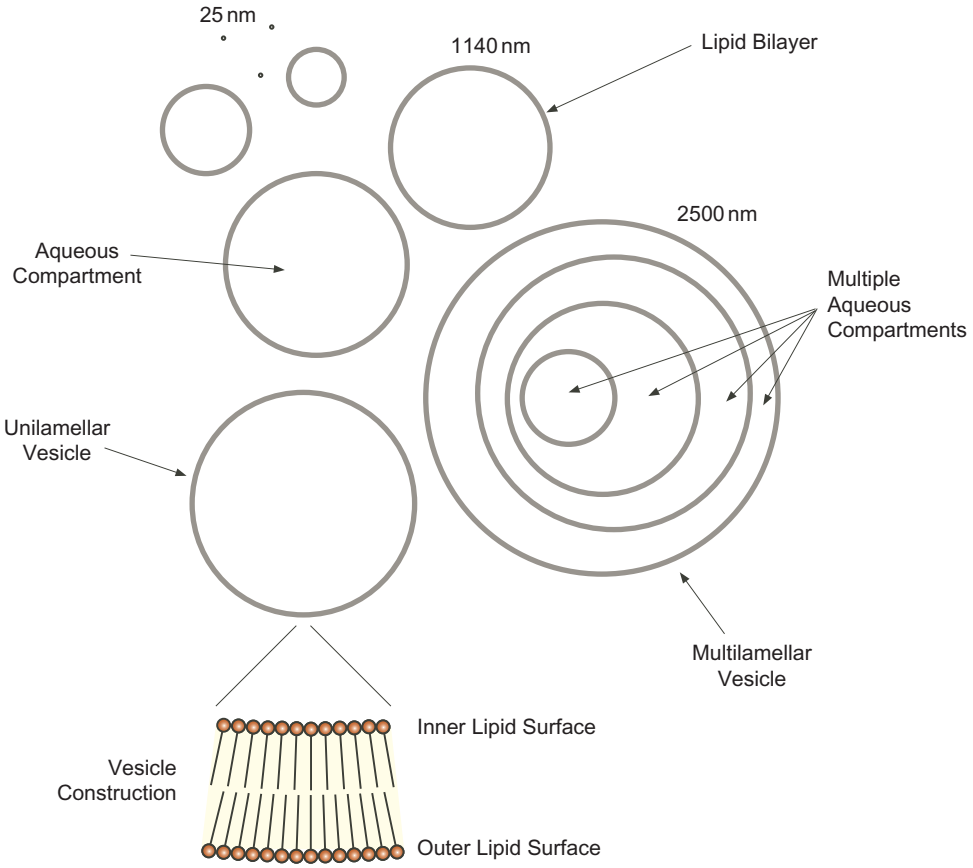

FIGURE 21.2 The highly varied morphologies of lipid bilayer construction.

molecules designed to target the liposome for specific interactions. Modification of the outer liposomal surface provides a multivalent scaffold that can accommodate many different molecules conjugated to it, including antibodies, detection molecules, high contrast agents, enzymes, drugs, or other molecules having some specific activity or function.

1.2. Preparation of Liposomes

Mixtures of phospholipids in aqueous solution will spontaneously associate to form liposomal structures. To prepare liposomes having morphologies useful for bioconjugation or delivery techniques, it is necessary to control this assemblage to create vesicles of the proper size and shape. Many methods are available to accomplish this goal, however all of them have several steps in common: (1) dissolving the lipid mixture in organic solvent, (2) dispersion of the lipid solution in an aqueous phase, and (3) fractionation to isolate the correct liposomal population.

In the first stage, the desired mix of lipid components is dissolved in organic solvent, usually chloroform:methanol (2:1 by volume), to create a homogeneous mixture. This mixture will include any phospholipid derivatized to contain reactive groups as well as other lipids used to form and stabilize the bulk of the liposomal structure. During all handling procedures using lipids or their derivatives, it is essential that the solutions be protected from oxidation and excessive exposure to light, especially the sun. Organic solvents should be maintained under a nitrogen or argon atmosphere to prevent introduction of oxygen. Water and buffers should be degassed using a vacuum and bubbled with inert gas before introducing lipid components.

The correct ratio of lipid constituents is important to form stable liposomes. For instance, a reliable liposomal composition for encapsulating aqueous substances may contain molar ratios of lecithin:cholesterol:negatively charged phospholipid (e.g., phosphatidyl glycerol (PG))) of 0.9:1:0.1. A composition that is typical when an activated phosphatidylethanolamine (PE) derivative is included may contain molar ratios of phosphatidylcholine (PC):cholesterol:PG:derivatized PE of 8:10:1:1. Another typical composition using a maleimide derivative of PE without PG is PC:maleimide-PE:cholesterol of 85:15:50 (Friede *et al.*, 1993). In general, to maintain

membrane stability, the PE derivative should not exceed a concentration ratio of about 1 to 10 mol PE per 100 mol of total lipid.

An example of a lipid mixture preparation based on mass would be to dissolve 100 mg of PC, 40 mg of cholesterol, and 10 mg of PG in 5 ml of chloroform/methanol solution. When using activated PE components, inclusion of 10 mg of the PE derivative to this recipe will result in a stable liposome preparation.

Once the desired mixture of lipid components is dissolved and homogenized in organic solvent, one of several techniques may be used to disperse the liposomes in aqueous solution. These methods may be broadly classified as (1) mechanical dispersion, (2) detergent-assisted solubilization, and (3) solvent-mediated dispersion.

Probably the most popular option is mechanical dispersion, simply because the greatest number of methods that utilize it have been developed. When using mechanical means to form vesicles, the lipid solution is first dried to remove all traces of organic solvent prior to dispersion in an aqueous media. The dispersion process is the key to producing liposomal membranes of the correct morphology. This method uses mechanical energy to break up large lipid agglomerates into smaller vesicles having the optimal size and shape characteristics necessary for encapsulation or bioconjugation.

Mechanical dispersion methods involve adding an aqueous solution (which may contain substances to be encapsulated) to the dried, homogeneous lipid mixture and manipulating it to effect dispersion. Major methods of mechanical dispersion include simple shaking (Bangham *et al.*, 1965), non-shaken aqueous contact (Reeves and Dowben, 1969), high-pressure emulsification (Mayhew *et al.*, 1984), water-in-oil emulsions (Wang *et al.*, 2011), sonication (Huang, 1969), extrusion through small-pore membranes (Olson *et al.*, 1980; Morton *et al.*, 2012), various freeze–thaw techniques (Pick, 1981), and the use of supercritical solvents such as carbon dioxide (Aburai *et al.*, 2011). Some devices are available commercially which automate the mechanical dispersion process, usually by high-pressure emulsification or sonication (Branson Ultrasonics Corp.).

Most of these methods result in a population of vesicles ranging from SUVs of only 25-nm diameter to very large MLVs. Classification of the desired liposomal morphology may be performed by chromatographic means using columns of Sepharose 2B or Sepharose 4B, by density-gradient centrifugation using Ficoll or metrizamide gradients, or by dialysis.

Liposome formation by detergent-assisted solubilization utilizes the amphipathic nature of detergent molecules to bring the lipid components more effectively into the aqueous phase for dispersion. The detergent molecules presumably bind and mask the hydrophobic tails of lipids from the surrounding water molecules. Detergent treatment may take place from a dried lipid mixture or after formation of small vesicles. Usually, nonionic detergents such as the Triton X family, alkyl glycosides, or bile salts such as sodium deoxycholate are employed for this procedure. The immediate structures which form as the detergent molecules solubilize the lipids from a dried state are small micelles. Upon removal of the detergent from the solution, the lipid micelles aggregate to create larger liposome structures. Liposomes of up to 1000 Å containing a single bilayer may be formed using detergent-assisted methods (Enoch and Strittmatter, 1979; Richmond *et al.*, 2011). Unfortunately, some detergent-removal processes may also remove other molecules that were to be entrapped in the liposomes during formation.

Solvent-mediated dispersion techniques used to create liposomes first involve dissolving the lipid mixture in an organic solvent to create a homogeneous solution, and then introducing this solution into an aqueous phase. The solvent may or may not be soluble in the aqueous phase to effect this process. There may also be components dissolved in the aqueous phase to be encapsulated in the developing liposomes.

Perhaps the simplest solvent dispersion method is that developed by Batzri and Korn (1973). Phospholipids and other lipids to be a part of the liposomal membrane are first dissolved in ethanol. This ethanolic solution is then rapidly injected into an aqueous solution of 0.16-*M* KCl using a syringe, resulting in a maximum concentration of no more than 7.5% ethanol. Using this method, single bilayer liposomes of about 25 nm diameter can be created that are indistinguishable from those formed by mechanical sonication techniques. The main disadvantages of ethanolic injection are the limited solubility of some lipids in the solvent (about 40-m*M* for PC) and the dilute nature of the resultant liposome suspension. However, for the preparation of small quantities of SUVs, this method may be one of the best available.

Other solvent dispersion methods utilize solvents that are insoluble in the aqueous phase. The key to the production of liposomes by this procedure involves the formation of a "water-in-oil" emulsion. To create the proper reverse-phase emulsion, a small quantity of aqueous phase must be introduced into a large quantity of organic phase containing the dissolved liposomes. The result is a milky dispersion containing the "homogenized" liposomes. A number of techniques have been developed to perform this procedure (Kim and Martin, 1981; Kim *et al.*, 1983; Pidgeon *et al.*, 1986). The emulsification process in each of these solvent-dispersion techniques involves the use of mechanical means (shaking, stirring, or sonication) to effect the formation of small droplets of aqueous solution uniformly dispersed in the lipid–organic phase.

For the preparation of large quantities of liposomes, mechanical dispersion using a commercially available emulsifier is probably the best route. For limited quantities, the use of simple shaking or ethanolic dispersion techniques works well.

Regardless of their method of fabrication, most liposome preparations need to be further classified and purified before use. To remove excess aqueous components that were not encapsulated during the vesicle formation process, gel filtration using a column of Sephadex G-50 or dialysis can be employed. To fractionate the liposome population according to size, gel filtration using a column of Sepharose 2B or 4B should be performed.

Small liposome vesicles often aggregate upon standing to form larger, more complex structures. Therefore, long-term storage in aqueous solution is usually not possible without major transformations in liposome morphology. Freezing also fractures the liposomal membrane, releasing any entrapped substances. The inclusion of cryoprotectants such as sugars or poly-hydroxyl-containing compounds can overcome the structural degradation problems upon freezing (Harrigan *et al.*, 1990; Talsma *et al.*, 1991; Park and Huang, 1992). Presumably, the hydroxyl groups in cryoprotectants can take the place of water in hydrogen bonding activities, thus providing structural support even under conditions in which water is removed. A procedure by Friede *et al.* (1993) allows freezing and lyophilization of SUVs in the presence of 4% sorbitol with complete retention of liposome integrity upon reconstitution. Thus, freeze-drying may be the best method for the long-term storage of intact liposomes.

For a review of liposome manufacturing methods and their use in targeting biomarkers to deliver active agents *in vivo*, see Maherani *et al.* (2011).

1.3. Chemical Constituents of Liposomes

The overall composition of a liposome—its morphology, chemical constituents (including a large variety of phospholipids and other lipids or fatty acids), charge, and any attached functional groups—can affect the properties of the vesicle both *in vitro* and *in vivo* (Allison and Gregoriadis, 1974; Alving, 1987; Therien and Shahum, 1989). Although there are literally dozens of lipid components that potentially can be included in a liposomal recipe, only a handful are commonly used.

Phospholipids are the most important of these liposomal constituents. Being the major component of cell membranes, phospholipids are composed of a hydrophobic, fatty acid tail and a hydrophilic head group. The amphipathic nature of these molecules is the primary force that drives the spontaneous formation of bilayers in aqueous solution and holds the vesicles together.

Naturally occurring phospholipids can be isolated from a variety of sources. One of the most common phospholipid raw materials is egg yolk. However, since the composition of egg phospholipid is from a biological source and can vary considerably depending on age of the eggs, the diet of the chickens, and the method of processing, newer enzymatic and synthetic chemical methods are now being employed to manufacture the required phospholipid derivatives in higher purity and yield.

Two main forms of lipid derivatives exist biologically: molecules containing a glycerol backbone and those containing a sphingosine backbone. The most important type for liposomal construction is a phosphodiglyceride derivative, which consists of a glycerol backbone that links two fatty acid molecules with a polar head group (Figure 21.3). The fatty acids are acyl bonded in ester linkages to the Nos. 1 and 2 carbon

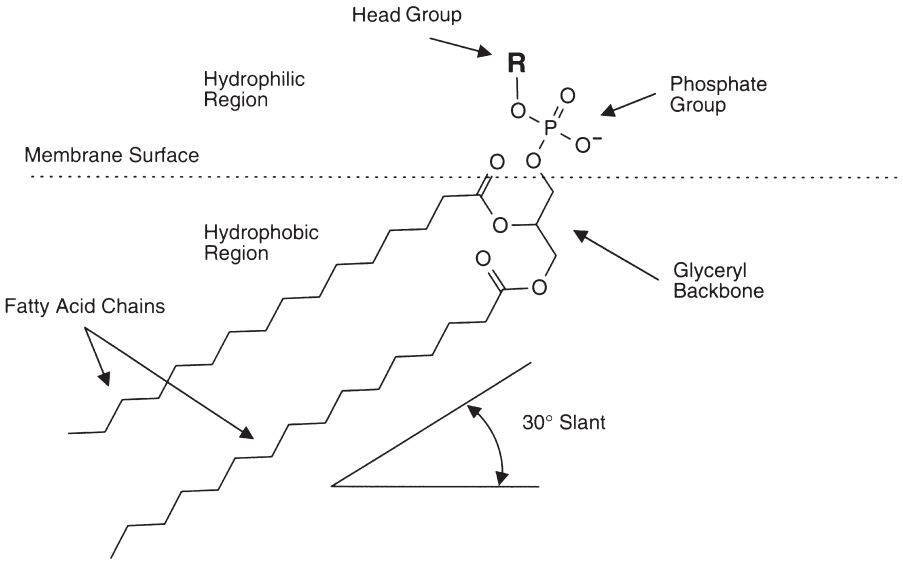

FIGURE 21.3 The basic construction of phosphodiglyceride molecules within lipid bilayers. The fatty acid chains are embedded in the hydrophobic inner region of the membrane, oriented at an angle to the plane of the membrane surface. The hydrophilic head group, including the phosphate portion, points out toward the hydrophilic aqueous environment. Complex lipid bilayers differ from this ideal presentation in that the fatty acid hydrophobic tails of each phospholipid molecule are entwined with other tails in a tightly crowded three-dimensional space within a highly dynamic membrane structure.

hydroxyls of the glycerol bridge. The No. 3 carbon hydroxyl of the glycerol group is phosphorylated and possesses a negative charge at physiological pH. This basic phosphodiglyceride construct of two fatty acids and one glycerylphosphate group is called phosphatidic acid. This is the simplest form of phospholipid available.

The fundamental phosphatidyl group can also be further derivatized at the phosphate to contain an additional polar constituent. Several common derivatives of phosphodiglycerides are naturally occurring, including PC (commonly called lecithin), phosphatidyl ethanolamine (PE), phosphatidyl serine (PS), phosphatidyl glycerol (PG), and phosphatidyl inositol (PI) (Figure 21.4). All of these phospholipids have polar groups that are linked to the phosphatidyl moiety in a phosphate ester bond. The most abundant of these derivatives in biological cell membranes is PC—the trimethyl derivative of PE, possessing a positive charge at physiological pH. Some or all of these phosphodiglyceride derivatives can be mixed to create a particular liposomal recipe.

The fatty acid constituents of phosphodiglycerides can vary considerably in nature among a number of different chain lengths and points of unsaturation. A given isolated phosphatidyl derivative from a biological source usually possesses a range of fatty acid components, varying in chain length from C16 to about C24. Some of the fatty acids may also contain points of unsaturation—one or more double bonds between certain carbon atoms within the chain (Matreya and Avanti Polar Lipids, suppliers). For instance, egg lecithin is not a single compound, but contains a mixture of PC containing about 31% saturated fatty acid having a chain length of 16 carbons, 16% saturated fatty acid with 18 carbons, about 48% also with 18 carbons but having at least one to two points of unsaturation, and the rest a variety of other fatty acid constituents. Naturally

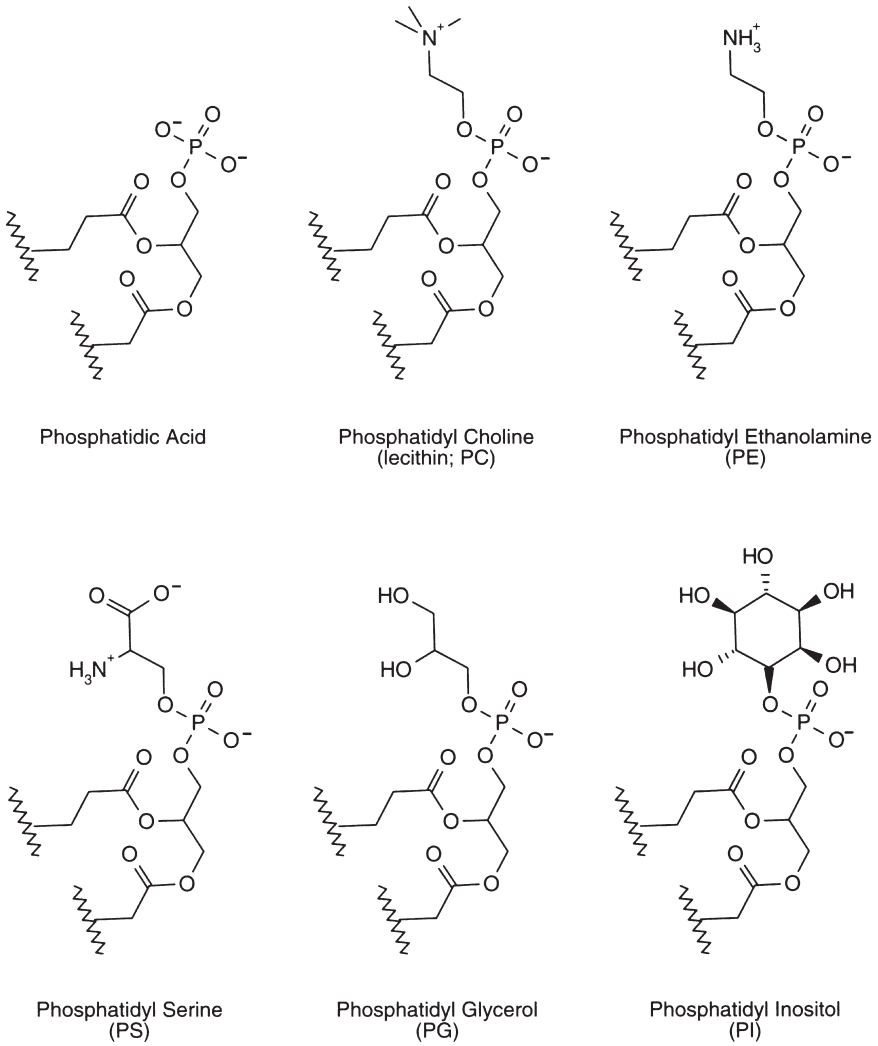

FIGURE 21.4 The head-group structures of the six commonly encountered phosphatidyl derivatives.

occurring, unsaturated fatty acids typically are of the *cis* conformation, not *trans*. The existence of unsaturation within a fatty acid is usually abbreviated as the chain length followed by a colon and the number of double bonds. For instance, *cis*-9-hexadecenoic acid (palmitoleic acid) contains one double bond at carbon 9 and it is abbreviated as C16:1.

By contrast, a given synthetic preparation of a major phospholipid possesses fatty acid constituents all of identical chain length and unsaturation. A synthetic PC derivative can be purchased that contains only, for instance, 1,2-dimyristoyl (C14) fatty acid substitutions on its glyceryl backbone (Genzyme). The use of synthetic rather than natural phospholipids for making liposomes thus produces reagents of known chemical purity, which is very important for regulatory requirements surrounding the introduction of products used topically or *in vivo*.

Despite the large variety of potential fatty acid components in natural-occurring phosphodiglycerides, only three major fatty acid derivatives of synthetic phospholipids are commonly used in liposome preparation: (1) myristic acid (n-tetradecanoic acid; containing 14 carbons), (2) palmitic acid (n-hexadecanoic acid; containing 16 carbons), and (3) stearic acid (n-octadecanoic acid; containing 18 carbons) (Figure 21.5).

The nomenclature for associating individual fatty acid groups with particular phosphodiglyceride derivatives is straightforward. For instance, a phosphatidic acid (PA) derivative which contains two myristic acid chains is commonly called dimyristoyl phosphatidic acid (DMPA). Likewise, a PC derivative containing two palmitate chains is called dipalmitoyl phosphatidyl choline (DPPC). Other phosphodiglyceride derivatives are similarly named.

The second form of lipid derivative that occurs naturally in membrane structures is derived from sphingosine. Unlike the phosphodiglyceride derivatives discussed above, sphingolipids contain no glycerol backbone. Instead, these lipids are constructed from a derivative of 4-sphingenine, containing an *N*-acyl-linked fatty acid group and possibly other constituents off the No. 1 carbon hydroxyl group (Figure 21.6). Sphingolipids are highly similar in their construction to glyceryl lipids, in that there are two hydrophobic tails present on a 3-carbon backbone (one of them contributed from 4-sphingenine itself and the other from the attached fatty acid), and there also exists a hydrophilic head group. This creates the typical amphipathic properties common to all lipid membrane components.

The simplest form of sphingolipid, ceramide, contains a fatty acid group, but no additional components on the No. 1 hydroxyl. Major derivatives of ceramide at the 1-hydroxyl position include a positively charged phosphocholine compound called sphingomyelin, a glucose derivative called glucosylcerebroside, and other complex carbohydrate derivatives termed gangliosides (Figure 21.7). Gangliosides are involved in various cellular recognition phenomena, including being part of the blood group determinants, A, B, and O, in humans.

The use of sphingolipids in liposome formation is possible due to the natural amphipathic properties of the molecules. Some sphingolipids can lend structural advantages to the integrity of liposomal membranes. Sphingomyelin, for example, is capable of hydrogen bonding with adjacent glyceryl lipids, thus increasing the order and stability of the vesicle construction. This stability may translate into a lower potential for passage of molecules through the membrane bilayer, forming vesicles that are better able to retain their contents than more fluid liposome constructions. The temperature of phase transition in sphingolipid-containing membranes is often greater than membranes

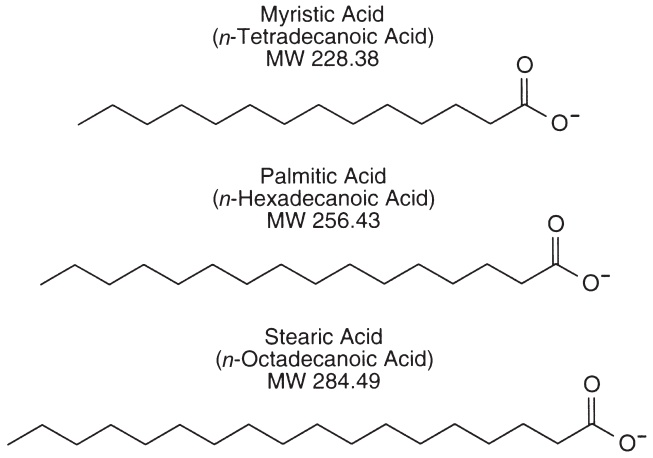

FIGURE 21.5 The three fatty acid components commonly used in liposome construction.

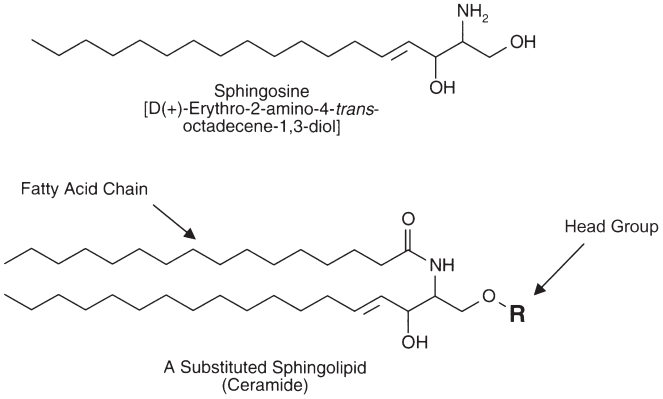

FIGURE 21.6 Sphingolipids are constructed of sphingosine derivatives containing an acylated fatty acid and a head group attached to the hydroxyl.

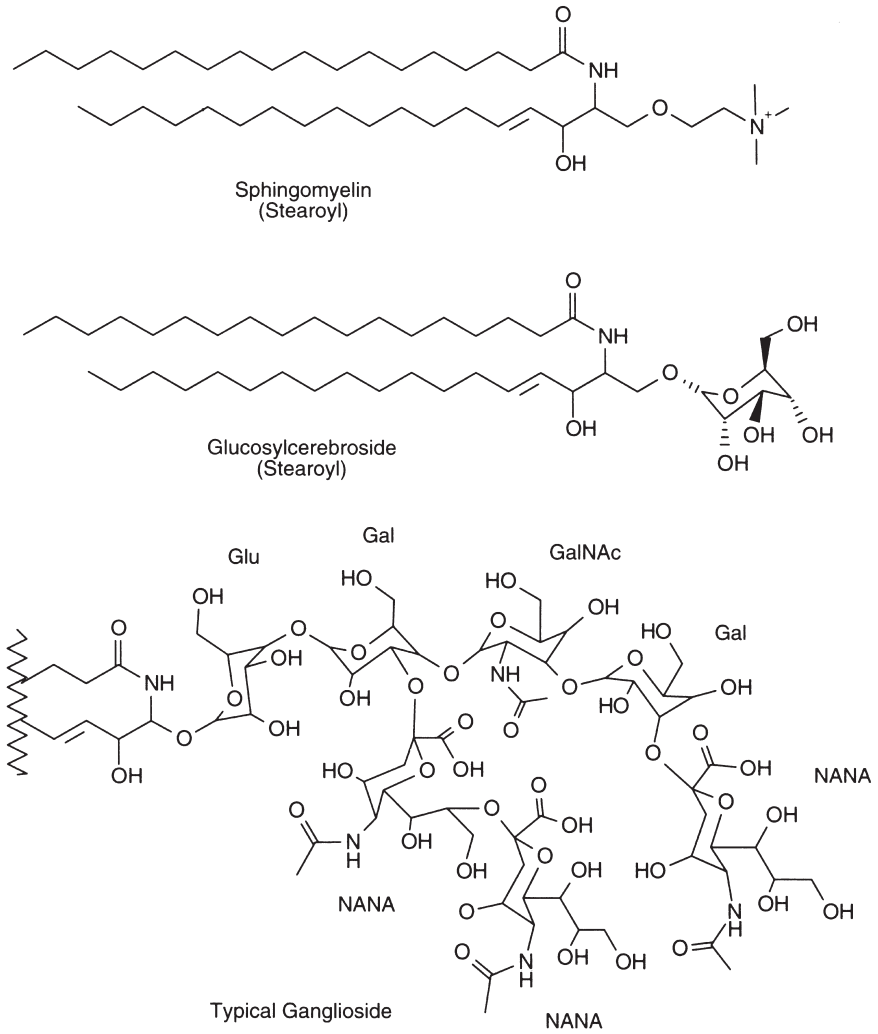

FIGURE 21.7 Common sphingolipid derivatives include small and highly complex head groups.

constructed of only phosphodiglyceride derivatives. Liposomes containing sphingomyelin or gangliosides also have prolonged lifetimes *in vivo* (Gregoriadis and Senior, 1980; Allen and Chonn, 1987) and may be advantageous for creating liposome immunogen complexes.

The main disadvantage of incorporating sphingolipids in liposomes is their high cost. Purified phosphodiglyceride derivatives may be obtained in bulk quantities and in highly defined synthetic preparations, whereas sphingolipid derivatives are not so readily available in similar purity.

Another significant component of many liposome preparations is cholesterol. In natural cell membranes, cholesterol makes up about 10 to 50% of the total lipid. For liposome preparation, it is typical to include a mole ratio of about 50% cholesterol in the total lipid recipe. The addition of cholesterol to phospholipid bilayers alters the properties of the resultant membrane in important ways. As it dissolves in the membrane, cholesterol orients itself with its polar hydroxyl group pointed toward the aqueous outer environment, approximately even, in a three-dimensional sense, with the glyceryl backbone of the bilayer's phosphodiglyceride components (Figure 21.8). Structurally, cholesterol is a rigid component in membrane construction, not having the same freedom of movement that the fatty acid tails of phosphodiglycerides possess. Adjacent phospholipid molecules are restricted in their freedom of movement throughout the length of their fatty acid chains that are abutting the cholesterol molecules. However, since the cholesterol components have the effect of creating spaces in the uniform hydrophobic morphology of the bilayer, the portion of the fatty acid chains below the abutted regions are increased in their freedom of movement.

Cholesterol's presence in liposome membranes has the effect of decreasing or even abolishing (at high

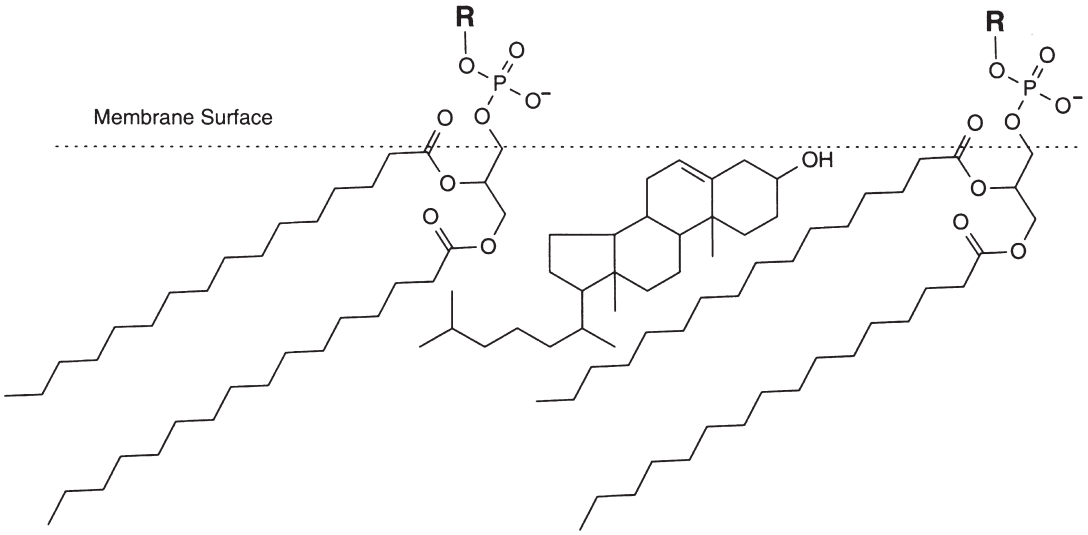

FIGURE 21.8 The orientation of cholesterol in phospholipid bilayers.

cholesterol concentrations) the phase transition from the gel state to the fluid or liquid crystal state that occurs with increasing temperature. It can also modulate the permeability and fluidity of the associated membrane—increasing both parameters at temperatures below the phase transition point and decreasing both above the phase transition temperature. Most liposomal recipes include cholesterol as an integral component in membrane construction.

1.4. Functional Groups of Phospholipids

For the production of liposomal conjugates, lipid derivatives must be incorporated into the bilayer construction that contain available functional groups that are able to be chemically crosslinked or modified. A number of phosphodiglyceride compounds can be employed for conjugation purposes. Each of these components contains a head group that can be directly derivatized or chemically modified to contain a reactive group. For instance, several lipid derivatives contain amine groups that can be utilized in nucleophilic reactions with crosslinkers or other modification reagents. These include phosphatidyl ethanolamine (PE), phosphatidyl serine (PS), and stearylamine. Carboxyl-containing molecules include all the individual fatty acids as well as PS. These can be coupled to amine-containing molecules by the use of the carbodiimide reaction (Chapter 4, Section 1). Hydroxyl-containing lipids include phosphatidyl glycerol (PG), fatty acid alcohols, phosphatidyl inositol (PI), and various gangliosides and cerebrosides of sphingolipid derivation. Lipids possessing hydroxyl groups on adjacent carbon atoms, such as those containing sugar constituents, may be oxidized with sodium periodate to produce reactive aldehyde residues (Chapter 2, Section 4.4). Coupling aldehydes to amine-containing molecules can be accomplished by reductive amination (Chapter 4, Section 4). Finally, the phosphate groups of phosphatidic acid (PA) residues may be used to conjugate with amine-containing molecules in a method similar to modification of the 5′-phosphates of DNA probes. This is performed through the use of the carbodiimide reaction with 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) (Chapter 23, Section 2.1). Figure 21.9 shows the structures and reactive sites of these lipid functional groups.

When liposomes are used as part of a conjugate system, the targeting molecules are usually attached covalently to these head group functionalities using standard crosslinking techniques (Derksen and Scherphof, 1985). Although all of the above-mentioned functional groups on lipid molecules can be used for conjugation procedures, most often the derivatization reactions are performed off the PE constituents within the liposomal mixture. The primary amine off the glycerylphosphate head of PE provides an ideal functional group for activation and subsequent coupling of targeting or detection molecules (Shek and Heath, 1983). Liposomes may be constructed with reactive groups already prepared on their PE constituents, all set to be conjugated with selected molecules having the correct functional group. Stock preparations of activated liposomes may even be prepared and lyophilized to be used as needed in coupling macromolecules (Friede *et al.*, 1993). All of the amine-reactive conjugation methods discussed in this section may be used with PE-containing liposomes.

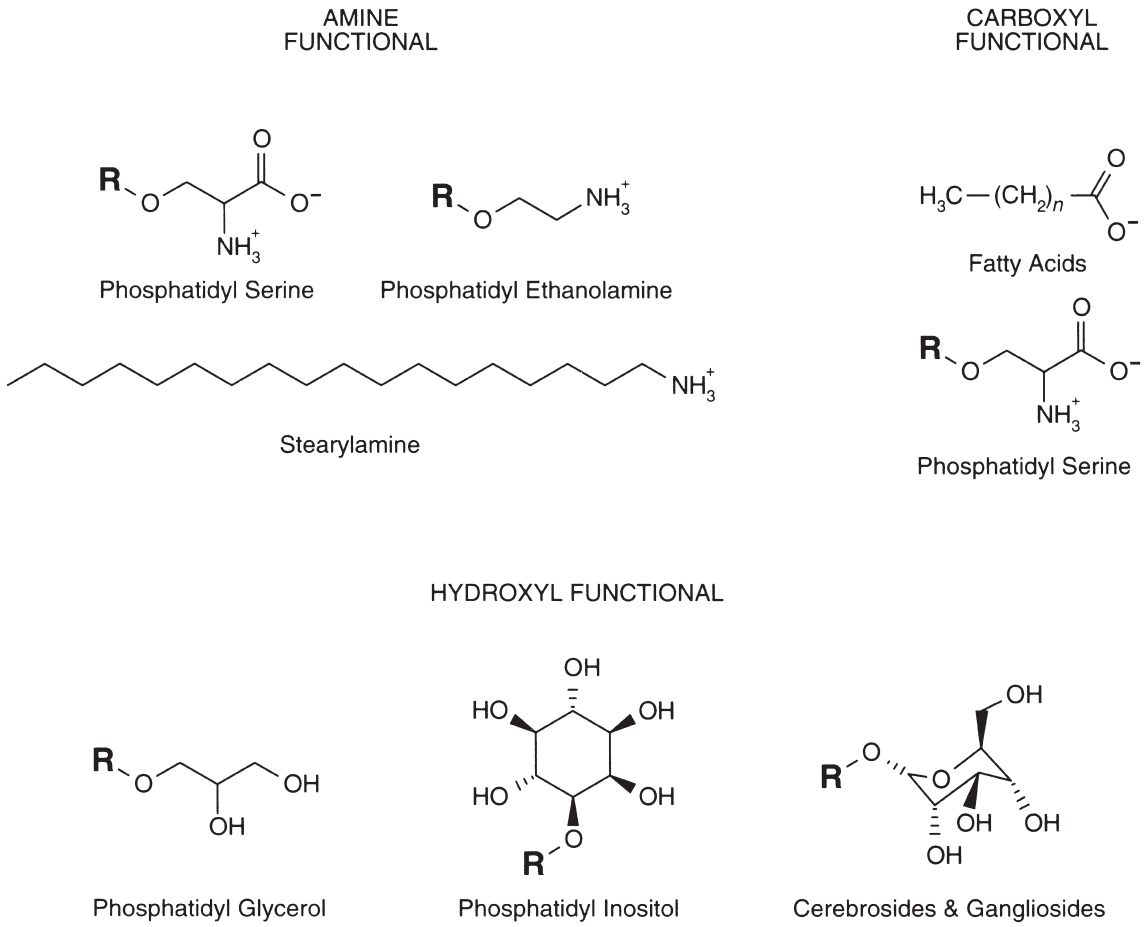

FIGURE 21.9 The major functional groups of lipids that may participate in bioconjugate techniques include amines, carboxylates, and hydroxyls.

2. DERIVATIZATION AND ACTIVATION OF LIPID COMPONENTS

Two approaches for the activation of lipid components may be used to create reactive groups in liposomes. A purified lipid may be activated prior to incorporation into the bilayer construction or the activation step may occur after formation of the intact liposome. Either way, the goal of the activation process is to provide a reactive species that can be used to couple with selected target groups on proteins or other molecules. While numerous crosslinking methods can be used with lipid functional groups, three main strategies are commonly used to conjugate proteins with liposomes: (1) reductive amination to couple aldehyde residues with amines; (2) carbodiimide-mediated coupling of an amine to a carboxylate or an amine to a phosphate group; and (3) multi-step, heterobifunctional crosslinker-mediated conjugation. Both reductive amination and heterobifunctional processes involve activation of particular lipid components.

2.1. Periodate Oxidation of Liposome Components

Reductive amination-mediated conjugation can be performed by periodate-oxidizing carbohydrate or glycerol groups on lipid components and using them to couple with amine-containing molecules. It may also be accomplished by using amines on liposomes (i.e., by the incorporation of PE or SA residues) and coupling them to aldehydes present on proteins or other molecules. Using the first approach, liposomes containing PG or glycosphingolipid residues are oxidized by sodium periodate, purified, and then used to conjugate with protein molecules in the presence of sodium cyanoborohydride (Figure 21.10) (Chapter 4, Section 4). A protocol for the formation of aldehyde groups on liposomes can be found in the method of Heath *et al.*, 1981.

Protocol

1. Prepare a 5-mg/ml liposome construction in 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4,

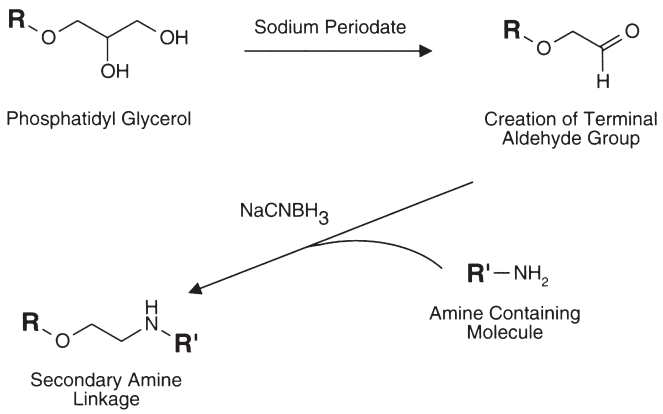

FIGURE 21.10 Hydroxyl-containing lipid components, such as phosphatidyl glycerol, can be oxidized with sodium periodate to produce aldehyde residues. Modification with amine-containing molecules can then take place using reductive amination.

containing, on a mole ratio basis, a mixture of PC:cholesterol:PG:other glycolipids of 8:10:1:2. The other glycolipids that can be incorporated include PI, lactosylceramide, galactose cerebroside, or various gangliosides. Other liposome compositions may be used, for example recipes without cholesterol, as long as a periodate-oxidizable component containing diols is present. Any method of liposome formation may be used.

2. Dissolve sodium periodate to a concentration of 0.6-*M* by adding 128 mg per ml of water. Add 200 µl of this stock periodate solution to each ml of the liposome suspension with stirring.
3. React for 30 min at room temperature in the dark.
4. Dialyze the oxidized liposomes against 20-m*M* sodium borate, 0.15-*M* NaCl, pH 8.4, to remove unreacted periodate. This buffer is ideal for the subsequent coupling reaction. Chromatographic purification using a column of Sephadex G-50 can also be performed.

The periodate-oxidized liposomes may be used immediately to couple with amine-containing molecules such as proteins (see Section 7.6, below), or they may be stored in a lyophilized state in the presence of sorbitol (Friede *et al.*, 1993) for later use.

2.2. Activation of PE Residues with Heterobifunctional Crosslinkers

The most common type of heterobifunctional reagent used for the activation of lipid components includes the amine- and sulfhydryl-reactive crosslinkers containing an *N*-hydroxysuccinimide (NHS) ester group on one end and either a maleimide, iodoacetyl, or pyridyl disulfide group on the other end (Chapter 6, Section 1). Principle reagents used to effect this activation process include SMCC (Chapter 6, Section 1.3), MBS (Chapter 6, Section 1.4), SMPB (Chapter 6, Section 1.6), SIAB (Chapter 6, Section 1.5), and SPDP (Chapter 6, Section 1.1). Other hydrophilic heterobifunctional crosslinkers containing a discrete polyethylene glycol (PEG) spacer may be used in a similar manner, which may provide superior characteristics in many liposomal conjugate applications (Chapter 18, Section 1).

Activation of PE residues with these crosslinkers can proceed by one of two routes: the purified PE phospholipid may be modified in organic solvent prior to incorporation into a liposome, or an intact liposome containing PE may be activated while suspended in aqueous solution. Most often, the PE derivative is prepared before the liposome is constructed. In this way, a stable, stock preparation of modified PE may be made and used in a number of different liposomal recipes to determine the best formulation for the intended application. However, it may be desirable to modify PE after formation of the liposomal structures to ensure that only the outer half of the lipid bilayer is altered. This may be particularly important if substances to be entrapped within the liposome are sensitive or may react with the PE derivatives.

Crosslinkers used to activate PE should contain at least moderately long spacer arms. The length of the spacer is important in providing enough distance from the liposome surface to accommodate the binding of another macromolecule. Short activating reagents often restrict protein accessibility to approach close enough to react with the functional groups on the bilayer surface. For instance, direct modification of PE with iodoacetate results in little or no sulfhydryl-modified IgG coupled to the associated liposomes. However, when an aminoethylthioacetyl spacer is used to move the iodoacetyl group farther away from the bilayer surface, good IgG coupling occurs (Hashimoto *et al.*, 1986). The use of longer discrete PEG-based crosslinkers may enhance the coupling of proteins to liposome surfaces, because the extreme water-solubility of the spacer provides greater aqueous phase access to approaching proteins, whereas hydrophobic linkers may tend to bury themselves within the bilayer structure. To use the PEG-based crosslinker analogs to the aliphatic crosslinker types described in the following activation reactions, refer to the corresponding compounds in Chapter 18, Section 1, having the same reactive groups on both ends.

For the activation of PE prior to liposome formation, it is best to employ a highly purified form of the molecule. While egg PE is abundantly available, it consists of a range of fatty acid derivatives—many of which are unsaturated—and is highly susceptible to oxidation. Synthetic PE, by contrast, can be obtained having a discrete fatty acid composition and is much more stable to oxidative degradation.

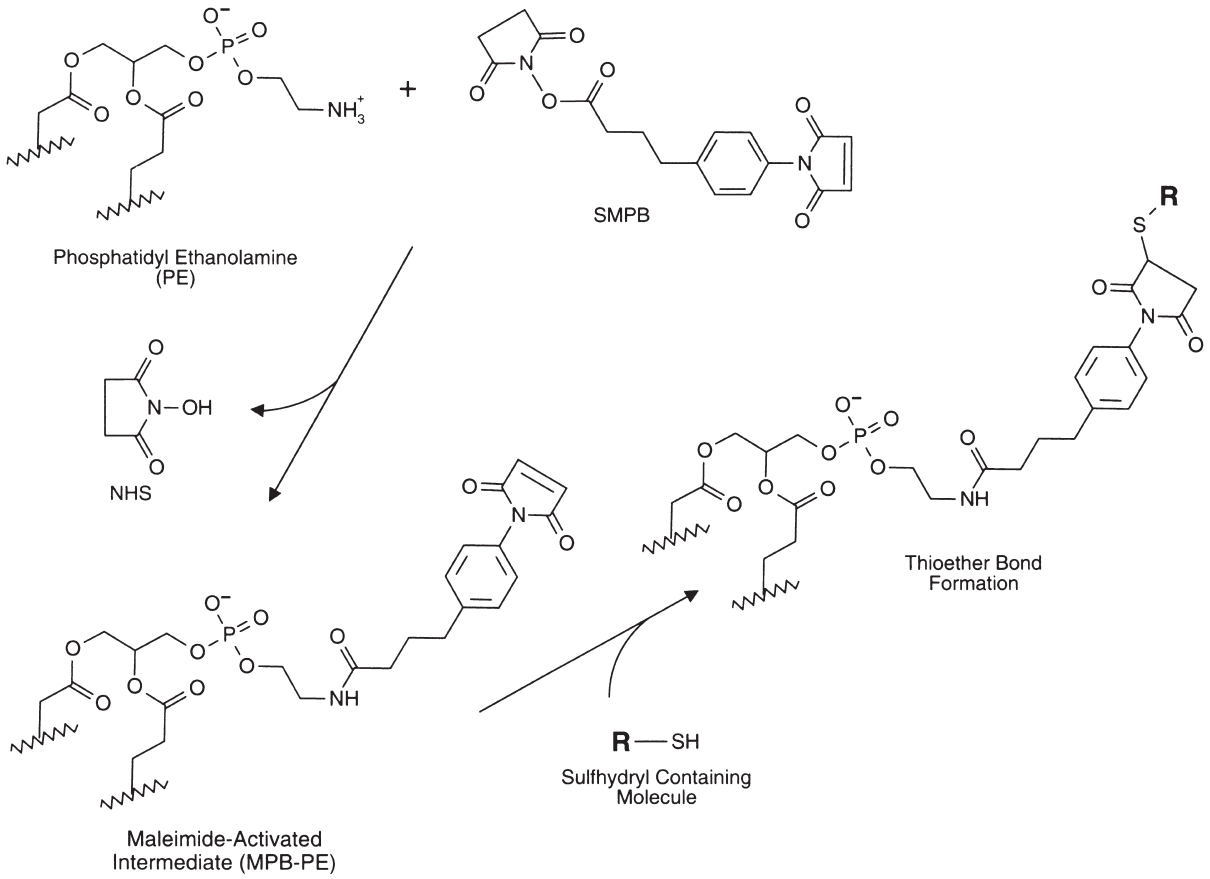

FIGURE 21.11 A sulfhydryl-reactive lipid derivative can be prepared through the reaction of SMPB with phosphatidyl ethanolamine (PE) to produce a maleimide-containing intermediate. Sulfhydryl-containing molecules may then be coupled to the modified phospholipid to form stable thioether linkages.

The following suggested protocols are modifications of those described by Martin and Papahadjopoulos (1982), Martin *et al.* (1990), and Hutchinson *et al.* (1989). Also see Sawant and Torchilin (2011) for a review of lipid-based bioconjugation methods. Although many methods were developed for use with SMPB, SPDP, and MBS, the same basic principles can be used to activate PE with any of the heterobifunctional crosslinkers mentioned above (Manjappa *et al.*, 2011). In addition, the use of hydrophilic NHS–PEG$_n$–maleimide compounds (Chapter 18, Section 1.2) may be a superior alternative to the use of crosslinkers with hydrophobic cross-bridges, as the PEG linkers will not dissolve as readily within the lipid bilayer structure. The reaction sequence for activation and coupling using SMPB is shown in Figure 21.11. The PE employed should be of a synthetic variety having fatty acid constituents of dimyristoyl-PE (DMPE), dipalmitoyl-PE (DPPE), or distearoyl-PE (DSPE) forms. For activation of pure PE, the heterobifunctional reagents should not be of the sulfo-NHS ester variety, since they are best used in aqueous reaction mediums and PE is activated under nonaqueous conditions. For activation of intact liposomes in aqueous suspension, then the sulfo-NHS variety of the crosslinkers may be the best choice, since they are very water soluble and relatively incapable of penetrating membranes, thus ensuring that only the outer surfaces of the vesicles will be modified. For PEG-based crosslinkers, typically only the NHS ester forms are available (not sulfo-NHS), but the reagents will perform well for activating PE derivatives within liposomes in aqueous solution.

Protocol for the Activation of DPPE with SMPB

1. Dissolve 100 µmoles of PE in 5 ml of argon-purged, anhydrous methanol containing 100 µmoles of triethylamine (TEA). Maintain the solution over an argon or nitrogen atmosphere. The reaction may also be performed in dry chloroform. Note: Methanol or chloroform and TEA should be handled in a fume hood.
2. Add 50 mg of SMPB (Thermo Fisher) to the PE solution. Mix well to dissolve.
3. React for 2 h at room temperature, while maintaining the solution under an argon or nitrogen atmosphere.

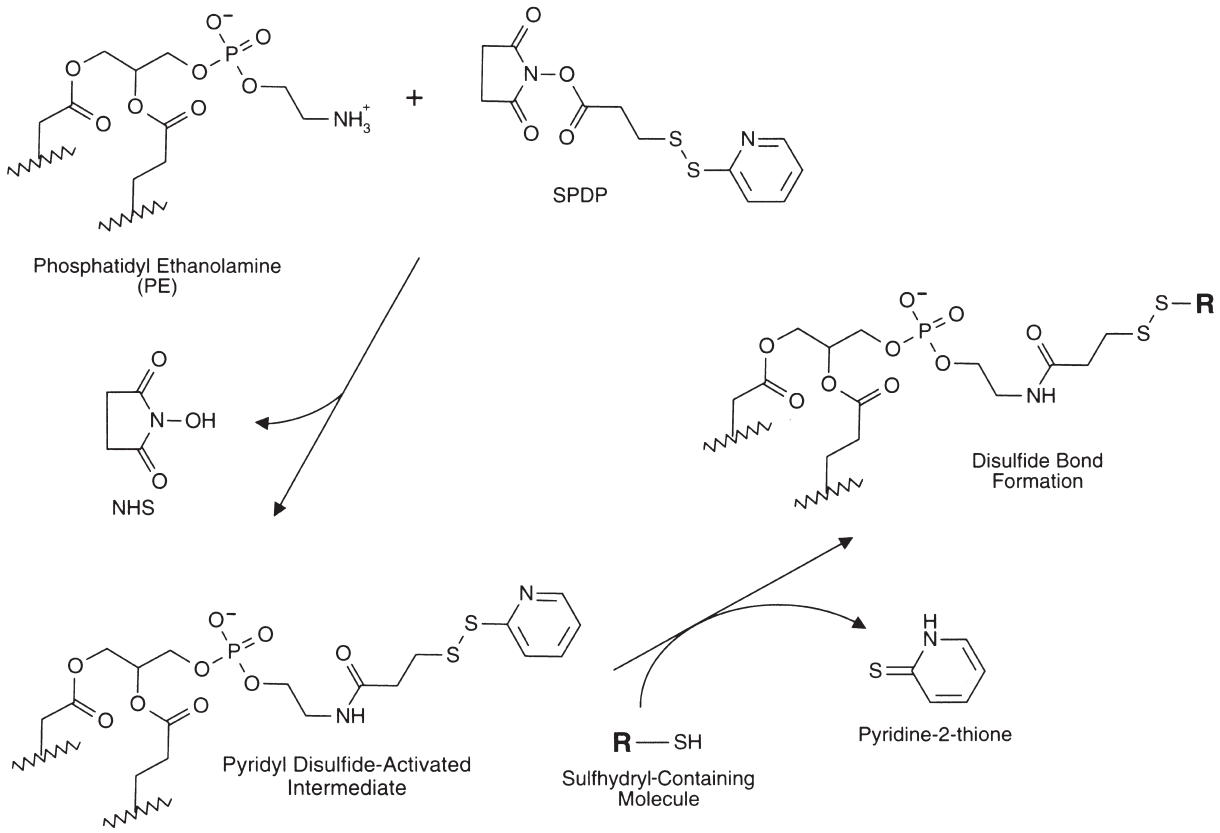

FIGURE 21.12 The reaction of SPDP with PE creates a maleimide derivative capable of coupling thiols. Reaction with a sulfhydryl-containing molecule forms a conjugate through a thioether linkage.

Reaction progress may be determined by thin-layer chromatography (TLC) using silica gel 60-F_{254} plates (Merck) and developed with a 65:25:4 (by volume) mixture of chloroform:methanol:water. The activated PE derivative will develop faster on TLC ($R_F = 0.52$ for MPB–PE) than the unmodified PE.

4. Remove the methanol from the reaction solution by rotary evaporation and redissolve the solids in chloroform (5 ml).
5. Extract the water soluble reaction byproducts from the chloroform with an equal volume of 1% NaCl. Extract twice.
6. Purify the MPB–PE derivative by chromatography on a column of silicic acid (Martin *et al.*, 1981). The following description is from Martin *et al.*, 1990. Add 2 g silicic acid to 10 ml of chloroform and pour the solution into a syringe barrel containing a plug of glass wool at the bottom. Apply the chloroform-dissolved lipids on the silicic acid column. Wash with 4 ml of chloroform, then elute with 4 ml each of the following series of chloroform:methanol mixtures: 4:0.25, 4:0.5, 4:0.75, and 4:1. During the chromatography, collect 2-ml fractions. The presence of purified MPB–PE may be monitored by TLC according to step 3.
7. Remove chloroform from the MBP–PE by rotary evaporation. Store the derivative at −20°C under a nitrogen atmosphere until use.

N-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) may also be used to activate pure PE lipids in a similar manner to SMPB. The result will be a derivative containing pyridyl disulfide groups rather than maleimide groups (Figure 21.12). Pyridyl disulfides react with sulfhydryls to form disulfide linkages. Either the standard SPDP or the long-chain version, LC-SPDP, may be employed in the following protocol.

Protocol for Activation of PE with SPDP

1. Dissolve 20 µmol of PE (15 mg) in 2 ml of argon-purged, anhydrous methanol containing 20 µmol of triethylamine (TEA; 2 mg). Maintain the solution over an argon or nitrogen atmosphere. The reaction may also be performed in dry chloroform. Note: Methanol or chloroform and TEA should be handled in a fume hood.
2. Add 30 µmol (10 mg) of SPDP (Thermo Fisher) to the PE solution. Mix well to dissolve.
3. React for 2 h at room temperature, while maintaining the solution under an argon atmosphere. Reaction

progress may be determined by thin-layer chromatography (TLC) using silica gel plates developed with a 65:25:4 (by volume) mixture of chloroform:methanol:water. The activated PE derivative (PDP–PE) will develop faster on TLC than the unmodified PE.

4. Remove the methanol from the reaction solution by rotary evaporation and re-dissolve the solids in chloroform (5 ml).
5. Extract the water soluble reaction by-products from the chloroform with an equal volume of 1% NaCl. Extract twice.
6. Purify the PDP–PE derivative by chromatography on a column of silicic acid (Martin *et al.*, 1981). The following description is from Martin *et al.* (1990). Add 2 g silicic acid to 10 ml of chloroform and pour the solution into a syringe barrel containing a plug of glass wool at the bottom. Apply the chloroform-dissolved lipids on the silicic acid column. Wash with 4 ml of chloroform, then elute with 4 ml each of the following series of chloroform:methanol mixtures: 4:0.25, 4:0.5, 4:0.75, and 4:1. During the chromatography, collect 2 ml fractions. The presence of purified PDP–PE may be monitored by TLC according to step 3.
7. Remove chloroform from the PDP–PE by rotary evaporation. Store the derivative at −20°C under a nitrogen atmosphere until use.

Other heterobifunctional reagents containing an NHS ester end can be used to activate PE in a similar manner to those protocols described above. A somewhat abbreviated protocol (eliminating the silicic acid chromatography step) for the activation of DPPE with MBS (Chapter 6, Section 1.4), as adapted from Hutchinson *et al.* (1989), follows. The NHS ester of MBS reacts with PE's free amine group to create an amide bond. The maleimide end of the crosslinker then remains available for subsequent conjugation with a sulfhydryl-containing molecule after liposome formation (Figure 21.13).

Protocol for the Activation of DPPE with MBS

1. Dissolve 40 mg of DPPE in a mixture of 16 ml dry chloroform and 2 ml dry methanol containing 20 mg triethylamine. Maintain under nitrogen to prevent lipid oxidation.
2. Add 20 mg of MBS to the lipid solution and mix to dissolve.
3. React for 24 hours at room temperature under nitrogen.

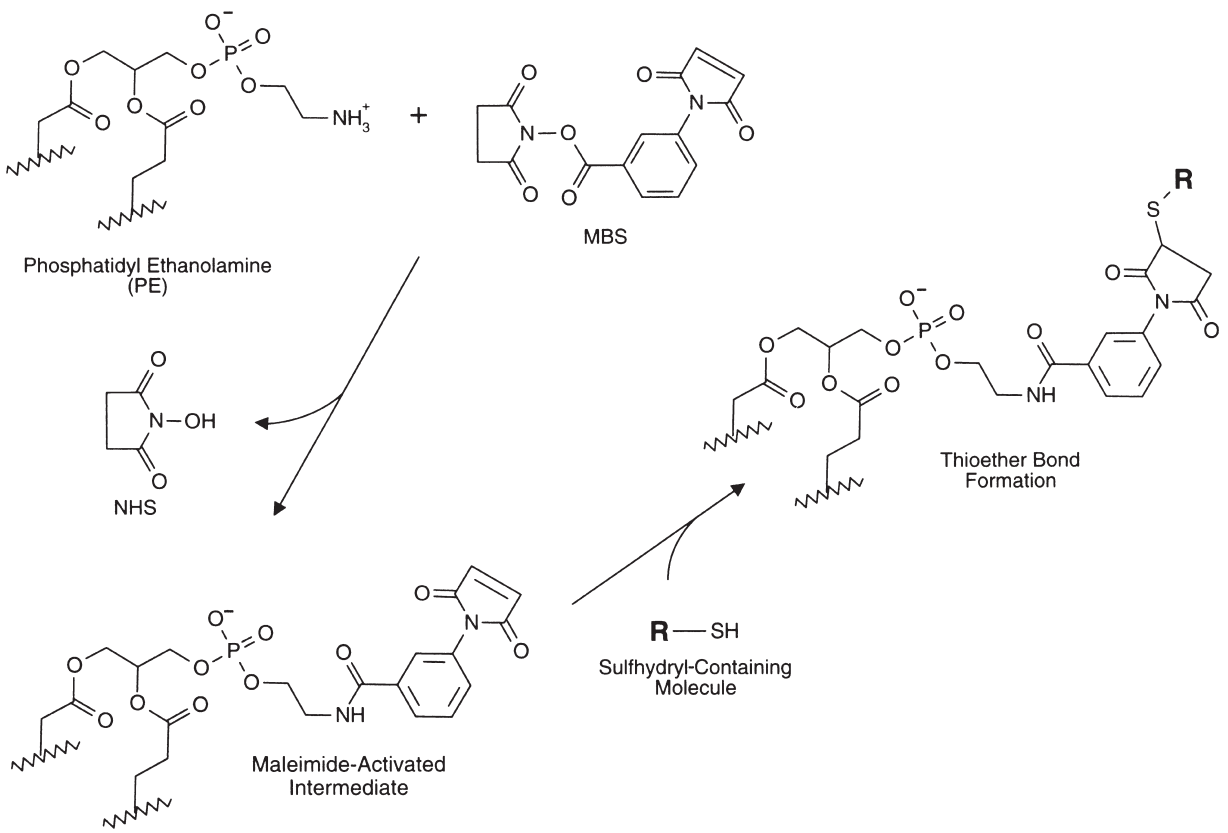

FIGURE 21.13 MBS reacted with PE produces a maleimide derivative that can couple to thiol compounds through a stable thioether bond.

4. Wash the organic phase three times with PBS, pH 7.3, to extract excess crosslinker and reaction by-products.
5. Remove the organic solvents by rotary evaporation under vacuum.
6. Analyze the MBS–DPPE derivative by TLC using a silica plate and developing with a solvent mix containing chloroform:methanol:glacial acetic acid in the volume ratio of 65:25:13. The R_f value of underivatized DPPE is 0.56, while that of the MBS–DPPE product is R_f 0.78.

The MBS–DPPE derivative can be stored dry under a nitrogen blanket at 4°C or dissolved in chloroform: methanol (9:1, v/v) under the same conditions.

If intact liposomes containing PE are to be activated with these crosslinkers, the methods employed are similar to those used to modify proteins and other macromolecules in aqueous solution. The following protocol is a generalized version for the activation of liposomes containing PE with SPDP (Figure 21.14).

Protocol for the Activation of Liposomes with SPDP

1. Prepare a 5 mg/ml liposome suspension in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, containing, for example, a mixture of PC:cholesterol:PG:PE at molar ratios of 8:10:1:1. Other lipid recipes may be used as long as they contain about this percentage of PE. In addition, if this level of cholesterol is maintained in the liposome, then the integrity of the bilayer will be stable up to a level of organic solvent addition of about 5%. This factor is important for adding an aliquot of the crosslinker to the liposome suspension as a concentrated stock solution in an organic solvent. Dispersion of the liposomes to the desired size and morphology may be performed by any common method (see Section 1.2, this chapter).
2. Dissolve SPDP (Thermo Fisher) at a concentration of 6.2 mg/ml in dimethylformamide (DMF) (makes a 20-m*M* stock solution). Alternatively, LC-SPDP may be used and dissolved at a concentration of 8.5 mg/ml in DMF (also makes a 20-m*M* solution). If the water soluble sulfo-LC-SPDP is used, a stock solution in water may be prepared just prior to adding an aliquot to the reaction. The sulfo-NHS form of the crosslinker contains a negatively charged sulfonate group which prevents the reagent from penetrating lipid bilayers. Thus, only the outer surfaces of the liposomes can be activated using sulfo-LC-SPDP. If this is desirable, prepare a 10-m*M* solution of sulfo-LC-SPDP by dissolving 5.2 mg/ml in water. Since an aqueous solution of the crosslinker will degrade by hydrolysis of the sulfo-NHS ester, it should be used quickly to prevent significant loss of activity. If a sufficiently large amount of liposomes will be modified, the solid sulfo-LC-SPDP may be added directly to the reaction mixture without preparing a stock solution in water.
3. Add 25 to 50 µl of the stock solution of either SPDP or LC-SPDP in DMF to each ml of the liposome suspension to be modified. If sulfo-LC-SPDP is used, add 50 to 100 µl of the stock solution in water to each ml of liposome suspension.
4. Mix and react for at least 30 min at room temperature. Longer reaction times, even overnight, will not adversely affect the modification.
5. Purify the modified liposomes from reaction byproducts by dialysis or gel filtration using a column of Sephadex G-50.

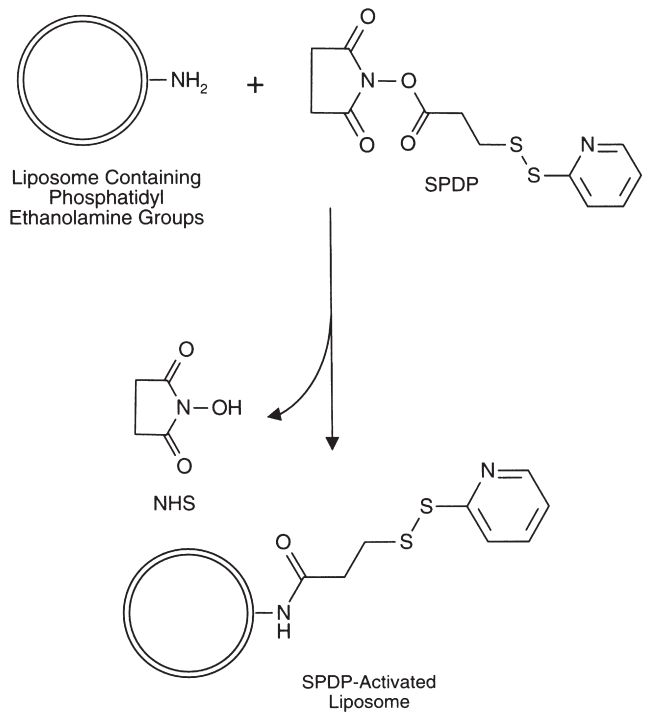

FIGURE 21.14 Intact liposomes containing PE components may be modified with SPDP to produce thiol reactive derivatives.

The SPDP-activated liposomes may be used immediately to couple with sulfhydryl-containing molecules such as proteins (see Section 7.7, this chapter), or they may be stored in a lyophilized state in the presence of sorbitol (Friede *et al.*, 1993) for later use.

3. USE OF GLYCOLIPIDS AND LECTINS TO EFFECT SPECIFIC CONJUGATIONS

Glycolipids are carbohydrate-containing molecules, usually of sphingosine derivation, possessing a hydrophobic, fatty acid tail that embeds them into membrane bilayers. The hydrophilic carbohydrate ends of these

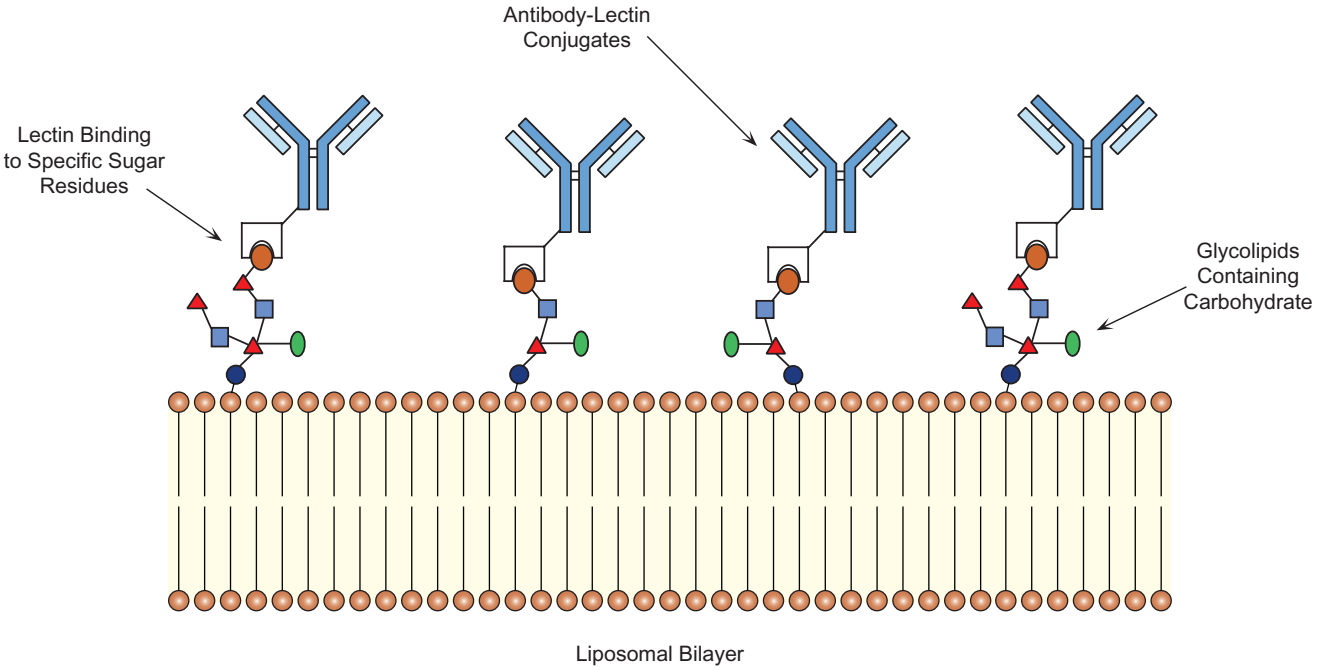

FIGURE 21.15 Glycolipids included in liposome construction may be used to couple antibody molecules by using conjugates of lectins with the proper specificity for binding the sugar groups.

amphipathic molecules orient toward the outer aqueous phase, protruding from the bilayer surface, and thus having the capability to interact with molecules dissolved in the surrounding environment. Sphingosine glycolipids may consist of the simple glucosylcerebroside molecules (containing a single glucose residue), lactosylceramide (containing up to four glucose and galactose residues), or complex gangliosides (containing elaborate oligosaccharides that may approach the complexity of those carbohydrate "trees" found on glycoproteins). In membranes of biological origin, glycoconjugates provide sites of cellular recognition for the binding or attachment of proteins and other molecules that possess binding sites able to interact with the particular saccharides present. Such proteins, called lectins, recognize unique sugars or polysaccharide sequences within the carbohydrates of glycoconjugates.

Liposomes partially constructed of glycolipids of known carbohydrate content may be targeted by lectin molecules possessing the requisite binding properties. The liposome may be labeled in this manner with a lectin conjugate, wherein the lectin possesses another molecule covalently attached to it having secondary detection or recognition properties. For instance, a liposome containing a glycolipid may be modified by a lectin–antibody complex, producing a conjugated antibody for specific antigen-targeting applications (Figure 21.15). In addition, since lectins are typically multivalent in character, having more than one binding site for a particular carbohydrate type, they can act as multifunctional crosslinking agents to agglutinate cells or liposomes containing the proper saccharide receptors.

The advantage of this approach to liposome conjugation is that the linkage between the lectin complex and the membrane bilayer is noncovalent and reversible. The addition of a saccharide containing the proper sequence or sugar type recognized by the lectin breaks the binding and releases the attached molecules. This property can be a significant disadvantage too, if stable linkages are desired.

Carbohydrate residues on the surface of liposomes may be used to bind selected receptor molecules on cell surfaces. This approach can provide a targeting ability for the vesicles *in vivo*, delivering drugs or toxic agents to intended cellular destinations (for review, see Leserman and Machy, 1987). Lectins may also be covalently conjugated to liposome surfaces to provide targeting capability toward cells or molecules containing the complementary carbohydrate needed for binding.

4. ANTIGEN OR HAPTEN CONJUGATION TO LIPOSOMES

Liposomes exert an adjuvant effect *in vivo*, and thus they may be used as carrier systems in the generation of a specific immune response directed against associated antigen or hapten molecules (Heath *et al.*, 1976). Since the main targets of liposomes are the

reticulo-endothelial system, particularly macrophages, they naturally associate with the very cells important for mediating humoral immunity. The antigenicity of a liposomal vesicle is to a large degree determined by its overall composition. Its morphology, phospholipid composition, charge, and any attached functional groups all affect the resultant antibody response (Allison and Gregoriadis, 1974; Alving, 1987; Therien and Shahum, 1989).

For instance, incorporation of beef sphingomyelin instead of egg lecithin into liposomal antigen-carrier systems can increase the antibody response to the associated antigen (Yasuda *et al.*, 1977). Liposomal recipes using immune modulators such as lipid A (0.8 nmole of lipid A per μmol of phospholipid) or attaching muramyl dipeptide to the surface of the bilayer can also stimulate the immune response (Daemen *et al.*, 1989). In addition, the fatty acid composition of the phospholipid components can dramatically affect liposome immunogenicity. In general, the higher the transition temperature of the associated phospholipids, the greater will be the immune response to the liposome. Thus, the relative order of immunogenicity related to fatty acid composition is: distearoyl > dipalmitoyl > dimyristoyl. It is also possible that the presence of a positive charge on the bilayer surface may increase the resultant immune response (Domen *et al.*, 1987; Muckerheide *et al.*, 1987b; Apple *et al.*, 1988; Domen and Hermanson, 1992).

Two methods may be used to make immunogenic antigen–liposome or hapten–liposome complexes: (1) the molecule may be dissolved in solution and encapsulated within the vesicle construction; or (2) it may be covalently coupled to the phospholipid constituents using standard crosslinking reactions (Shek and Sabiston, 1982a,b). If the antigen molecules are not chemically coupled to the liposome, then they must be entrapped within them to effect an enhancement of the antibody response. If antigen is simply mixed with preformed liposomal vesicles, then there is no beneficial modulation of immunogenicity (Therien and Shahum, 1989). Encapsulation of soluble or particulate vaccines into giant liposomes provides a means of extending the half-life of the vaccine molecules *in vivo* and potentiating the immune response toward the vaccine (Antimisiaris *et al.*, 1993).

When haptens or antigens are covalently attached to liposomes, it is typically performed through the head groups using various phospholipid derivatives and crosslinking reagents as described previously (Derksen and Scherphof, 1985). Usually, these derivatization reactions are performed using PE constituents within the liposomal mixture. The primary amine on PE molecules provides an ideal functional group for activation and subsequent coupling of hapten molecules (Shek and Heath, 1983). All of the amine-reactive activation methods discussed in this section using heterobifunctional crosslinkers may be used with PE containing liposomes to prepare immunogen conjugates. In addition, the crosslinking methods in Chapter 19, dealing specifically with hapten–carrier conjugation, should be consulted for potential use with liposomes.

The following protocols provide suggested crosslinking strategies for producing an antigen or hapten complex with liposomes. The first procedure is a simple encapsulation of antigen molecules. The second method involves the coupling of a sulfhydryl-containing peptide hapten to a liposome that had been previously activated with SMPB (Figure 21.16) (see Section 2, this chapter). They are based on the methods of Van Regenmortel *et al.* (1988).

Protocol for the Encapsulation of Antigen into Liposomal Vesicles

1. Prepare a homogeneous lipid mixture by dissolving the desired components in chloroform. A suggested recipe may be to use a mixture of DPPC:DPPG:cholesterol at a molar ratio of 7.5:2.5:5. Evaporate the chloroform using a rotary evaporator under vacuum. Maintain lipids under nitrogen or argon to prevent air oxidation.
2. Dissolve the hapten or antigen to be encapsulated at a concentration of 21 μmol/ml in degassed, nitrogen-purged 10-m*M* HEPES, 0.15-*M* NaCl, pH 6.5.
3. Create liposomal vesicles using any established method (see Section 1, this chapter) by mixing the antigen solution with the lipid mixture to obtain a final concentration of 5 mg/ml lipid in the aqueous buffer. A suggested procedure may be to redissolve the lipids in a minimum quantity of diethyl ether, and then mix the buffer with the ether phase at a ratio necessary to give a 5 mg/ml concentration of lipid in the buffer. Use sonication to emulsify the liposomal preparation. Remove diethyl ether by vacuum evaporation. Periodically mix by vortexing to maintain a homogeneous suspension of liposomes.
4. Remove free antigen from encapsulated antigen by gel filtration using a column of Sephadex G-75 or by dialysis using 10-m*M* HEPES, 0.15-*M* NaCl, pH 6.5. Store the liposome preparation under an inert gas at 4°C in the dark until use.

Protocol for the Coupling of Peptide Haptens Containing Sulfhydryl Groups to Liposomal Vesicles

1. Prepare a homogeneous lipid mixture by dissolving in chloroform a mixture of DPPC:DPPG:cholesterol:MPB-DPPE at a mole ratio of 6.3:2.12:4.25:1.5. Preparation of MPB-activated DPPE can be found in Section 2, this chapter.

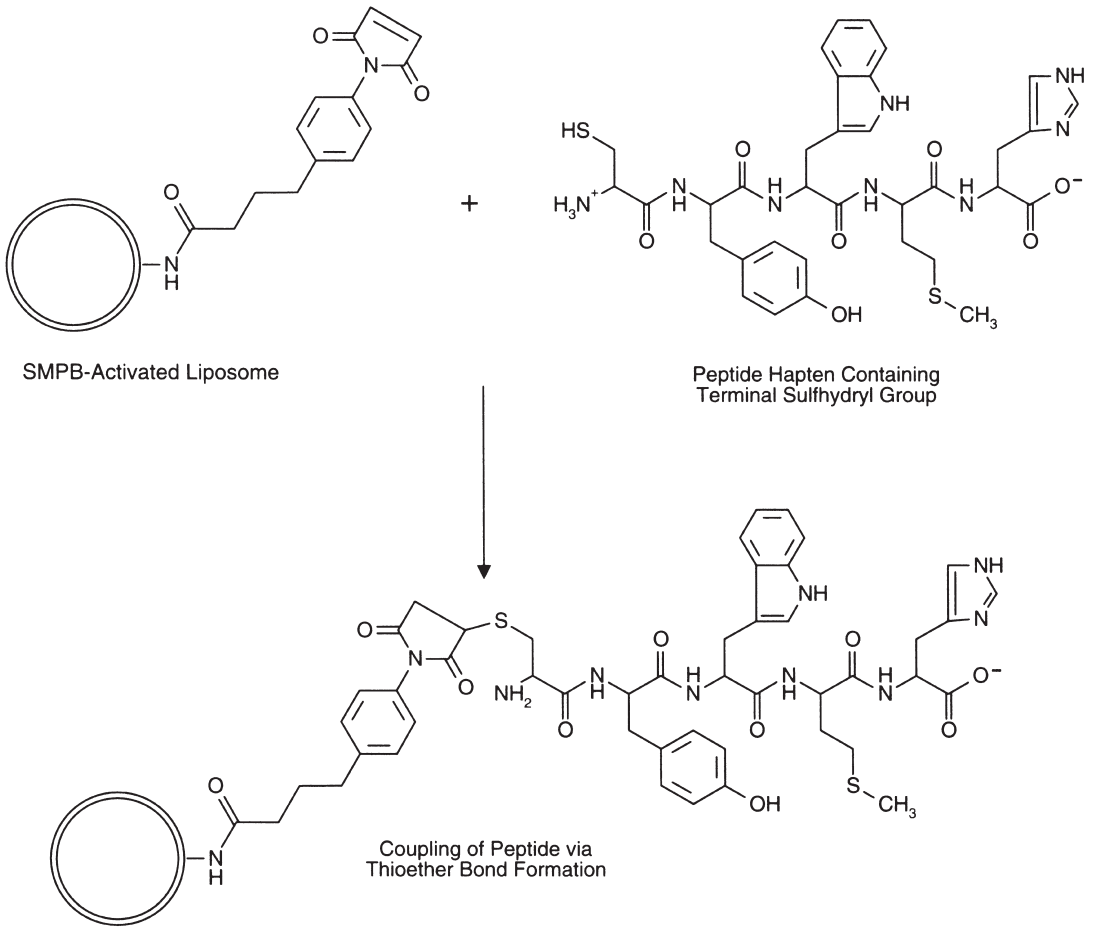

FIGURE 21.16 SMPB-activated liposomes may be modified with peptide hapten molecules containing cysteine thiol groups. The resultant immunogen may be used for immunization purposes to generate an antibody response against the coupled peptide.

Maintain all solutions under nitrogen or argon. The lipid derivative provides reactive maleimide groups for the coupling of sulfhydryl-containing molecules. Evaporate the chloroform using a rotary evaporator under vacuum.

2. Create liposomal vesicles using any established method (see Section 1, this chapter) by mixing the lipid mixture with degassed, nitrogen-purged 10-m*M* HEPES, 0.15-*M* NaCl, pH 7.0, to obtain a final concentration of 5 mg/ml lipid in the aqueous buffer. Use sonication to emulsify the liposomal preparation. Remove diethyl ether by vacuum evaporation. Periodically mix by vortexing to maintain a homogeneous suspension of liposomes.
3. Dissolve a sulfhydryl-containing peptide hapten at a concentration of 25 µmole/ml in degassed, nitrogen-purged 10-m*M* HEPES, 0.15-*M* NaCl, pH 7.0. Add the peptide solution to the liposome suspension at a molar ratio necessary to obtain at least a 5:1 excess of thiol groups to the amount of maleimide groups present (as MPB-DPPE).
4. React overnight at room temperature. Maintain an inert-gas blanket over the vessel to prevent lipid oxidation.
5. Purify the derivatized liposomes from excess peptide by gel filtration using a column of Sephadex G-75 or by dialysis. Store the immunogenic vesicles at 4°C under nitrogen or argon and protected from light until use.

5. PREPARATION OF ANTIBODY–LIPOSOME CONJUGATES

Covalent attachment of antibody molecules to liposomes can provide a targeting capacity to the vesicle that can modulate its binding to specific antigenic determinants on cells or to molecules in solution. Antibody-bearing liposomes may possess encapsulated components that can be used for detection or therapy (Figure 21.17). For instance, fluorescent molecules encapsulated within antibody-targeted vesicles

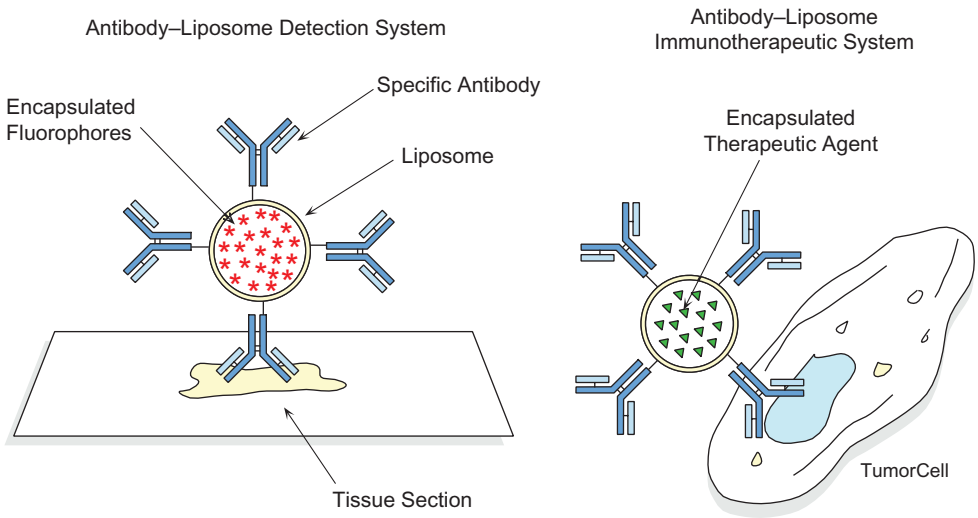

FIGURE 21.17 Antibody–liposome conjugates can be used as targeting reagents for detection or therapeutic applications. The liposome may be constructed to contain fluorescent molecules for detection purposes or bioactive agents for therapy. The coupled antibody creates the targeting component on the complex for binding to specific antigenic determinants.

can be used as imaging tools or in flow cytometry (Truneh *et al.*, 1987). Specific antibodies coupled to the vesicle surface can improve diagnostic assays involving agglutination of latex particles (Kung *et al.*, 1985). Liposomes possessing antibodies directed against tumor cell antigens can deliver encapsulated toxins or drugs to the associated cancer cells, effecting toxicity and cell death (Heath *et al.*, 1983, 1984; Matthay *et al.*, 1984; Straubinger *et al.*, 1988; Kirpotin *et al.*, 2012; Tong *et al.*, 2012).

Encapsulation of chemotherapeutic agents within lipid bilayers reduces systemic toxicity and local irritation often caused by anticancer drugs (Gabizon *et al.*, 1986; Crielaard *et al.*, 2012). The liposomal membrane acts as a slow-release agent so that cytotoxic components do not come into contact with non-tumor cells. Liposome binding to cells causes internalization and release of the encapsulated drugs. Antibody targeting can increase the likelihood of vesicle binding to the desired tumor cells.

However, there are problems associated with the use of antibody–liposome conjugates for drug delivery *in vivo*. Particularly, since lipid vesicles are huge compared to similar immunotoxin conjugates (Chapter 20, Section 3), their passage to particular tissue destinations may be difficult or impossible. Liposomes are almost entirely limited to the reticuloendothelial system. Their ability to pass through tissue barriers to target cells in other parts of the body is limited by their size. If liposomal conjugates can reach their intended destination, their contents are delivered to the cells by endocytosis. Endocytic vesicles arising from the surface of cells have diameters in the range of 1000 to 1500 Å. This limits the size of liposomes that can be used to small vesicles that can bind to the surface of a cell and be internalized efficiently. Large liposomes, by contrast, will not be internalized and therefore not be able to deliver their contents (Leserman and Machy, 1987).

The methods for coupling antibody molecules to liposomal surfaces are not unlike those described for general protein coupling (Section 7, this chapter), below. Antibodies may be coupled through sulfhydryl residues using liposomes containing PE groups that are derivatized with heterobifunctional crosslinkers such as SMCC (Chapter 6, Section 1.3), MBS (Chapter 6, Section 1.4), SMPB (Chapter 6, Section 1.6), SIAB (Chapter 6, Section 1.5), SPDP (Chapter 6, Section 1.1), and heterobifunctional PEG-based crosslinkers (Chapter 18, Section 1.2). They may also be coupled through their amine groups using reductive amination to periodate-oxidized glycolipids (Sections 2 and 7.6, this chapter).

6. PREPARATION OF BIOTINYLATED OR (STREPT)AVIDIN-CONJUGATED LIPOSOMES

Liposome conjugates may be used in various immunoassay procedures. The lipid vesicle can provide a multivalent surface to accommodate numerous antigen–antibody interactions and thus increase the sensitivity of an assay. At the same time, it can function as a vessel to carry encapsulated detection components needed for the assay system. This type of enzyme-linked immunosorbent assay (ELISA) is called a

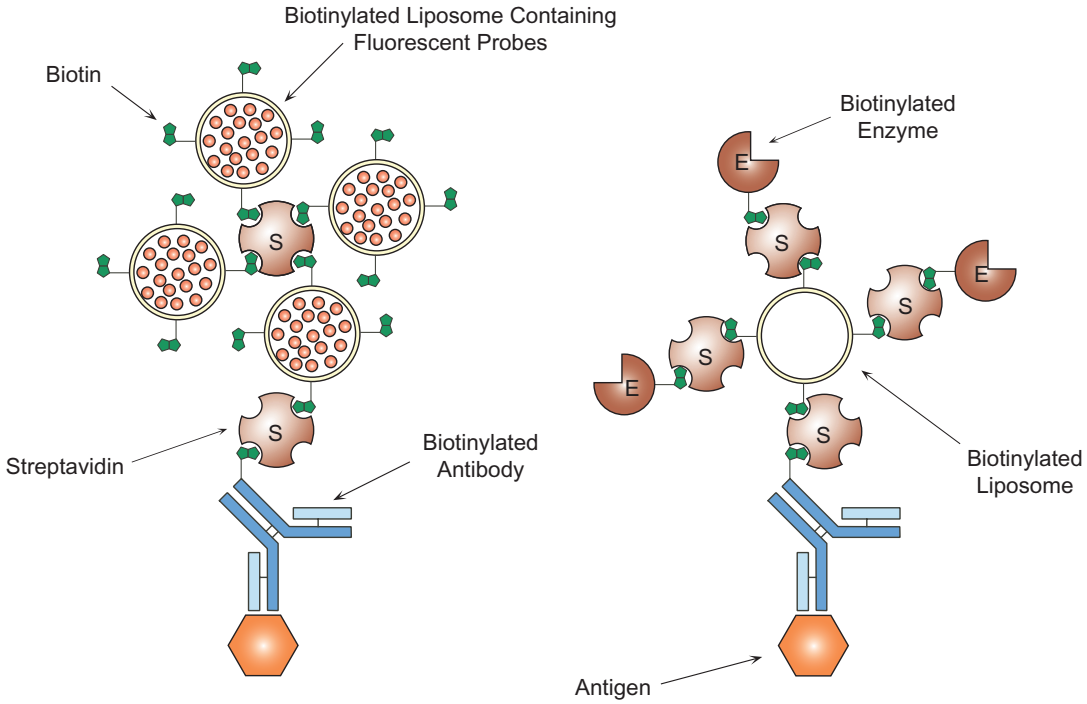

FIGURE 21.18 Biotinylated liposomes can be used in immunoassay systems to enhance the signal for detection or measurement of specific analytes. The liposome components may be constructed to include encapsulated fluorescent molecules to facilitate detection of antigens within tissue sections.

liposome immunosorbent assay or LISA. One method of using liposomes in an immunoassay is to modify the surface so that it can interact to form biotin–avidin or biotin–streptavidin complexes. The avidin–biotin interaction can be used to increase detectability or sensitivity in immunoassay tests (Chapter 11) (Savage *et al.*, 1992).

Liposomes containing biotinylated phospholipid components can be used in a bridging assay system with avidin and a biotinylated antibody molecule, creating large multivalent complexes able to bind antigen (Plant *et al.*, 1989) (Figure 21.18). The inside of the vesicles may contain fluorescent detection reagents that can be used to localize or quantify target analytes. One small liposome provides up to 10^5 molecules of fluorophore to allow excellent detectability of a binding event. LISA systems using biotinylated liposomes to detect antigen molecules can increase the sensitivity of an immunoassay up to 100-fold over that obtainable using traditional antibody–enzyme ELISAs.

Biotin–liposome conjugates are being used to target tumor cells and bring encapsulated drugs to the site of cancer cells for enhanced tumor accumulation of biotherapeutic agents. Soininen *et al.* (2012) studied the biodistribution of biotinylated doxorubicin bound to biotinylated liposomes using the avidin–biotin interaction. In addition, biotinylated liposomes can be used to target the lymphatic system for extended lymph node retention (Cai *et al.*, 2011).

Biotinylated liposomes are usually created by modification of PE components with an amine-reactive biotin derivative, for example the use of the popular reagent NHS–LC-Biotin (Chapter 11, Section 6.2). The NHS ester end of this compound reacts with the primary amine on PE residues, forming an amide bond linkage (Figure 21.19). However, since many of the traditional biotinylation reagents contain hydrophobic spacers, their use with amphipathic liposomal constructions may not be optimal. Hydrophobic spacers may have a tendency to dissolve into the lipid bilayer, thus decreasing their accessibility to the aqueous phase. A better choice of biotinylation agent may be to use one of the NHS–PEG$_n$–biotin compounds (Chapter 18, Section 1.3), because their hydrophilic PEG spacers provide better binding potential toward (strept)avidin conjugates than does a hydrophobic biotin spacer. A hydrophilic PEG-based biotin compound creates a water soluble biotin modification on the outer aqueous surface of the liposome bilayer. In addition, since the modification occurs at the hydrophilic end of the phospholipid molecule, after vesicle formation the biotin component can protrude out from the liposomal surface with high freedom of motion. In this configuration, the surface-immobilized

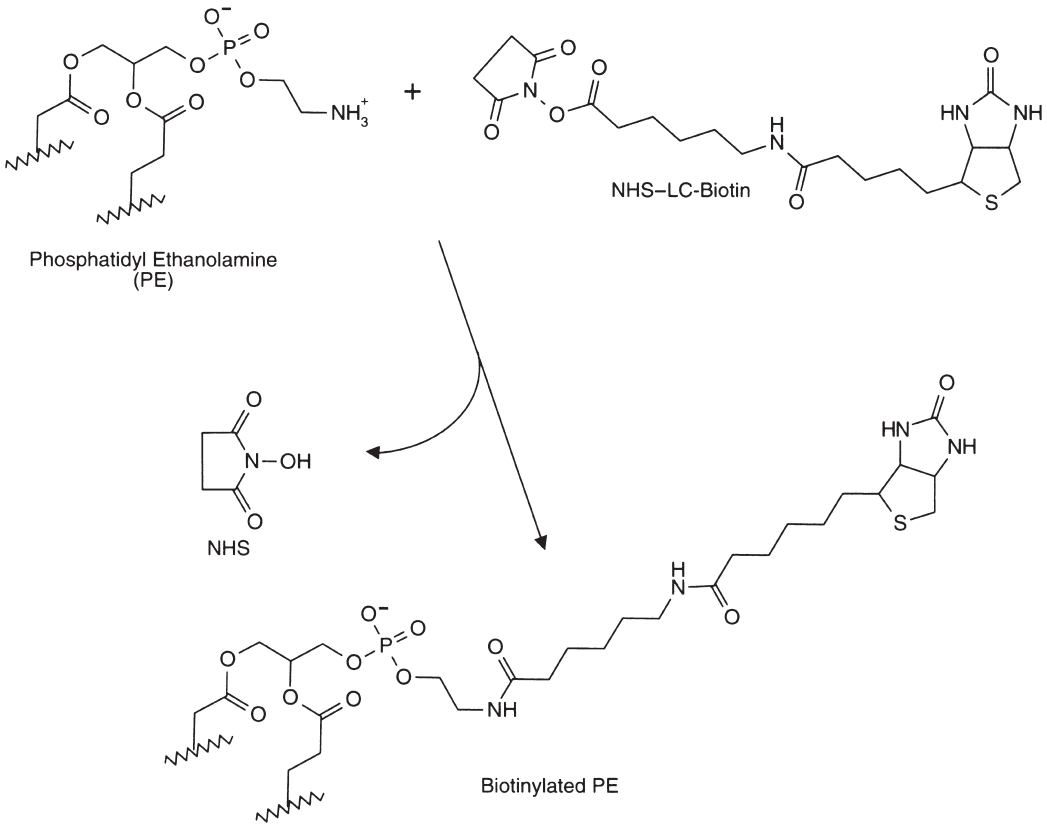

FIGURE 21.19 Biotinylated liposomes may be formed using biotinylated PE. Reaction of NHS–LC-biotin with the amine group of PE will result in an amide bond linkage with a long spacer arm terminating in a biotin group.

biotins are able to efficiently bind (strept)avidin-containing reagents added to the outer aqueous environment.

Biotinylation may be performed before or after liposome formation, but having a stock supply of biotin-modified PE is an advantage, since it can then be used to test a number of liposomal recipes. In addition, only a very small percentage of the total lipid should be biotinylated to prevent avidin-induced aggregation in the absence of antigen. It is difficult to precisely control the biotin content if direct biotinylation of intact liposomes is performed. Using pure biotinylated phospholipid allows incorporation of measured amounts of biotin binding sites into the final liposomal membrane. The preparation of biotinylated PE (B-PE) can be performed similarly to the methods described for activation of PE with SMPB (Section 2, this chapter) or it may be obtained commercially.

The following method for the formation of a biotinylated liposome is adapted from Plant *et al.* (1989). It assumes prior production of B-PE.

Protocol

1. Prepare a biotinylated liposome construct by first dissolving in chloroform, the lipids DMPC:cholesterol:dicetylphosphate (Sigma) at mole ratios of 5:4:1, and adding to this solution 0.1 mol% B-PE. Larger mole ratios of B-PE to total lipid may result in nonspecific aggregation of liposomes in the presence of (strept)avidin. Maintain all lipids under an inert atmosphere to prevent oxidation.
2. Evaporate 2 µmol of total homogenized lipid in chloroform using a stream of nitrogen or a rotary vacuum evaporator.
3. Re-dissolve the dried lipid in 50 µ of dry isopropanol.
4. Take the lipid solution up into a syringe and inject it into 1 ml of degassed, nitrogen-purged 20-m*M* Tris, 0.15-*M* NaCl, pH 7.4, which is being vigorously stirred using a vortex mixer. To encapsulate a fluorescent dye using this procedure, include 100-m*M* 5,6-carboxyfluorescein (or another suitable fluorophore) in the buffer solution before adding the lipids. The fluorescent probe used in the encapsulation procedure should be chemically nonreactive so that no lipid components are covalently modified during the process.

The biotinylated liposomes prepared by this procedure may be stored under an inert-gas atmosphere at 4°C for long periods without degradation.

7. CONJUGATION OF PROTEINS TO LIPOSOMES

Covalent attachment of proteins to the surface of liposomal bilayers is performed through reactive sites created on the head groups of phospholipids with the intermediary use of a crosslinker or other activating agent. The lipid functional groups described in Section 1 of this chapter are modified according to the methods discussed in Section 2 to be reactive toward specific target groups in proteins. Conjugation of liposomes with proteins may be performed with homobifunctional or heterobifunctional crosslinking reagents, carbodiimides, reductive amination, by NHS ester activation of carboxylates, or through the noncovalent use of the avidin–biotin interaction.

Characterizing the resultant complex for the amount of protein per liposome is somewhat more difficult than in other protein conjugation applications. The protein–liposome composition is highly dependent on the size of each liposomal particle, the amount of protein charged to the reaction, and the mole quantity of reactive lipid present in the bilayer construction. An approach to solving this problem is presented by Hutchinson *et al.* (1989). In analyzing at least 17 different protein–liposome preparations, the ratio of protein:lipid content (μg protein/μg lipid) in most of the complexes ranged from a low of about 4 to as much as 675. In some instances, however, up to 6000 molecules of a particular protein could be incorporated into each liposome.

Coupling of protein molecules to liposomes may occasionally induce vesicle aggregation. This may be due to the unique properties or concentration of the protein used, or it may be a result of liposome-to-liposome crosslinking during the conjugation process. Adjusting the amount of protein charged to the reaction as well as the relative amounts of crosslinking reagents employed may have to be performed to solve an aggregation problem.

The following sections will present suggested protocols for creating protein-bearing liposomes. Each method utilizes specific lipid modifications to form reactive groups capable of targeting amines, sulfhydryls, aldehydes, or carboxylates on the protein molecules.

7.1. Coupling via the NHS Ester of Palmitic Acid

Huang *et al.* (1980) coupled monoclonal antibodies to liposomes using an NHS ester modification of palmitic acid incorporated into the bilayer construction (Lapidot *et al.*, 1967). The NHS ester reacts with amine groups on the protein molecule, producing stable amide bond linkages (Figure 21.20). The specificity of the antibody-bearing liposomes for mouse L-929 cells was documented, illustrating the preservation of antibody binding activity.

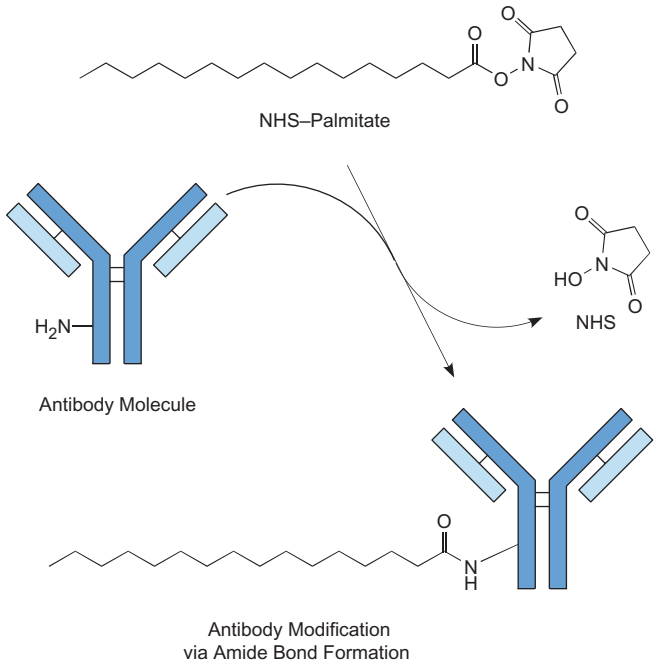

FIGURE 21.20 The NHS ester derivative of palmitic acid can be used to couple antibody molecules through amide bonds. These complexes then may be incorporated into liposomes.

Protocol

(A) PREPARATION OF NHS-PALMITATE

1. Dissolve 3.45 mg of *N*-hydroxysuccinimide (NHS) in 30 ml dry ethyl acetate.
2. Add 30 mMol of palmitic acid to the NHS solution. Maintain a nitrogen blanket over the solution.
3. Dissolve 6.18 gm of dicyclohexyl carbodiimide (DCC; Chapter 4, Section 1.4) in 10 ml of ethyl acetate and add it to the NHS/palmitic acid solution.
4. React overnight at room temperature under a nitrogen blanket.
5. Remove the insoluble dicyclohexyl urea (DCU) byproduct by filtration using a glass-fiber filter pad and vacuum.
6. Remove solvent from the filtered solution by using a rotary evaporator under vacuum.
7. The NHS–palmitate may be purified by recrystallization using ethanol. Dissolve the activated fatty acid in a minimum quantity of hot ethanol. Immediately upon dissolving, filter it through a filter funnel containing a fluted glass-fiber filter pad, both of which have been warmed to the same temperature as the ethanol solution. Allow the NHS–palmitate to recrystallize overnight at room temperature. Remove solvent from the recrystallized solid by filtration. Dry under vacuum in a desiccator.

8. Analyze the NHS–palmitate for purity using TLC on silica plates. Develop the chromatography using a solvent mixture of chloroform:petroleum diethyl ether (bp 40–60°C) of 8:2. Excess NHS and NHS–palmitate may be detected by staining with 10% hydroxylamine in 0.1-*N* NaOH, followed after 2 min by a 5% solution of $FeCl_3$ in 1.2-*N* HCl (creates red-colored spots).

(B) COUPLING OF PROTEIN TO NHS-PALMITATE

1. Add 2 mg of protein to 44 µg NHS–palmitate in 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, containing 2% deoxycholate.
2. Incubate at 37°C for 10 h.
3. Remove excess palmitic acid by chromatography on a column of Sephadex G-75. Use PBS, pH 7.4, containing 0.15% deoxycholate to perform the gel filtration. Collect the fractions containing derivatized protein, as monitored by absorbance at 280 nm.

(C) ADDITION OF PROTEIN–PALMITATE CONJUGATE TO LIPOSOMAL MEMBRANES

Since the protein–palmitate derivative cannot be dissolved in organic solvent during homogenization of lipid to form liposomal membranes, it must be inserted into intact liposomes by detergent dialysis.

1. Construct a liposome by dissolving the desired lipids in chloroform to fully homogenize the mixture, drying them to remove solvent, and using any established method of forming bilayer vesicles in aqueous solution (e.g., sonication; see Section 1.2, this chapter).
2. Add protein–palmitate conjugate to the formed liposomes in a ratio of 20:1 (w/w). Add concentrated deoxycholate to give a final concentration of 0.7%. Mix thoroughly using a vortex mixer.
3. Dialyze the liposome preparation against PBS, pH 7.4.
4. The liposome vesicles may be characterized for size by chromatography on a column of Sepharose 4B.

7.2. Coupling via Biotinylated PE Lipid Derivatives

Biotinylated PE (B-PE) incorporated into liposomal membranes can be used to interact non-covalently with (strept)avidin–protein conjugates or with other biotinylated proteins using (strept)avidin as a bridging molecule (Plant *et al.*, 1989). It is important that a long-chain spacer be used in constructing the B-PE derivative to allow enough spatial separation from the bilayer surface to accommodate avidin docking (Hashimoto *et al.*, 1986). Thus, any biotinylated protein can be coupled to the liposome surface through the strength of the (strept)avidin–biotin interaction. Section 6 (this chapter) describes the preparation of B-PE derivatives and their addition into vesicle construction. Incubation of (strept)avidin conjugates or (strept)avidin plus a biotinylated protein with the biotinylated liposome in PBS, pH 7.4, will form essentially nonreversible complexes, immobilizing the proteins to the outer surface of the bilayers. This method can be used to couple biotin-modified antibody molecules to liposomes (Figure 21.21). Removal of non-complexed protein may be performed using gel filtration chromatography on a column of Sephadex G-50 or G-75.

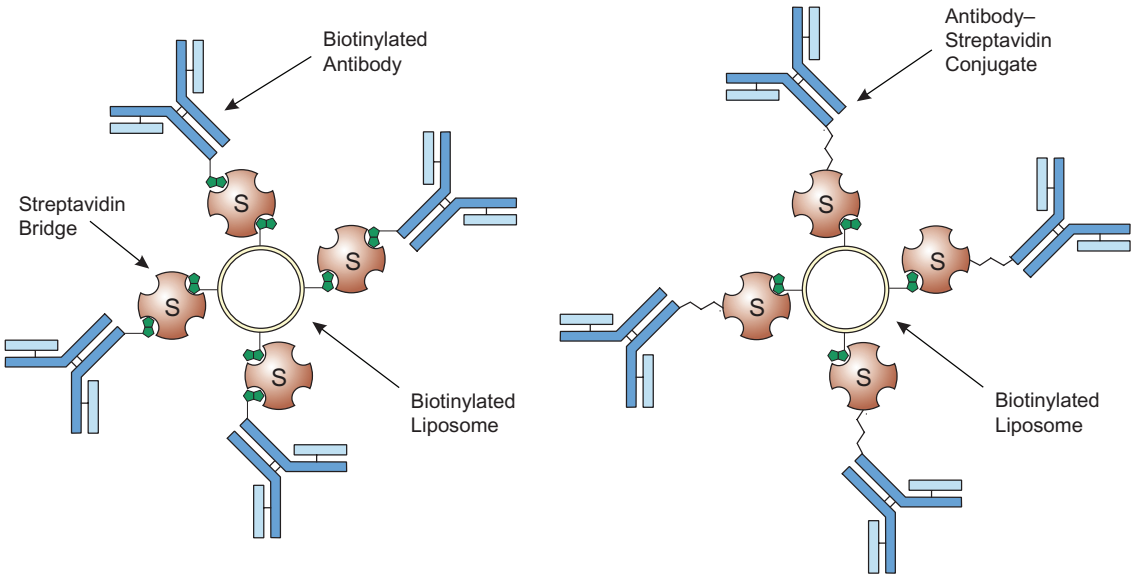

FIGURE 21.21 Antibodies can be conjugated to liposomes using an indirect approach by building a multilayered (strept)avidin–biotin complex on the surface. Biotinylated liposomes may be complexed with biotinylated antibodies using (strept)avidin as a bridging molecule or may be complexed with an antibody–(strept)avidin conjugate.

7.3. Conjugation via Carbodiimide Coupling to PE Lipid Derivatives

Underivatized PE in liposomal membranes contains an amine group that can participate in the carbodiimide reaction with carboxylate groups on proteins or other molecules (Dunnick *et al.*, 1975). The water soluble carbodiimide EDC (Chapter 4, Section 1.1) activates carboxylate groups to form active-ester intermediates that can react with PE to form an amide linkage. Unfortunately, EDC coupling of proteins to surfaces often results in considerable protein-to-protein crosslinking, since proteins contain an abundance of both amines and carboxylates. There is also potential for vesicle aggregation by proteins coupling to more than one liposome. Martin *et al.* (1990) suggested avoiding this polymerization problem by first blocking the amine groups of the protein with citraconic acid, which has been used successfully with antibodies (Jansons and Mallett, 1980).

However, even with the potential for protein–protein conjugation, carbodiimide coupling of peptides and proteins to liposomes can be performed with EDC without blocking polypeptide amines. The approach is similar to that described for the EDC conjugation of hapten molecules to carrier proteins to form immunogen complexes (Chapter 19, Section 3). Thus, this method may be used to prepare peptide hapten–liposome conjugates for immunization purposes (Figure 21.22). The procedure also works particularly well for coupling molecules containing only carboxylates to the amines on the liposomes.

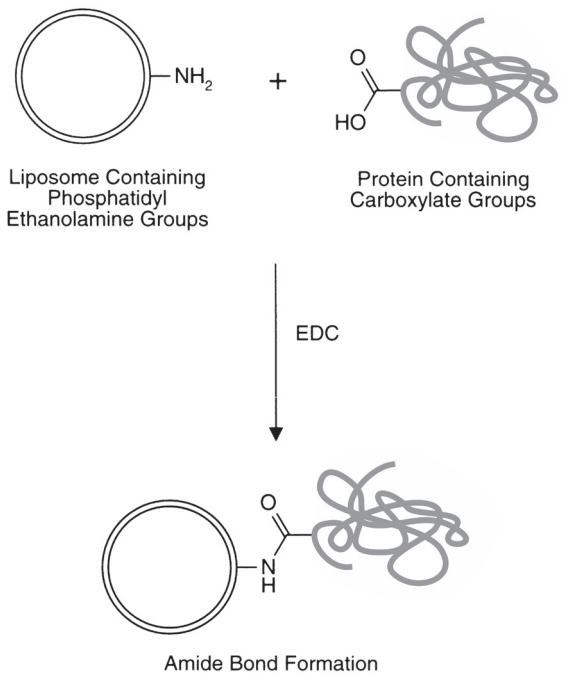

FIGURE 21.22 A protein may be conjugated with a liposome containing PE groups using a carbodiimide reaction with EDC.

Protocol

1. Prepare liposomes containing PE by any desired method. For instance, the common recipe mentioned in Section 1.2 (this chapter) that involves mixing PC:cholesterol:PG:PE in a molar ratio of 8:10:1:1 may be used. Thoroughly emulsify the liposome construction to obtain a good population of SUVs. The final liposome suspension should be in 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Adjust the concentration to about 5 mg lipid/ml buffer.
2. Add the protein or peptide to be conjugated to the liposome suspension. The protein may be dissolved first in PBS, pH 7.2, and an aliquot added to the reaction lipid mixture. The amount of protein to be added can vary considerably, depending on the abundance of the protein and the desired final density required. Reacting from 1 mg protein per ml liposome suspension up to about 20 mg protein/ml can be performed.
3. Add 10 mg EDC per ml of lipid/protein mixture. Solubilize the carbodiimide using a vortex mixer.
4. React for 2 h at room temperature. If liposome aggregation or protein precipitation occurs during the crosslinking process, scale back the amount of EDC added to the reaction.
5. Purify the conjugate by gel filtration using a column of Sephadex G-75.

7.4. Conjugation via Glutaraldehyde Coupling to PE Lipid Derivatives

Glutaraldehyde is among the earliest homobifunctional crosslinkers employed for protein conjugation (Chapter 5, Section 6.2). It reacts with amine groups through several routes, including the formation of Schiff base linkages which can be reduced with borohydride or cyanoborohydride to create stable secondary amine bonds. Although very efficient in reacting with proteins, glutaraldehyde typically causes extensive polymerization accompanied by precipitation of high molecular weight oligomers during the reaction. Even with this significant disadvantage, the reagent is still used routinely in protein conjugation techniques. Some control over the glutaraldehyde conjugation processes may be accomplished using the protocols discussed in Chapter 15, Section 2.1.

Liposomes containing PE residues can be reacted with glutaraldehyde to form an activated surface possessing reactive aldehyde groups. A two-step glutaraldehyde reaction strategy is probably best when working with liposomes, since precipitated protein would be difficult to remove from a vesicle suspension.

The following protocol describes the two-step method wherein the liposome is glutaraldehyde-activated, purified away from excess crosslinker, and then coupled to a protein by reductive amination (Figure 21.23).

Protocol

1. Prepare a liposome suspension, containing PE, at a total-lipid concentration of 5 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.8. Maintain all lipid-containing solutions under an inert gas atmosphere. Degas all buffers and bubble them with nitrogen or argon prior to use.
2. Add glutaraldehyde to this suspension to obtain a final concentration of 1.25%.
3. React overnight at room temperature under a nitrogen blanket.
4. Purify the activated liposomes from excess glutaraldehyde by gel filtration (using Sephadex G-50) or by dialysis against PBS, pH 6.8.
5. Dissolve the protein or peptide to be conjugated at a concentration of 10 mg/ml in 0.5-*M* sodium carbonate, pH 9.5. Mix the activated liposome suspension with the polypeptide solution at the desired molar ratio to effect the conjugation. Mixing the equivalent of 4 mg of protein per mg of total lipid usually results in acceptable conjugates.
6. React overnight at 4°C under an atmosphere of nitrogen.
7. To reduce the resultant Schiff bases and any excess aldehydes, add sodium borohydride to a final concentration of 10 mg/ml.

7.5. Conjugation via DMS Crosslinking to PE Lipid Derivatives

Dimethyl suberimidate (DMS) is a homobifunctional crosslinking agent containing amine-reactive imidoester groups on both ends. The compound is reactive toward the ε-amine groups of lysine residues and N-terminal α-amines in the pH range of 7 to 10 (pH 8–9 is optimal). The resulting amidine linkages are positively charged at physiological pH, thus maintaining the positive charge contribution of the original amine.

bis-Imidoesters like DMS may be used to couple proteins to PE-containing liposomes by crosslinking with the amines on both molecules (Figure 21.24). However, single-step crosslinking procedures using homobifunctional reagents are particularly subject to uncontrollable polymerization of protein in solution. Polymerization is possible because the procedure is performed with the liposomes, protein, and crosslinker all in solution at the same time.

The reaction is carried out in 0.2-*M* triethanolamine, pH 8.2. DMS should be the limiting reagent in the reaction to avoid blocking all amines on both molecules with only one end of the crosslinker, thus eliminating any conjugation. The amounts of total lipid and protein

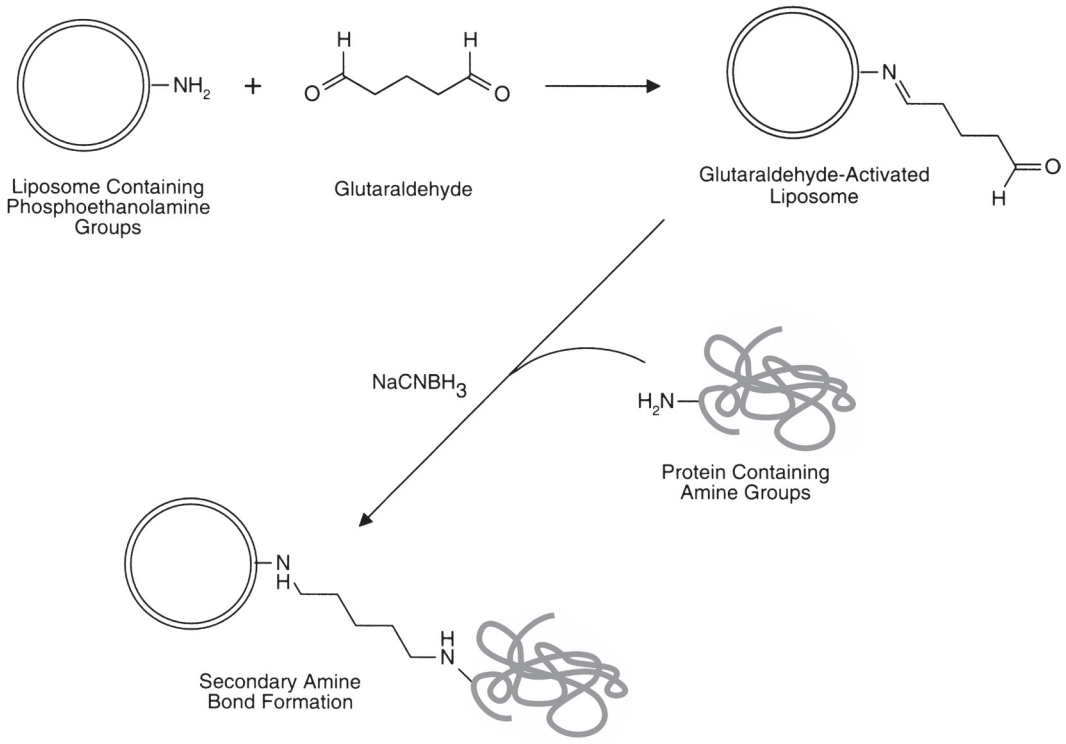

FIGURE 21.23 Glutaraldehyde activation of PE-containing liposomes may be used to couple protein molecules.

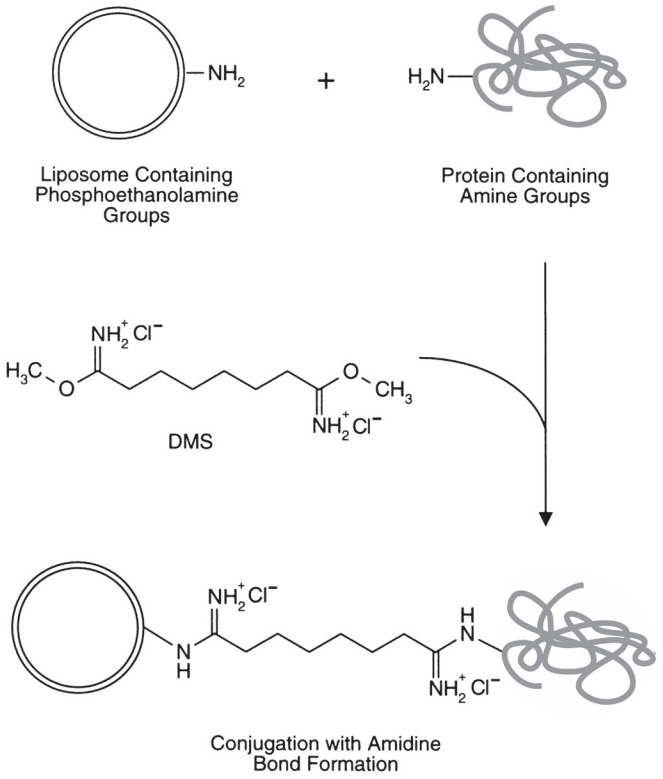

FIGURE 21.24 The homobifunctional crosslinker DMS may be used to conjugate PE-containing liposomes with proteins via amidine bond formation.

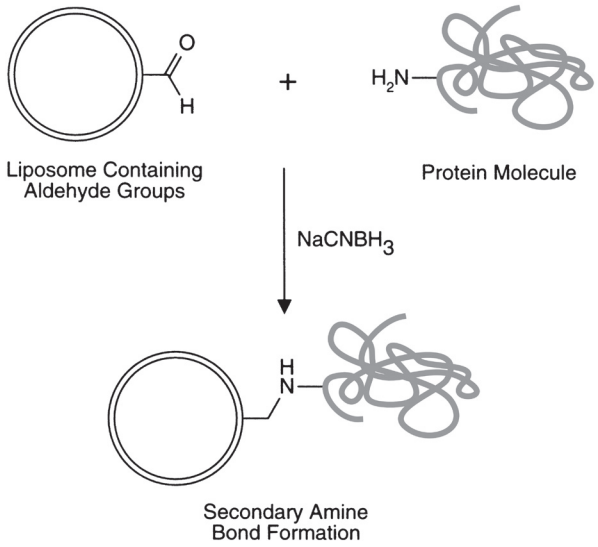

FIGURE 21.25 Glycolipids incorporated into liposomes may be oxidized with periodate to produce aldehydes suitable for coupling proteins via reductive amination.

in solution may have to be adjusted to optimize each conjugation reaction and avoid precipitation of protein or aggregation of liposomes.

7.6. Conjugation via Periodate Oxidation Followed by Reductive Amination

Periodate-oxidized liposomes which contain glycolipid moieties may be used to couple proteins and other amine-containing molecules by reductive amination. Section 2 (this chapter) describes the oxidative procedure that results in the formation of reactive aldehyde groups on the liposomal surface. Amine-containing polypeptides form Schiff base linkages with the aldehyde groups under alkaline conditions. The addition of a reducing agent such as borohydride or cyanoborohydride reduces the labile Schiff bases to form stable secondary amine bonds (Figure 21.25).

The following generalized method is based on the procedure described by Heath *et al.* (1981) for the coupling of immunoglobulins to liposomes containing glycosphingolipids.

Protocol

1. Prepare a periodate-oxidized liposome suspension containing glycolipid components according to Section 2 of this chapter. Adjust the concentration of total lipid to about 5 mg/ml.
2. Dissolve the protein to be coupled in 20-m*M* sodium borate, 0.15-*M* NaCl, pH 8.4, at a concentration of at least 10 mg/ml.
3. Add 0.5 ml of protein solution to each ml of liposome suspension with stirring.
4. Incubate for 2 h at room temperature to form Schiff base interactions between the aldehydes on the vesicles and the amines on the protein molecules.
5. In a fume hood, dissolve 125 mg of sodium cyanoborohydride in 1 ml water (makes a 2-*M* solution). *Caution: Highly toxic compound; handle with care*. This solution may be allowed to sit for 30 min to eliminate most of the hydrogen-bubble evolution that could affect the vesicle suspension.
6. Add 10 µl of the cyanoborohydride solution to each ml of the liposome reaction.
7. React overnight at 4°C.
8. Remove unconjugated protein and excess cyanoborohydride by gel filtration using a column of Sephadex G-50 or G-75.

7.7. Conjugation via SPDP-Modified PE Lipid Derivatives

N-Succinimidyl 3-(2-pyridyldithio)propionate (SPDP) is one of the most popular heterobifunctional crosslinking agents available, especially for protein conjugation (Chapter 6, Section 1.1). The activated NHS ester end of SPDP reacts with amine groups in proteins and other

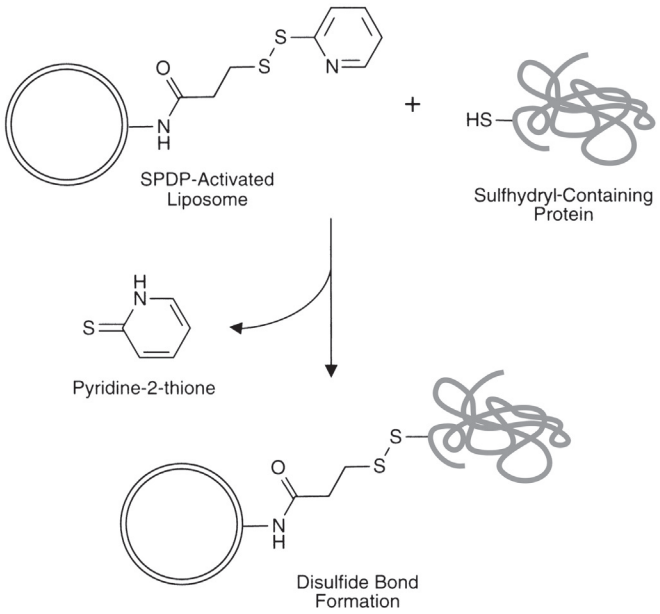

FIGURE 21.26 SPDP-activated liposomes can be used to couple sulfhydryl-containing proteins, forming disulfide linkages.

molecules to form an amide linkage (Figure 21.26). The 2-pyridyldithiol group at the other end reacts with sulfhydryl residues to form a disulfide linkage with sulfhydryl-containing molecules (Carlsson *et al.*, 1978).

SPDP is also a popular choice for coupling sulfhydryl-containing molecules to liposomes. PE residues in vesicles may be activated with this crosslinker to form pyridyl disulfide derivatives that can react with sulfhydryls to form disulfide linkages. Unlike the iodoacetyl- and maleimide-based crosslinkers discussed previously, the linkage formed with SPDP is reversible by simple disulfide reduction. Pure PE may be activated with SPDP prior to its incorporation into a liposome, or intact liposomes containing PE may be activated using the methods described in Section 2 (this chapter). Activation of PE with an SPDP crosslinker forms the intermediate reactive pyridyldithiopropionate-PE (PDP–PE) derivative. Stearylamine can also be activated with SPDP to be used in liposome conjugation (Goundalkar *et al.*, 1983). If the long-chain version, sulfo-LC-SPDP, is used with intact vesicles, the crosslinker will be water soluble and may be added directly to the buffered suspension without prior organic solvent dissolution. The negatively charged sulfonate group on its NHS ring prevents the reagent from penetrating the hydrophobic region of the lipid bilayer. Thus, only the outer surface of the liposomes will be modified. Using preactivated PE, both inner and outer surfaces end up containing reactive pyridyl disulfide groups. If liposome-sequestered components have the potential to react with this functional group or are sensitive, activation of intact liposomes with sulfo-LC-SPDP may be the better tactic.

Hydrophilic PEG-based heterobifunctional crosslinkers that are similar in design to SPDP are also available (Quanta BioDesign and Thermo Fisher). These compounds have the general design NHS–PEG_n–pyridyl disulfide and contain a water soluble spacer arm instead of the aliphatic spacers present in SPDP and sulfo-LC-SPDP (see Chapter 18, Section 1.2, and Chapter 15, Section 2.2). Use of the PEG-based reagents will result in better biocompatibility of the modified liposome surface and more accessibility of the reactive group for subsequent conjugation with proteins and other thiol-containing ligands. To use these reagents in the following coupling protocols, simply replace the SPDP compound in the activation procedure described previously (Section 2.2) with the corresponding PEG-based reagent by using an equivalent mole quantity for the reaction.

The following protocol is a suggested method for coupling sulfhydryl-containing proteins to SPDP-activated vesicles.

1. Prepare a 5 mg/ml liposome suspension containing a mixture of PC:cholesterol:PG:PDP–PE in molar ratios of 8:10:1:1. The PDP–PE activated lipid may be prepared according to the method described in Section 2.2, this chapter. The emulsification may be performed by any established method (Section 1, this chapter). Suspend the vesicles in 50-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* ethylenediamine triacetic acid (EDTA), pH 7.2.
2. Add at least 5 mg/ml of a sulfhydryl-containing protein or other molecule to the SPDP-modified vesicles to effect the conjugation reaction. Molecules lacking available sulfhydryl groups may be modified to contain them by a number of methods (Chapter 2, Section 4.1). The conjugation reaction should be performed in the presence of at least 10-m*M* EDTA to prevent metal-catalyzed sulfhydryl oxidation.
3. React overnight with stirring at room temperature. Maintain the suspension in a nitrogen or argon atmosphere to prevent lipid oxidation.
4. The modified liposomes may be separated from excess protein by gel filtration using Sephadex G-75 or by centrifugal floatation in a polymer gradient (Derksen and Scherphof, 1985).

7.8. Conjugation via SMPB-Modified PE Lipid Derivatives

Succinimidyl-4-(*p*-maleimidophenyl)butyrate (SMPB, Chapter 6, Section 1.6), is a heterobifunctional crosslinking agent that has an amine-reactive NHS ester on one end and a sulfhydryl-reactive maleimide group on the

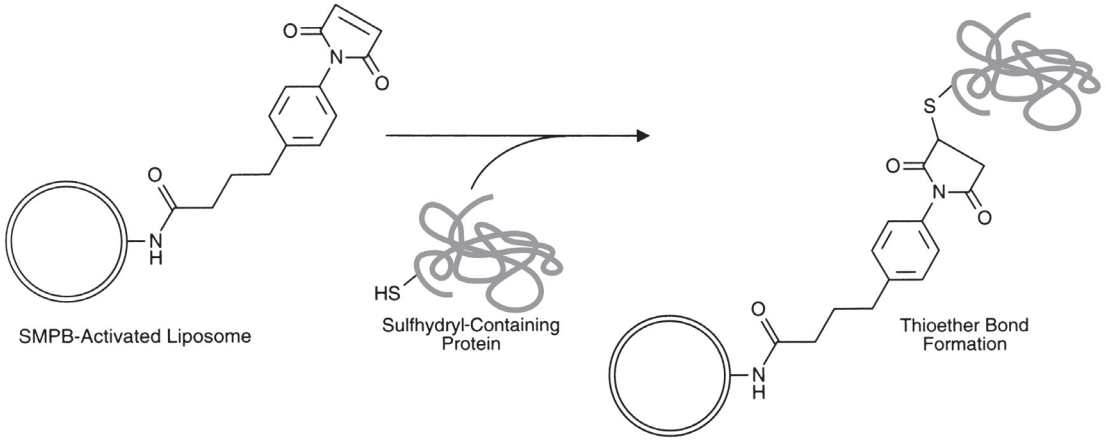

FIGURE 21.27 SMPB-activated liposomes may be used to couple thiol-containing protein molecules, forming stable thioether linkages.

other. Conjugates formed using SMPB are linked by stable amide and thioether bonds.

SMPB can be used to activate PE residues to contain sulfhydryl-reactive maleimide groups (Section 2, this chapter). Lipid vesicles formed with reactive maleimidophenylbutyrate–PE (MPB–PE) components can thus couple proteins through available SH groups, forming thioether linkages (Derksen and Scherphof, 1985) (Figure 21.27). A comparison with SPDP-produced conjugates concluded that SMPB formed more stable complexes that survived in serum for longer periods (Martin and Papahadjopoulos, 1982). The following protocol is a generalized method for the conjugation of proteins to SMPB-activated liposomes.

1. Prepare a liposome suspension, containing MPB–PE, at a total lipid concentration of 5 mg/ml in 0.05-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Activation of DPPE with SMPB is described in Section 3.4. A suggested lipid composition for vesicle formation is PC:cholesterol:PG:MPB–PE mixed at a molar ratio of 8:10:1:1. The presence of relatively high levels of cholesterol in the liposomal recipe dramatically enhances the conjugation efficiency of the component MPB–PE groups (Martin *et al.*, 1990). Any method of emulsification to create liposomes of the desired size and morphology may be used (Section 1.2, this chapter)
2. Dissolve a sulfhydryl-containing protein at a concentration of at least 5 mg/ml in 0.05-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2. The sulfhydryl groups on the protein molecule may be indigenous or created by any of the methods described in Chapter 2, Section 4.1.
3. Mix the protein solution with the liposome suspension in equal volume amounts.
4. React overnight at room temperature with stirring. Maintain an atmosphere of nitrogen over the reaction to prevent lipid oxidation.
5. Separate unreacted protein from modified liposomes by gel filtration using a column of Sephadex G-75 or by centrifugal floatation in a polymer gradient (Derksen and Scherphof, 1985).

7.9. Conjugation via SMCC-Modified PE Lipid Derivatives

Succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) is a heterobifunctional crosslinker with significant utility in crosslinking proteins, particularly in the preparation of antibody–enzyme (Chapter 20) and hapten–carrier (Chapter 19) conjugates (Hashida and Ishikawa, 1985; Dewey *et al.*, 1987). It is normally used in a two-step crosslinking procedure, wherein the NHS ester end of the reagent is first reacted with primary amine groups on proteins or other molecules to form stable amide bonds. This creates a reactive intermediate containing terminal maleimide groups on the modified molecule. The maleimide end is specific for coupling to sulfhydryls when the reaction pH is in the range of 6.5 to 7.5 (Smyth *et al.*, 1964). Addition of a sulfhydryl-containing protein forms a stable thioether linkage with the SMCC-activated molecule.

In a similar manner, PE may be activated through its head-group primary amine to possess reactive maleimide groups capable of coupling sulfhydryl-containing proteins to liposomes (Figure 21.28). The method of derivatizing DPPE with SMCC is essentially the same as that described for SMPB (Section 2, this chapter). SMCC, however, contains a more stable maleimide reactive group toward hydrolysis in aqueous reaction environments, due to the proximity of an aliphatic cyclohexane ring rather than the aromatic phenyl group of SMPB. In protein conjugation to liposomes, this stability may translate into higher activity and more efficient crosslinking. A general protocol for the coupling of sulfhydryl-containing proteins to liposomes containing

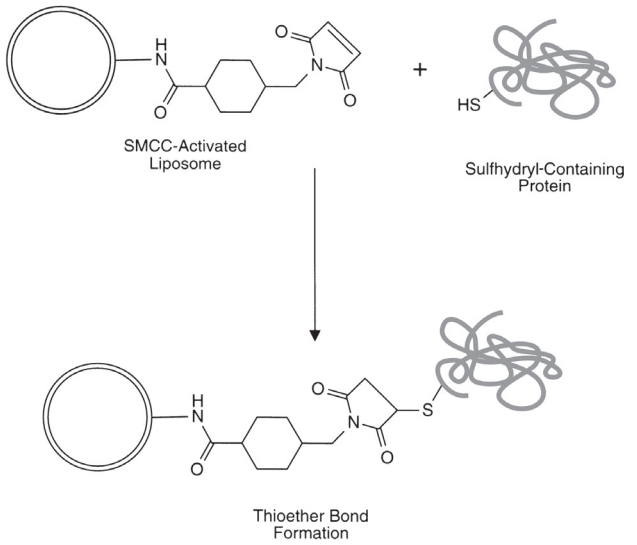

FIGURE 21.28 The reaction of an SMCC-activated liposome with a sulfhydryl-containing protein forms stable thioether bonds.

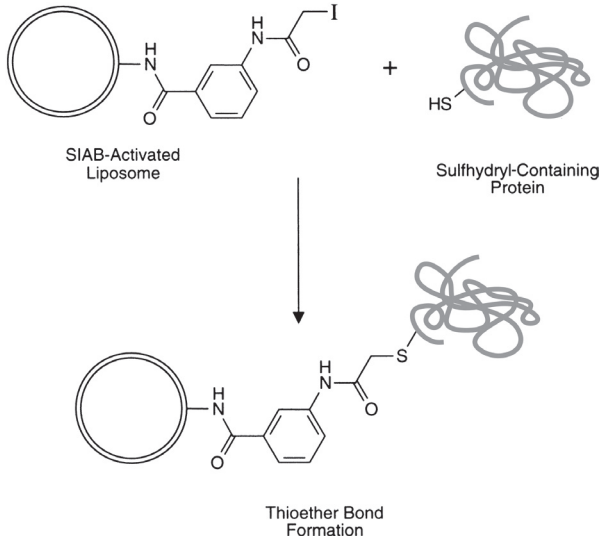

FIGURE 21.29 SIAB-activated liposomes can couple with sulfhydryl-containing proteins to produce thioether linkages.

SMCC–PE is essentially the same as that described previously for SMPB (Section 7.8, this chapter).

7.10. Conjugation via Iodoacetate-Modified PE Lipid Derivatives

Iodoacetate derivatives have been used for decades to block or crosslink sulfhydryl groups in proteins and other molecules (Chapter 2, Section 5.2). At mildly alkaline pH values (pH 8–8.5), iodoacetyl derivatives are almost entirely selective toward the cysteine SH groups in proteins. Disulfide reduction or thiolation reagents can be used to create the required sulfhydryl groups on proteins containing no free sulfhydryls.

Crosslinking reagents containing an amine-reactive NHS ester on one end and an iodoacetyl group on the other end are particularly useful for two-step protein conjugation. Heterobifunctional reagents like SIAB (Chapter 6, Section 1.5), SIAX (Chapter 6, Section 1.8), or SIAC (Chapter 6, Section 1.9) can be used to modify amine-containing molecules, resulting in iodoacetyl derivatives capable of coupling to sulfhydryl-containing molecules.

Liposomes containing PE lipid components may be activated with these crosslinkers to contain iodoacetyl derivatives on their surface (Figure 21.29). The reaction conditions described in Chapter 6, Section 1.5, may be used, substituting a liposome suspension for the initial protein being modified in that protocol. The derivatives are stable enough in aqueous solution to allow purification of the modified vesicles from excess reagent (by dialysis or gel filtration) without loss of activity. The only consideration is to protect the iodoacetyl derivative from light, which may generate iodine and reduce the activity of the intermediate. Finally, the modified liposome can be mixed with a sulfhydryl-containing molecule to effect the conjugation through a thioether bond.

Alternatively, pure PE may be derivatized to contain iodoacetyl groups prior to vesicle formation. This may be performed using heterobifunctional crosslinkers or through the use of iodoacetic anhydride according to Hashimoto *et al.* (1986). However, a single iodoacetyl group on PE was found not to be sufficiently extended from the vesicle surface to allow efficient protein coupling. Only after creating a longer spacer by reacting 2-mercaptoethylamine with the initial iodoacetamide derivative and then reacting a second iodoacetic anhydride to form an extended, reactive arm, did the derivative possess enough length to give it efficient conjugation ability (Figure 21.30). This example illustrates the importance of a longer spacer in avoiding steric problems during conjugation to liposomal vesicles surface.

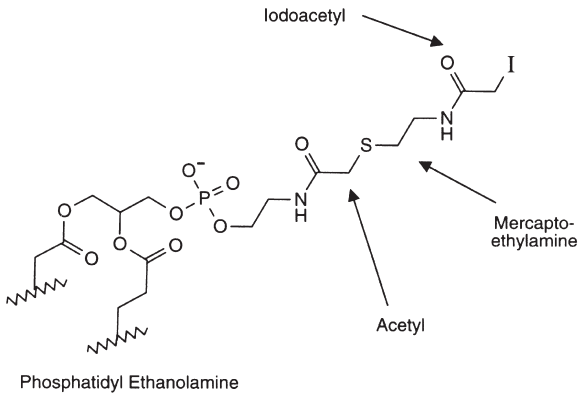

FIGURE 21.30 An iodoacetamide derivative of PE containing an extended spacer arm can be constructed through a carbodiimide coupling of iodoacetic acid to PE, followed by reaction with 2-mercaptoethylamine, and finally another reaction with iodoacetate.

CHAPTER

22

Enzyme Modification and Conjugation

Enzymes are widely used in bioconjugate chemistry as detection components in assay systems. The catalytic activity of an enzyme can be used to turn substrate molecules into chromogenic, fluorescent, or chemiluminescent products, which are easily detectable or quantifiable by imaging, microscopy, or spectroscopy. If an enzyme is conjugated to a targeting molecule specific for some analyte of interest, then an assay system can be constructed to localize or measure the analyte. The most common targeting molecule is an antibody having antigen-binding specificity for the substance to be measured. An enzyme conjugated to such an antibody can be used to visualize the presence of antigen. Due to the advantages of this simple concept, enzyme-linked immunoadsorbent assays (ELISAs) have become the most important type of immunoassay system available.

The rapid turnover rate of some enzymes allows ELISAs to be designed that far surpass the sensitivity of radiolabeling techniques. In addition, substrates can be chosen to produce soluble products that can be accurately quantified by their absorbance or fluorescence. Alternatively, substrates are available that form insoluble, highly colored precipitates, excellent for localizing antigens in blots, cells, or tissue sections. The flexibility of enzyme-based assay systems makes the chemistry of enzyme conjugation one of the most important application areas in bioconjugate techniques.

In addition, the immobilization of enzymes for use in catalytic transformations (called immobilized reactors) has also become an important field in the use of these proteins. Specialized immobilized reactors are being used to cleave or modify biological molecules, to synthesize complex organic compounds, to produce food products, and for the production of bioenergy molecules from biomass feedstock. See Chapter 1 for a review of immobilized reactor applications and Chapter 15 for the activation and coupling methods that can be used to covalently attach enzymes to various types of insoluble support materials.

The following sections briefly describe the principal enzymes used for conjugation with other protein molecules, particularly in the design of ELISA and other immunoassay systems.

1. PROPERTIES OF COMMON ENZYMES

1.1. Horseradish Peroxidase (HRP)

HRP (donor:hydrogen peroxide oxidoreductase; EC 1.11.1.7), derived from horseradish roots, is a enzyme of molecular weight 40,000 that can catalyze the reaction of hydrogen peroxide with certain organic, electron-donating substrates to yield highly colored products (Figure 22.1). The reaction of HRP with its fundamental substrate, H_2O_2, forms a stable intermediate that can dissociate in the presence of a suitable electron donor, oxidizing the donor and potentially creating a color change. The donor can consist of oxidizable molecules like ascorbate, cytochrome *c*, ferrocyanide, or the leuco forms of many dyes. A large variety of

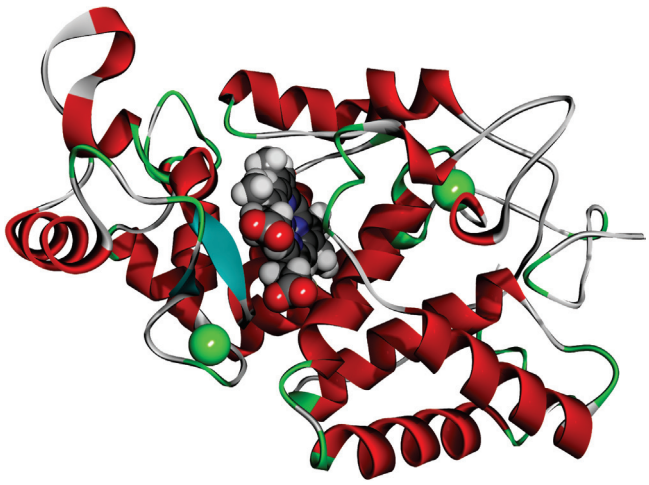

FIGURE 22.1 Horseradish peroxidase shown as the ribbon structure with the heme ring in its active center and two bound calcium ions. The molecular model is based on structure 1H58 in the RCSB Protein Databank by Berglund *et al.* (2002).

Bioconjugate Techniques, Third Edition.

electron-donating dye substrates are commercially available for use as HRP detection reagents. Some of them can be used to form soluble colored products for use in spectrophotometric detection systems, while other substrates form insoluble products that are especially appropriate for staining techniques. In addition, substrates are available that create fluorescent or chemiluminescent products upon oxidation with HRP. The chemiluminescent substrates are among the most sensitive of all detection reagents, facilitating the detection of as little as attogram quantities of many targeted analytes. The pH optimum for HRP is 7.0 although particular substrate detection reactions may be performed at pH values slightly different from neutrality.

The use of antibody–HRP or streptavidin–HRP conjugates in peroxidase-catalyzed enhanced chemiluminescent assays can result in one of the most sensitive detection methods for assaying targeted analytes in ELISA and western blotting applications. The reaction cascade that occurs during HRP catalysis can be dramatically improved by the addition of various enhancer molecules, which create oxidized intermediates leading to the oxidation and light emission of a chemiluminescent substrate such as luminol. Vdovenko *et al.* (2012) analyzed this reaction using a multi-factorial design of experiments (DOE) approach to identify the best combination and concentrations of H_2O_2, luminol, and two different enhancer compounds (3-(10′-phenothiazinyl) propane-1-sulfonate and 4-morpholinopyridine. This combination at an optimized concentration resulted in the best signal-to-noise ratio and the longest chemiluminescent emission.

HRP is a hemoprotein containing photohemin IX as its prosthetic group. The presence of the heme structure gives the enzyme its characteristic color and maximal absorptivity at 403 nm. The ratio of its absorbance in solution at 403 nm to its absorbance at 275 nm, called the RZ or Reinheitzahl ratio, can be used to approximate the purity of the enzyme. However, at least seven isoenzymes exist for HRP (Shannon *et al.*, 1966; Kay *et al.*, 1967; Strickland *et al.*, 1968), and their RZ values vary from 2.50 to 4.19. Thus, unless the RZ ratio is precisely known or determined for the particular isoenzyme of HRP utilized in the preparation of an antibody–enzyme conjugate, subsequent measurement after crosslinking would yield questionable results in the determination of the amount of HRP present in the conjugate.

HRP is a glycoprotein that contains significant amounts of carbohydrate. Its polysaccharide chains are often used in crosslinking reactions to couple the enzyme to targeting molecules. Mild oxidation of its associated glycan sugar residues with sodium periodate generates reactive aldehyde groups that can be used for conjugation to amine-containing molecules. Reductive amination of oxidized HRP to antibody molecules in the presence of sodium cyanoborohydride is perhaps the simplest method of preparing highly active conjugates with this enzyme (Chapter 4, Section 1.4, and Chapter 20, Section 1.3).

Other methods of HRP conjugation include the use of the homobifunctional reagent glutaraldehyde (Chapter 5, Section 6.2, and Chapter 15, Section 2.1) and the heterobifunctional crosslinker, SMCC (succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate) (Chapter 6, Section 1.3). Using glutaraldehyde, a two-step protocol is usually employed to try to limit the extent of oligomer formation. Even using the most highly controlled reactions, however, this method often causes unacceptable amounts of precipitated conjugate. Despite this disadvantage, glutaraldehyde conjugation is still routinely used, especially in the preparation of some antibody–enzyme reagents that go into established diagnostic assays. The use of the *N*-hydroxysuccinimide (NHS) ester–maleimide crosslinker, SMCC, provides far better control over the conjugation process. SMCC is usually reacted first with HRP to create a derivative containing sulfhydryl-reactive maleimide groups. HRP activation of the native enzyme should result in the modification of a maximum of about two amine groups on the protein, because HRP only contains two lysines. An increase in the activation level can be realized if the enzyme first is modified with ethylenediamine (EDA) using the carbodiimide EDC according to the methods described in Chapter 19 for the production of cationized bovine serum albumin (cBSA). The EDA-modified HRP is also more stable than the unmodified version, so cationization may have benefits in the retention of enzyme activity. The maleimide-activated enzyme can be purified and freeze-dried, providing a ready source of modified HRP to react with a sulfhydryl-containing antibody. Several preactivated forms of this enzyme are available from Thermo Fisher.

The size of HRP is an advantage in preparing antibody–enzyme conjugates, since the overall complex size also can be designed to be small. Relatively low-molecular-weight conjugates are able to penetrate cellular structures better than large, polymeric complexes. This is why HRP conjugates are often the best choice for immunohistochemical (IHC) and immunocytochemical staining techniques. Small conjugate size means greater accessibility to antigenic structures within tissue sections.

Another distinctive advantage of HRP is its robust nature and stability, especially under the conditions employed for crosslinking. HRP is stable for years in a freeze-dried state, and the purified enzyme can be stored in solution at 4°C for many months without significant loss of activity. The enzyme also retains excellent activity after being modified with a conjugation reagent or after being periodate-oxidized to

form aldehyde groups on its polysaccharide chains. Depending on the methods used for crosslinking, HRP conjugates can be constructed to have a high ratio of enzyme to antibody or a low ratio—both retaining high specific activity.

The disadvantages associated with HRP are several. The enzyme only contains two available primary ε-amine groups—extraordinarily low for most proteins—thus limiting its ability to be activated with amine-reactive heterobifunctionals. HRP is sensitive to the presence of many antibacterial agents, especially azide. It is also reversibly inhibited by cyanide and sulfide (Theorell, 1951). Finally, while the enzymatic activity of HRP is extremely high, its useful life span or practical substrate development time is somewhat limited. After about an hour of substrate turnover, in some situations its activity can be decreased severely.

Nevertheless, HRP is by far the most popular enzyme used in antibody–enzyme conjugates. One survey of enzyme use stated that HRP is incorporated in about 80% of all antibody conjugates, most of them utilized in diagnostic assay systems.

1.2. Alkaline Phosphatase

Alkaline phosphatases [AP, orthophosphoric monoester phosphorylase (alkaline optimum); EC 3.1.3.1] represent a large family of almost ubiquitous isoenzymes found in organisms from bacteria to animals (Figure 22.2). In mammals, there are two forms of AP, one form present in a variety of tissues and another form found only in the intestines. They share common attributes in that the phosphatase activity is optimal at pH 8 to 10, is activated by the presence of divalent cations, and is inhibited by cysteine, cyanide compounds, arsenate various metal chelators, and phosphate ions.

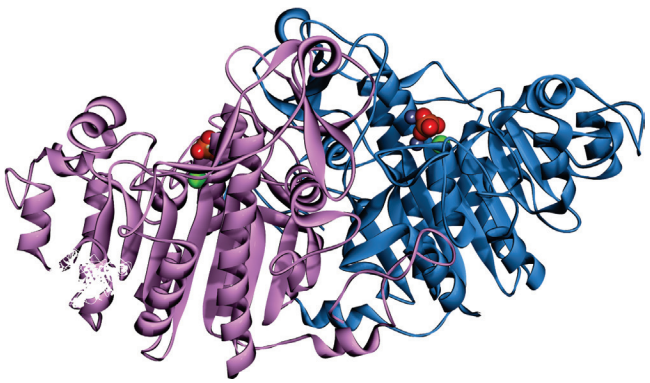

FIGURE 22.2 Alkaline phosphatase shown as the dimer ribbon structure with two molecules of phosphate bound in its active sites. The molecular model is based on structure 3TG0 in the RCSB Protein Databank by Bobyr *et al.* (2012).

Most conjugates created with AP utilize the form isolated from calf intestine.

AP isoenzymes can cleave associated phosphomonoester groups from a wide variety of substrates. The exact biological function of these enzymes is not fully understood, although they definitely function as the opposite of kinase enzymes—removing phosphate groups from phosphorylated proteins and thus affecting signal transduction processes within cells. They behave *in vivo* in their classic phosphohydrolase role at alkaline pH values, but at neutral pH AP isoenzymes can act as phosphotransferases. In this sense, suitable phosphate acceptor molecules can be utilized in solution to increase the reaction rates of AP on selected substrates. Typical phosphate acceptor additives include diethanolamine Tris, and 2-amino-2-methyl-1-propanol. The presence of these additives in substrate buffers can dramatically increase the sensitivity of AP-based ELISA determinations, even when the substrate reaction is performed in alkaline conditions.

Calf intestinal AP has a molecular weight of about 140,000. The active site of AP contains two zinc ions and a single magnesium ion, both of which are essential for activity (Kim and Wyckoff, 1991). Substrate development with AP should thus be carried out in buffered environments containing small concentrations of these divalent cations to maintain optimal active site conformation. Avoid the presence of metal chelators such as EDTA, since they may extract these ions from the enzyme and inhibit activity. The pH optimum for APs can vary from pH 8 to 10, depending on the type of isoenzyme. Calf intestinal AP peaks in activity at the higher pH values of this range, and substrate reactions are commonly performed in diethanolamine buffer at pH 9.8. The calf intestinal enzyme has the highest catalytic rate constant yet discovered for AP isoenzymes, and it is available commercially in high activity for bioconjugation applications.

Purified preparations of calf intestinal AP maintained in solution are usually stored in the presence of a stabilizer, which is typically 3-*M* NaCl. The enzyme may also be lyophilized, but it may experience activity loss with each freeze–thaw cycle. AP is not stable under acidic conditions. Lowering the pH of an AP solution to 4.5 reversibly inhibits the enzyme. It is recommended that all handling, storage, and use of AP be carried out under conditions > pH 7.0 to maintain the highest possible catalytic activity.

AP is often a difficult enzyme to work with when preparing enzyme conjugates. Activity losses may occur upon modification with a crosslinking agent or after coupling to an antibody molecule. Simply following established protocols for making antibody–AP conjugates does not always ensure retention of enzyme activity. Sometimes activity losses can be traced to

particular batches or to certain suppliers of the enzyme. Using a highly purified, high-activity AP preparation helps to maintain good resultant activity in the conjugate.

Ironically, AP is the enzyme of choice for some applications due to its stability. Since it can withstand the moderately high temperatures associated with hybridization assays better than HRP, AP often is the enzyme of choice for labeling oligonucleotide probes (Kaatz *et al.*, 2012). AP is also capable of maintaining enzymatic activity for extended periods of substrate development. Increased sensitivity can be realized in ELISA procedures by extending the substrate incubation time to hours and sometimes even days, provided that the background interference is low. These properties make AP the second most popular choice for antibody–enzyme conjugation (behind HRP), being used in almost 20% of all commercial enzyme-linked assays.

Conjugation methods typically employed with AP include glutaraldehyde-mediated crosslinking (Chapter 5, Section 6.2) and the use of the heterobifunctional reagents SMCC (Chapter 6, Section 1.3) or SPDP (*N*-succinimidyl 3-(2-pyridyldithio)propionate) (Chapter 6, Section 1.1). Heterobifunctional crosslinkers provide the best control over the crosslinking process and typically result in antibody–enzyme conjugates of high activity. Many conjugation protocols incorporate a sodium phosphate buffer system to reversibly block the AP active site during chemical modification. This prevents derivatization from occurring in the catalytic site, thus better retaining activity in the resultant conjugate.

1.3. β-Galactosidase

β-Galactosidase (β-Gal; β-D-galactoside galactohydrolase; EC 3.2.1.23; also called lactase) catalyzes the hydrolysis of β-D-galactoside in the presence of water to galactose and alcohol. This type of enzyme is found widespread in many microorganisms, plants, and animals. β-Gal can be used to determine lactose in biological fluids and it is employed in food processing operations, particularly in immobilized form. The enzyme is often used as a reporter enzyme for monitoring gene activation and transcription (Beucher *et al.*, 2012; Ju *et al.*, 2012). β-Gal also has good characteristics when conjugated to antibody molecules or streptavidin for use in ELISA systems (Wallenfels and Weil, 1972; Byrne and Johnson, 1975; Kato *et al.*, 1975a,b).

β-Gal has a molecular weight of 540,000 and is composed of four identical subunits of MW 135,000, each with an independent active site (Melcher and Messer, 1973) (Figure 22.3). The enzyme has divalent metals as cofactors, with chelated Mg^{2+} ions required to maintain active site conformation. The presence of NaCl or dilute solutions (5%) of low-molecular-weight alcohols (methanol, ethanol, etc.) causes enhanced substrate turnover. β-Gal contains numerous sulfhydryl groups and is glycosylated.

Commercially available β-gal is usually isolated from *E. coli* and has a pH optimum at 7 to 7.5. By contrast, mammalian β-galactosidases usually have a pH optimum within the range of 5.5 to 6; thus, interference from endogenous β-gal during immunohistochemical staining can be avoided.

Due to the relatively high molecular weight of the enzyme, conjugates formed with antibodies and β-gal can be much bulkier than those associated with alkaline phosphatase or horseradish peroxidase. For this reason, antibody conjugates made with β-gal may have more difficulty penetrating tissue structures during immunohistochemical or immunocytochemical staining techniques than those made with the other enzymes.

Although numerous research articles have been written describing the preparation and use of antibody conjugates with β-gal, the enzyme remains a minor player in ELISA procedures. Less than 1% of all commercial ELISA products utilize this enzyme.

β-Gal may be conjugated to antibody molecules using the heterobifunctional reagent SMCC. This crosslinker is reacted first with an antibody through its amine-reactive NHS ester end to form a maleimide-activated derivative. This is in contrast with most antibody–enzyme conjugation schemes utilizing SMCC, wherein the enzyme is typically modified first and a sulfhydryl-containing antibody is coupled secondarily. However, since β-gal already contains abundant free sulfhydryl residues that can participate in coupling to a maleimide-activated protein, conjugations with this enzyme often are done with the antibody being the first

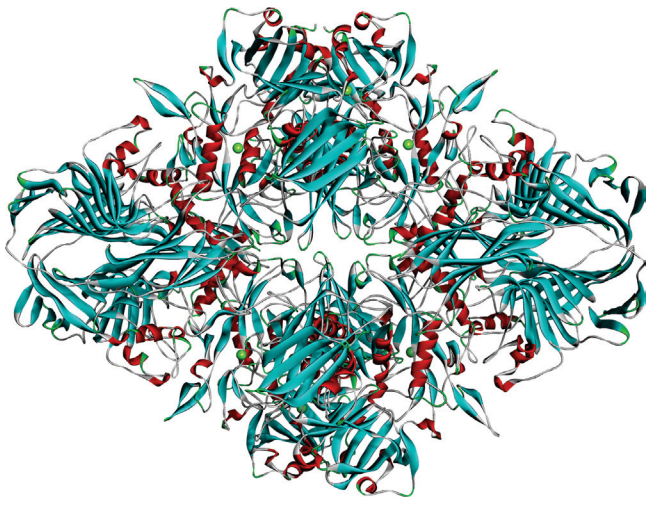

FIGURE 22.3 β-Galactosidase shown as the four-subunit biological assembly. The molecular model is based on structure 1BGL in the RCSB Protein Databank by Jacobson *et al.* (1994).

component modified. This route avoids having to create sulfhydryls on the antibody molecule, either by reduction or modification with a thiolation reagent. Thus, antibody–β-gal conjugates usually are simpler to make than using other enzymes.

1.4. Glucose Oxidase

Glucose oxidase (β-D-glucose: oxygen 1-oxidoreductase; EC 1.1.3.4; GO) is a flavoenzyme that catalyzes the oxidation of β-D-glucose to D-gluconolactone. The intermediate product of the catalysis is a reduced enzyme–$FADH_2$ complex that, in the presence of oxygen, gets oxidized back to enzyme–FAD with release of hydrogen peroxide. The enzyme consists of two identical subunits (MW 80,000 each) bound together by disulfide linkages (O'Malley and Weaver, 1972). GO contains two tightly bound flavin adenine dinucleotide (FAD) cofactors, one per subunit, which are critical to its oxidoreductase activity (Figure 22.4). Each subunit also contains one molecule of chelated iron. The intact protein consists of about 74% amino acids, 16% neutral carbohydrate, and 2% amino sugars (total molecular weight 160,000). GO operates under a relatively broad pH range of 4 to 7, but its pH optimum is 5.5. The commercially available preparation of GO is typically isolated from *Aspergillus niger*.

Glucose oxidase is widely used in diagnostic assays for the determination of glucose concentration in physiological fluids. Detectability of the oxidation products is done through an enzyme-coupled reaction wherein liberated H_2O_2 is reacted with peroxidase and a suitable chromogenic substrate. The development of substrate color thus is proportional to the amount of H_2O_2 released which is in turn related to the amount of glucose originally present. The production of hydrogen peroxide also can be quantified using a luminescence procedure with luminol to produce light in proportion to the glucose concentration (Williams *et al.*, 1976).

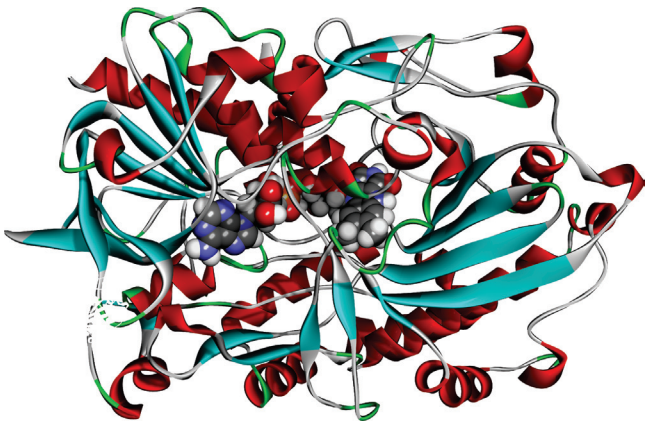

FIGURE 22.4 A single subunit of glucose oxidase shown as the ribbon structure with the $FADH_2$ cofactor. The biological assembly typically exists as the dimer. The molecular model is based on structure 3QVP in the RCSB Protein Databank by Kommoju *et al.* (2011).

GO is often used in solution phase reactions as well as being immobilized on "dip-sticks" and electrodes. Methods for the coupling of enzymes to solid supports can be found in Chapter 15. Although the overall clinical usage of GO is widespread, its use as conjugated to antibodies in enzyme-linked assay systems is minor compared to the popularity of other enzymes like HRP and AP. Of the total number of commercial diagnostic assays utilizing antibody–enzyme conjugates, GO is employed in less than 1% of clinical tests. The enzyme remains, however, an important tool in many assays developed for research use (Berron *et al.*, 2011; Holland *et al.*, 2011). One particular advantage to the enzyme is that there is no endogenous GO activity in mammalian tissues, making it an excellent choice for immunohistochemical staining procedures.

Antibody conjugates with GO can be made using the crosslinking agents glutaraldehyde (Chapter 5, Section 6.2) or SMCC (Chapter 6, Section 1.3). The heterobifunctional reagent SMCC provides the best control over the conjugation process and usually results in high-activity preparations. Also consider PEG-based heterobifunctional reagents as described in Chapter 18, Section 1.2, because the hydrophilicity of their crossbridge provides greater water solubility and less nonspecific binding in assay systems.

2. PREPARATION OF ACTIVATED ENZYMES FOR CONJUGATION

Enzymes may be modified to contain reactive groups useful for conjugation with other proteins. This operation may be carried out using homobifunctional (Chapter 5) or heterobifunctional (Chapters 6, 17, and 18) reagents that can covalently couple to some chemical target on the enzyme and result in a terminal reactive group that can crosslink with another molecule. Enzyme activation may also take advantage of the presence of polysaccharide constituents—oxidizing them with sodium periodate to form reactive aldehydes.

Whatever the method of conjugate creation, the most important considerations are retention of activity in the complex and prevention of extensive oligomer generation, which may cause precipitation. The following methods discuss some of the more common methods for producing enzyme conjugates. The list, however, is by no means exhaustive of every possible procedure used in the literature. Many other crosslinkers and reaction strategies as described in this book may be used with success, including the incorporation of polyvalent scaffolds to attach greater numbers of enzymes to a

targeting molecule and thus enhance detectability, such as dendrimers (Chapter 8) and polymers (Chapter 18, Section 2).

2.1. Glutaraldehyde-Activated Enzymes

Glutaraldehyde is a homobifunctional crosslinker containing an aldehyde residue at both ends of a 5-carbon chain. Its primary reactivity is toward amine groups, but the reaction may occur by more than one mechanism. As discussed in Chapter 5, Section 6.2, and Chapter 15, Section 2.1, glutaraldehyde is able to crosslink proteins to create stable secondary amine linkages. Glutaraldehyde exists in a number of different forms in aqueous solution, such as hemiacetal and aldol ring structures as well as large α-, β-unsaturated polymers containing carbon–carbon double bonds. The double bonds of these polymers can undergo an addition reaction with amines that results in covalent bond formation even without a reductant being present. Fresh glutaraldehyde may contain little polymer formation, except if it is exposed to highly alkaline conditions. However, the older the preparation of glutaraldehyde, the more likely it is that it contains appreciable amounts of polymer. Thus, reactions with this crosslinking agent can result in indistinct conjugation products and may be difficult or impossible to reproduce or scale up as the conjugation need arises.

The high reactivity and indistinct forms of glutaraldehyde make it difficult to control the size and composition of the final conjugate. Proteins crosslinked with this reagent often form substantial amounts of precipitated products due to polymerization. The degree of oligomer formation can be moderated somewhat by using a two-step protocol, but the first protein activated with the molecule can still form large-molecular-weight complexes.

Despite the obvious disadvantages of glutaraldehyde-mediated conjugation, the crosslinker continues to be used to form enzyme–antibody complexes and to create bioconjugates used in other applications. Many diagnostic tests still utilize antibody–enzyme conjugates prepared through glutaraldehyde crosslinking procedures.

The one- and two-step procedures for enzyme activation and conjugation using glutaraldehyde can be found in Chapter 20, Section 1.2.

2.2. Periodate Oxidation Techniques

Molecules containing polysaccharide chains may be oxidized to possess reactive aldehyde residues by treatment with sodium periodate. Any adjacent carbon atoms containing hydroxyl groups will be affected, cleaving the carbon–carbon bond and transforming the hydroxyls into aldehydes. Glycoproteins may be oxidized in this manner to form reactive intermediates useful for crosslinking procedures involving reductive amination (Chapter 4, Section 4). This conjugation technique can direct the coupling process away from polypeptide active regions, thus helping to preserve catalytic activity or binding sites.

Enzymes that contain carbohydrate, such as HRP or GO, may be oxidized with periodate to create reactive derivatives that subsequently can be used to label antibodies or other targeting molecules at their amine groups. The aldehyde–HRP intermediate may be stored for extended periods in a frozen or lyophilized state without loss of activity (either enzymatic or coupling potential). Avoid, however, storage in a liquid state, since polymerization may occur—resulting in precipitation and loss of activity as Schiff base interactions between proteins builds up in solution.

The protocols for periodate oxidation of HRP and its conjugation with other proteins may be found in Chapter 20, Section 1.3.

2.3. SMCC-Activated Enzymes

The heterobifunctional crosslinker SMCC, or its water soluble analog sulfo-SMCC, can be used to activate enzymes through their amines, leaving terminal maleimide groups on the protein surface (Chapter 6, Section 1.3). The NHS ester end of the crosslinker reacts with ε-lysine or N-terminal amines to form amide bonds. The maleimide end of the reagent is stable enough in aqueous solution to allow purification of the activated enzyme prior to conjugation with a second protein. The maleimide group can react with sulfhydryl groups to create thioether linkages. A maleimide-activated enzyme may be stored in a lyophilized state for extended periods without loss of sulfhydryl-coupling capability.

The use of this type of heterobifunctional reagent allows controlled conjugations to take place, precisely regulating the exact ratio of each protein in the final complex and the size of the resultant conjugate. In addition, the second-stage conjugation through sulfhydryl groups provides directed coupling at discrete sites within a protein molecule, thus providing the potential to better avoid active centers or binding regions. For instance, antibody molecules can be coupled to enzymes in their hinge region after mild disulfide reduction to effect the crosslink in an area away from the antigen binding site.

Protocols for the activation of enzyme molecules with SMCC (or sulfo-SMCC) can be found in Chapter 20, Section 1.1. Conjugates formed using this method usually result in high-activity complexes giving excellent sensitivity for use in immunoassays or other appli-

cations. In addition, refer to Chapter 18, Section 1.2, for the use of similar NHS ester–maleimide crosslinkers that contain a discrete PEG cross-bridge to make the reagent much more hydrophilic. Antibody—enzyme conjugates formed from NHS–PEG_n–maleimide reagents perform better in assays than those made from crosslinkers with aliphatic cross-bridges, such as SMCC, because the hydrophobic nature of the aliphatic group often causes nonspecific binding of the conjugate to non-relevant components in a sample. Thus, antibody—enzyme conjugates formed using PEG-based reagents typically have better signal-to-noise ratios in assays, which can be very important when developing diagnostic or commercial assays.

2.4. Hydrazide-Activated Enzymes

Hydrazide groups can react with carbonyl groups to form stable hydrazone linkages. Derivatives of proteins formed from the reaction of their carboxylate side chains with adipic acid dihydrazide (Chapter 5, Section 8.1) and the water soluble carbodiimide EDC (Chapter 4, Section 1.1) create activated proteins that can covalently bind to aldehyde residues. Hydrazide-modified enzymes prepared in this manner can bind specifically to aldehyde groups formed by periodate oxidation of carbohydrates (Chapter 2, Section 4.4). These reagents can be used in assay systems to detect or measure glycoproteins in cells, tissue sections, or blots (Gershoni *et al.*, 1985).

Other molecules can be used in this type of assay approach, too. Hydrazide-modified (strept)avidin, lectins, biocytin, fluorescent probes, and other detectable molecules can be used to detect or image glycoconjugates in biological samples (Wilchek and Bayer, 1987).

The activation of enzymes using adipic acid dihydrazide and EDC is identical to the procedure outlined for the modification of (strept)avidin (Chapter 11, Section 5). Simply replace the (strept)avidin component for an equivalent mole amount of the enzyme of choice. Alternatively, hydrazide groups may be created on enzymes using the heterobifunctional chemoselective reagents described in Chapter 17, Section 2.

2.5. SPDP-Activated Enzymes

SPDP is a heterobifunctional crosslinker containing an NHS ester on one end and a pyridyl disulfide group on the other end (Chapter 6, Section 1.1). The NHS ester end can be used to modify amine groups on enzymes, forming amide bonds. The result of this procedure is to create sulfhydryl-reactive pyridyl disulfide groups on the surface of each enzyme molecule that are able to complex with thiol-containing proteins and other molecules. SPDP-activated enzymes may be purified and stored for extended periods without breakdown of the coupling capacity. The reaction with a sulfhydryl group forms a reversible disulfide linkage that can be cleaved with reducing agents.

The two-step nature of SPDP crosslinking provides control over the conjugation process. Complexes of defined composition can be constructed by adjusting the ratio of enzyme to secondary molecule in the reaction as well as the amount of SPDP used in the initial activation. The use of SPDP in conjugation applications is extensively cited in the literature, perhaps making it one of the more popular crosslinkers available. It is commonly used to form immunotoxins, antibody–enzyme conjugates, and enzyme-labeled DNA probes. A standard activation and coupling procedure using SPDP can be found in Chapter 6, Section 1.1.

3. PREPARATION OF BIOTINYLATED ENZYMES

Biotinylated enzymes can be used as detection reagents in (strept)avidin–biotin assay procedures. Particularly, in the bridged avidin–biotin (BRAB) approach or the ABC technique (Chapter 11, Section 2), a biotin-labeled enzyme is used as the signaling agent after the binding to an antigen of a biotinylated antibody and a (strept)avidin bridging molecule. The biotins on the surface of the enzyme can bind with extraordinary affinity to (strept)avidin–antibody complexes, providing near-covalent interaction potential with high specificity.

Adding a biotin label to an enzyme molecule is simple, given the wide variety of options available. A biotinylation reagent is chosen that has a reactive group that will couple to functional groups on the enzyme (Chapter 11, Section 6, and Chapter 18, Section 1.3). For instance, NHS–LC-biotin can be used to modify amine groups—a popular choice for many biotinylation procedures involving proteins (Chapter 11, Section 6.2). When free sulfhydryls are present, as in β-gal, a thiol-reactive biotin label may be more appropriate, such as biotin–BMCC (Chapter 11, Section 6.3). However, a better choice than these popular reagents may be to use hydrophilic biotinylation compounds containing a PEG spacer arm, which results in better solubility of the biotinylated enzyme (Chapter 18, Section 1.3). Biotin–PEG reactive compounds are available in different reactivities and spacer lengths to accommodate virtually any application. Enzymes and other proteins modified with these biotinylation reagents retain their water solubility better than when using aliphatic biotin compounds. The hydrophilic PEG spacer prevents aggregation of modified proteins and dramatically reduces nonspecific binding in assays.

CHAPTER

23

Nucleic Acid and Oligonucleotide Modification and Conjugation

Molecular biology techniques incorporating highly sensitive detection methods involving fluorescence, chemiluminescence, or chromogenic enzyme substrates are used widely for assaying oligonucleotide interactions. A major factor in the development of assay and detection systems for RNA and DNA measurement is the ability to modify a nucleic acid with a detectable component while not affecting base pairing. The attachment of a small label, such as a fluorescent molecule, or a large catalytic enzyme to an oligonucleotide probe forms the basis for constructing sensitive hybridization reagents that can be used to detect genomic sequences (Gottfried and Weinhold, 2011; Paredes *et al.*, 2011; Zohar and Muller, 2011). Unfortunately, the methods developed to crosslink or label proteins do not always apply to the modification of nucleic acids. The major reactive sites on proteins involve groups that are familiar and relatively easy to modify and derivatize, such as primary amines, sulfhydryls, glycans, or carboxylates. Oligonucleotides contain none of these groups and they may also be unreactive with many of the common electrophilic bioconjugation reagents discussed throughout this book.

To modify the unique chemical groups on nucleic acids, novel methods have been developed that allow derivatization through discrete sites on the available bases, sugars, or phosphate groups (see Chapter 2, Section 3 for a discussion of RNA and DNA structure). These chemical methods can be used to add a functional group or a label to an individual nucleotide or to one or more sites in oligonucleotide probes or full-sized genomic DNA or RNA polymers.

If an individual nucleotide is modified in the appropriate way, various enzymatic techniques can be used to polymerize the derivative into an existing oligonucleotide molecule. Alternatively, nucleotide polymers can be treated with chemical activators that can facilitate the attachment of a label at particular reactive sites. Thus, there are two main approaches to modifying DNA or RNA molecules: enzymatic or chemical. Both procedures can produce highly active conjugates for sensitive assays to quantify or localize the binding of an oligo probe to its complementary strand in a complex mixture.

The following sections describe the major enzymatic and chemical modification procedures used to label nucleic acids and oligonucleotides.

1. ENZYMATIC LABELING OF DNA

Enzymatic techniques can employ a variety of DNA- or RNA-specific enzymes, including polymerases, transferases, or ligases, to add controlled amounts of modified nucleotides to an existing oligonucleotide strand. The most common procedures utilize DNA polymerase I, terminal deoxynucleotide transferase (TdT), or T4 RNA ligase 1. The polymerase is most often used with a template to add modified nucleoside triphosphates to the end of a DNA molecule or to various sites within the middle of a sequence. The terminal transferase enzyme can add modified nucleotides to the 3′ end of a chain without a template. The T4 RNA ligase 1 enzyme similarly can add a single modified 5′ phosphoryl-terminated nucleotide to the 3′ hydroxyl-terminated end of an RNA strand. The following sections describe procedures for enzymatic labeling using random primed labeling, nick translation, PCR, 3′ tailing with terminal transferase, and 3′ labeling of RNA using T4 RNA ligase I.

1.1. Random-Primed Labeling

Three main procedures of enzyme labeling make use of a DNA polymerase to make a complementary modified oligo to a parent template: (1) random-primed labeling, (2) nick translation, and (3) polymerase

Bioconjugate Techniques, Third Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-382239-0.00023-6

chain reaction (PCR). In random-primed labeling, modified and unmodified deoxy nucleoside triphosphates (dNTPs) are added to a DNA template using a random mixture of hexa-deoxynucleotides to serve as 3′-OH primers. The form of polymerase typically used is the Klenow fragment which lacks the 5′–3′ exonuclease activity of intact *E. coli* DNA polymerase I (Feinberg and Vogelstein, 1983, 1984; Kessler *et al.*, 1990). The reaction creates a large selection of random complementary strands, which can be labeled in this process using virtually any affinity ligand or detection component attached to the dNTPs that is compatible with the polymerase enzyme. Random primed labeling is one of the most proficient methods of adding modified nucleotides in multiple positions along the length of an oligo strand. If it is used to incorporate ^{32}P radiolabeled nucleotides, which can be done at high density without affecting the resultant hybridization efficiency of the probe, then this method is likely the best route to making probes. It is also a simple way of tagging probes prepared from a restriction digest template with randomly incorporated, labeled nucleotides. When using biotin-labeled or fluorescently labeled nucleotides, however, the amount of labeling that is done on the complementary oligo needs to be controlled to not affect hybridization. The ratio of modified to unmodified dNTPs ultimately determines the degree of labeling within the growing complementary strands. The modified dNTPs that get incorporated into the labeled oligo can include detection molecules such as fluorescent dyes (Chapter 10) or affinity molecules such as a biotin (Chapter 11), which can be used with streptavidin conjugates to detect hybridization events. The preparation of non-self-quenching levels of fluorescent dye incorporation into DNA strands has been optimized to give highly sensitive probes (Yu *et al.*, 2012). Figure 23.1 illustrates the reactions that take place during a random primed labeling process.

Protocol for Random Primed Labeling of DNA

1. Denature 1 µg of probe DNA (single stranded) with 5 µg of random hexanucleotide primers by boiling for 5 min and then rapidly chill on ice. Incubate at least 10 min to allow the primers to hybridize to random sites within the probe DNA.
2. Add to a tube on ice, 5 µl of 10× random primed labeling buffer (0.5-*M* Tris, 0.1-*M* $MgCl_2$, 10-m*M* 2-mercaptoethanol, pH 6.6, containing 0.5 mg/ml BSA), 1 µl each of three types of unmodified deoxynucleoside triphosphates (dNTPs at 100-µ*M* concentration), 1 µl of a labeled dNTP (at 100-µ*M*), plus 48 µl of water. Then add 2 µl of DNA polymerase (5–10 units).
3. Combine the probe DNA/hexanucleotide preparation with the reaction solution and incubate for 2 h at 37°C.
4. Quench the reaction by the addition of 2 µl of 0.5-*M* EDTA, 2 µl of 10-mg/ml tRNA, and 150 µl of 10-m*M* Tris, pH 7.5.
5. Purify the labeled DNA from excess reactants by precipitation (or by use of a spin column—Qiagen). For the precipitation method, add 20 µl of 4-*M* LiCl and 500 µl of ethanol (chilled to −20°C). Mix well.
6. Store at −20°C for 30 min, and then separate the precipitated DNA by centrifugation at 12,000 *g*.
7. Remove the supernatant and wash the pellet with 70% and 100% ethanol, centrifuging after each wash.
8. Re-dissolve the labeled DNA pellet in water and store at −20°C until used.

1.2. Nick Translation Labeling

Nick translation labeling involves the use of a dual enzyme system acting on double-stranded DNA (Rigby *et al.*, 1977; Langer *et al.*, 1981; Höltke *et al.*, 1990). The enzymes pancreatic deoxyribonuclease I (DNase I) and *E. coli* DNA polymerase I act in tandem on a DNA helix to incorporate labeled nucleotides (dNTPs) into the sequence. DNase I is capable of breaking phosphodiester bonds in intact DNA double-stranded molecules. If it is used in the presence of magnesium ions, it limits the hydrolysis caused by the enzyme to a single strand at a time within the DNA helix. If DNase is further restricted in the amount added to the reaction, the number of breaks in the double helix can be controlled. The result of this reaction is the breaking of phosphodiester bonds along the DNA double helix, leaving an OH on the 3′ end and a phosphate on the 5′ end at the nick site. The addition of DNA polymerase I results in removal of the base at the 5′ end of the nick and replacement of it with a new nucleotide by attachment to the open 3′ OH group. By adding the appropriate labeled and unlabeled dNTPs to this reaction, the polymerase causes the breaks to be filled as quickly as they form from the added pool of nucleotides. Each time the polymerase enzyme adds a nucleotide, however, it attaches the new nucleotide at its 5′ phosphate end to the open 3′ OH group in a new phosphodiester bond, but it leaves the new 3′ OH end open. Thus, as a nucleotide is added into the gap, the nick in the strand moves toward the 3′ end of the DNA strand. Since a new nick opens in the chain each time a nucleotide is added, the reaction sequence repeats over and over again as the polymerase creates a new complementary strand and the nick moves (or is translated) down the DNA. The labeled and unlabeled nucleotides are incorporated into the growing sequence, resulting in the addition of a number of labels along the length of the new strand. Since a known quantity of labeled to unlabeled dNTPs is present during the

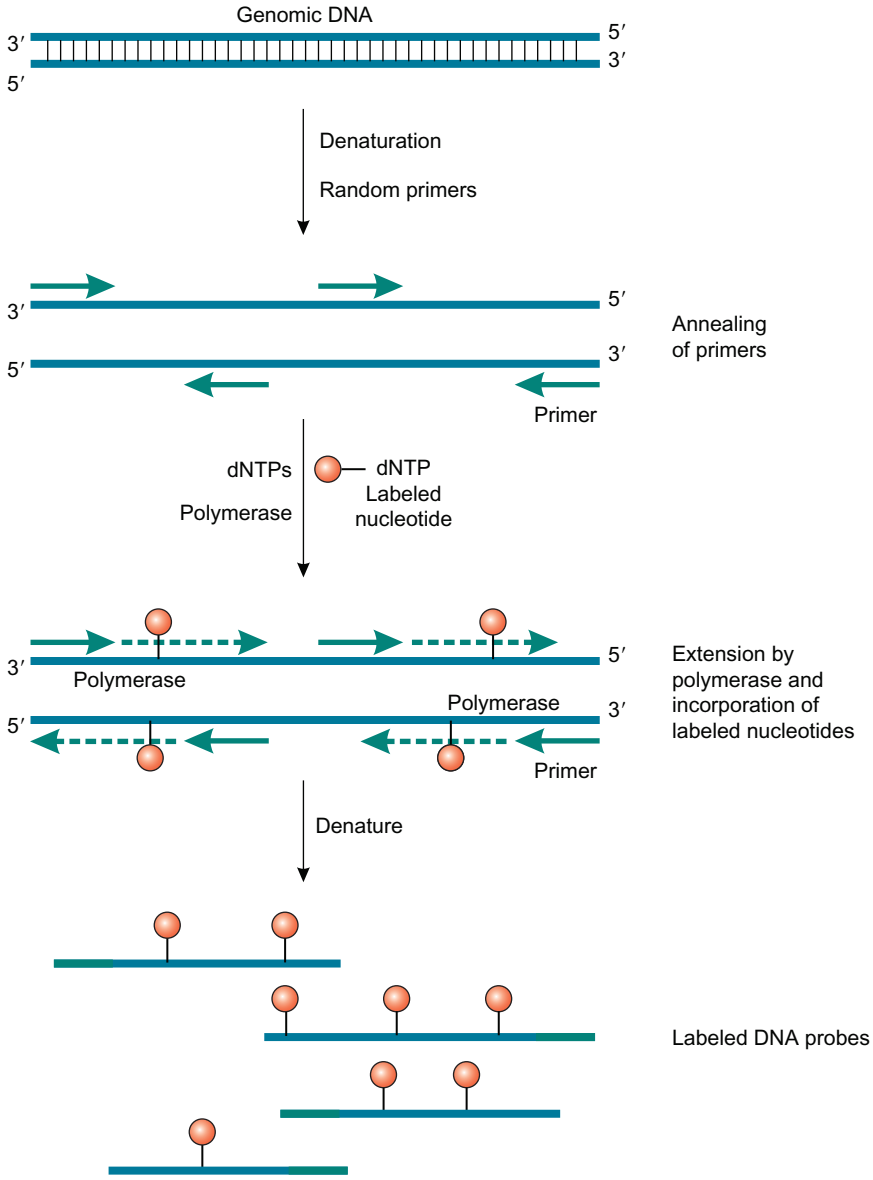

FIGURE 23.1 In a random primed labeling reaction a set of random primers is annealed to a denatured DNA sample and a complementary strand is synthesized using a polymerase enzyme in the presence of labeled and unlabeled dNTPs. The result is the generation of new oligonucleotides containing labeled nucleotides incorporated within their sequences.

reaction, the degree of labeling occurs at a predictable level as the parent DNA strands are modified (Figure 23.2).

Nick translation can be used to incorporate affinity tags such as biotin and fluorescent labels into an oligo probe for use in hybridization assays. Care should be taken to limit the number of modifications along the DNA strand so as not to affect the resultant hybridization efficiency with a target sequence. The labeling of a DNA strand with non-self-quenching fluorescent dyes has been optimized to result in the highest theoretical limit of incorporating modified nucleotides (Yu *et al.*, 2012).

Protocol for the Labeling of DNA by Nick Translation

1. In a tube kept cold on ice, add 10 µl of 10× nick-translation buffer (0.5-*M* Tris, 0.1-*M* $MgCl_2$, 0.08-*M* 2-mercaptoethanol, pH 7.5, containing 0.5 mg/ml bovine serum albumin (BSA), 0.5 µg of double-stranded probe DNA to be labeled, 1 µl of DNase I at a concentration of 2 ng/ml, 1 µl each of three types of unmodified deoxynucleoside triphosphates (dNTPs at 100-µ*M* concentration), 1 µl of a labeled dNTP (at 300-µ*M*), 32 µl water. Then add 1 µl of DNA polymerase containing 5 to 10 units of activity.

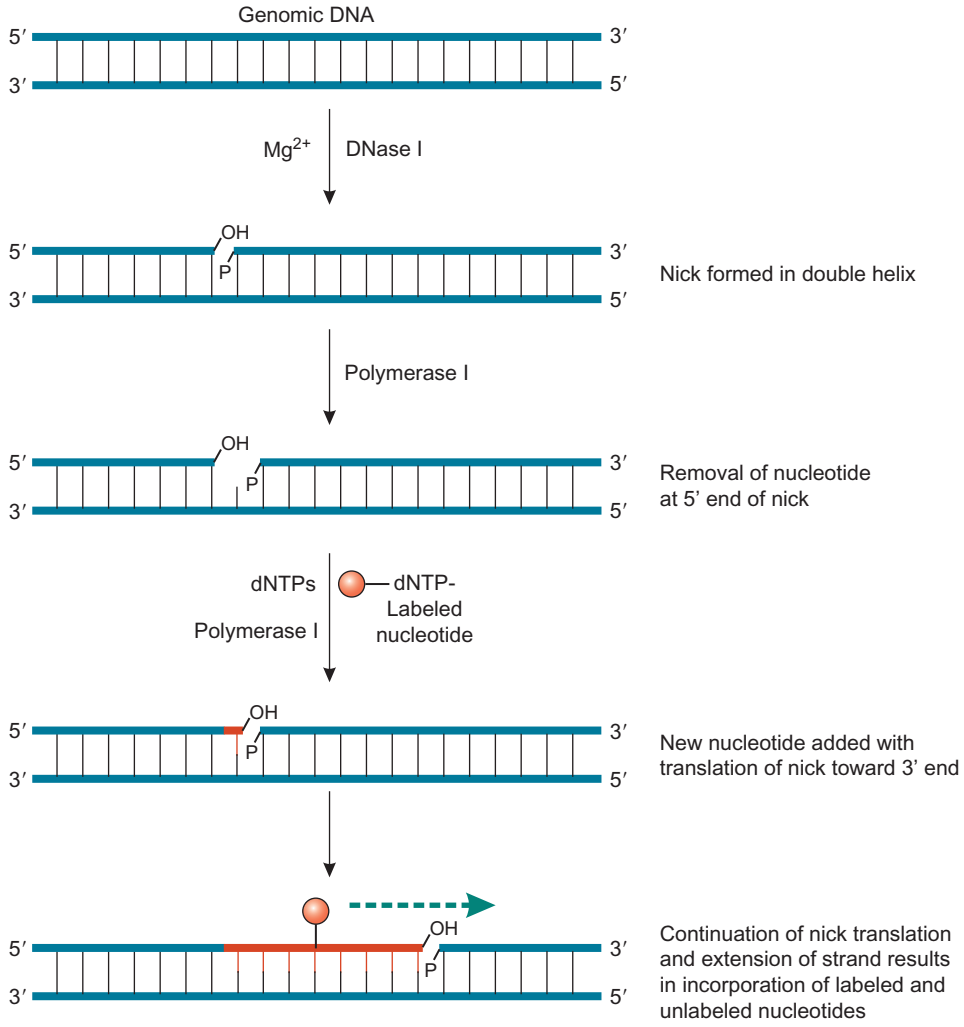

FIGURE 23.2 Nick translation labeling of DNA starts with the creation of defects within the sequence of existing DNA double-helix molecules by cleavage of phosphodiester bonds with DNase along the backbone of one strand. Polymerase then repairs these nicks beginning with the removal of the adjacent nucleotide and the immediate filling back in of those gaps with new nucleotides from the added dNTP pool. As each new nucleotide is added, the polymerase leaves the 3′ OH group open, thus translating the nick toward the 5′ end. As the reaction sequence is repeated, the polymerase enzyme continues to remove existing nucleotides and replace them with new ones at the site of the new nick. The result of these reactions is numerous labeled and unlabeled nucleotides being incorporated as a complementary sequence along the length of each DNA strand, starting at the site of the original nick.

2. React for 1 h at 15°C.
3. Quench the reaction by the addition of 4 µl of 0.25-*M* EDTA, 2 µl of 10-mg/ml tRNA, and 150 µl of 10-m*M* Tris, pH 7.5.
4. Purify the labeled DNA from excess reactants by precipitation (or by use of a spin column—Qiagen). For the precipitation method, add 20 µl of 4-*M* LiCl and 500 µl of ethanol (chilled to −20°C). Mix well.
5. Store at −20°C for 30 min, and then separate the precipitated DNA by centrifugation at 12,000 *g*.
6. Remove the supernatant and wash the pellet with 70% and 100% ethanol, centrifuging after each wash.
7. Re-dissolve the labeled DNA pellet in water and store at −20°C until used.

1.3. PCR Labeling

Enzymatic labeling of DNA by use of PCR techniques perhaps provides one of the most powerful ways of not only adding a label, but also of amplifying the labeled polymer to produce numerous copies of itself at the same time. First invented by Mullis (who went on to win the Nobel Prize; see Saiki *et al.*, 1985, 1988), PCR utilizes heat-stable forms of DNA polymerase, for example the commonly employed *Taq* polymerase isolated from thermophilic eubacterium (*Thermus aquaticus*). The stability of the enzyme allows repeated elevated-temperature denaturation of target DNA, followed by hybridization of primers onto the single strands. *Taq* DNA polymerase then

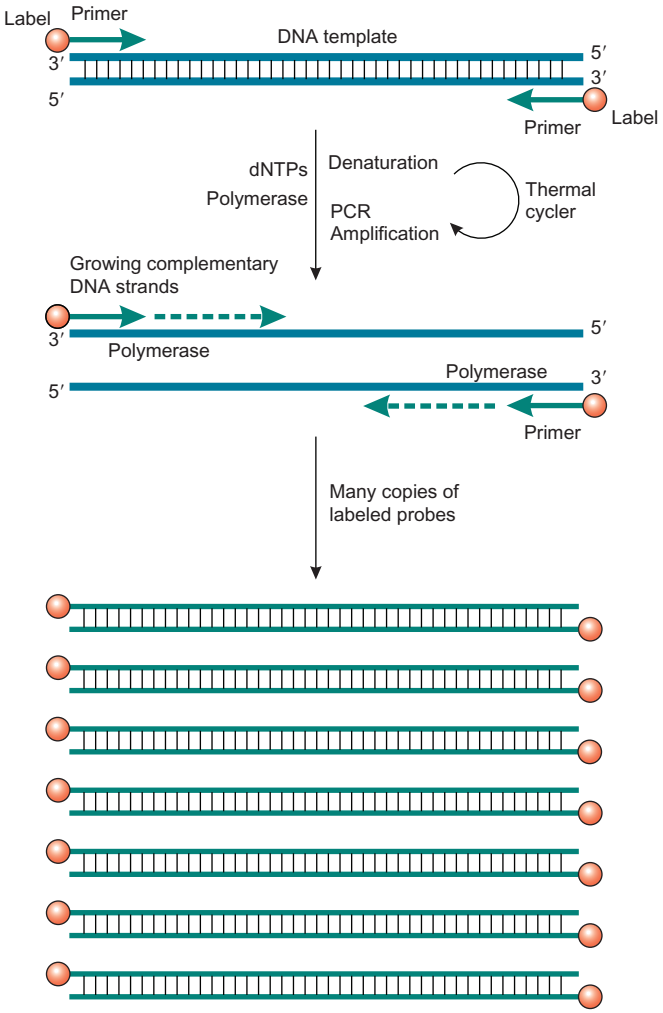

FIGURE 23.3 Labeling oligonucleotides by PCR can be carried out through the use of labeled primers or by the inclusion of labeled dNTPs within the reaction mixture. The polymerase enzyme simultaneously amplifies the original DNA template and incorporates labels within each of the copies.

creates a complementary sequence to the single strands by elongation of the primers. If repeated cycles of denaturation, hybridization, and elongation are done, the result is an exponential amplification of the original DNA strands (for a review of PCR, see van Pelt-Verkuil *et al.*, 2010; Innis *et al.*, 1990). Labeling of these amplified strands can be accomplished by one of two routes: using labeled primers that add the labels to the 3′ end regions of each new strand or by using labeled dNTPs that add labels to various sites within the complementary sequence. Either way, the *Taq* polymerase enzyme incorporates the labels into the growing DNA copies made during each PCR cycle (Figure 23.3). The fluorescent labeling and amplification of target DNA by PCR has resulted in extremely sensitive assays that can detect the target nearly down to the single molecule level (Hindson *et al.*, 2011).

Another popular technique for PCR labeling uses the enzyme Moloney murine leukemia virus (MMLV) reverse transcriptase to create a complementary labeled DNA (cDNA) probe from an RNA transcript. MMLV reverse transcriptase is an RNA-dependent DNA polymerase that can be used with labeled primers or labeled dNTPs to create the labeled cDNA oligo probe. RT-PCR-based labeling and detection has been used to create highly sensitive assays for viruses (Lung *et al.*, 2011).

There are many methods for performing PCR labeling that use different commercial enzyme and reagent formulations. The following method is a generalized one that can be customized to conform to any desired procedure. The preparation of the initial stock solutions is carried out in water.

Protocol for the Labeling of DNA Using PCR

1. Prepare a 10× PCR reaction buffer consisting of 100-m*M* Tris, 500-m*M* KCl, 20-m*M* $MgCl_2$, pH 8.4.
2. Prepare the following stock solutions in nuclease-free water:
   - **a.** DNA template at a concentration of about 0.5 to 1.0 ng/µl.
   - **b.** Primers at a concentration of about 25 to 50 µ*M*.
   - **c.** dNTPs in a single stock solution at a concentration of 33-m*M*. Reduce the concentration of the particular unlabeled dNTP by the concentration of the labeled dNTP that is to be added to the reaction. For instance, if a biotin–dUTP derivative is to be incorporated into the PCR product, then reduce the concentration of dTTP in the nucleotide stock solution. Some optimization of the concentration of the labeled dNTP may have to be done to obtain the best labeled oligo for a particular application.
   - **d.** Labeled dNTP solution at a concentration of 5-m*M*.
   - **e.** BSA at 10 mg/ml.
   - **f.** Taq polymerase at 5 U/µl.
   - **g.** $MgCl_2$ at 50-m*M*.
3. Mix the following quantities of each reagent in a PCR reaction tube:
   - **a.** 2.5 µl of 10× PCR reaction buffer
   - **b.** 1 to 2 µl of the DNA template
   - **c.** 1 µl of primers
   - **d.** 0.5 µl of the unlabeled dNTP mixture
   - **e.** 0.5 to 2.0 µl of the labeled dNTP
   - **f.** 2 µl of the $MgCl_2$ solution
   - **g.** 1 µl of the BSA solution
   - **h.** 0.2 to 0.4 µl of the Taq polymerase solution
   - **i.** Add water to make the total volume to 25 µl.
4. Perform PCR amplification/labeling using a thermal cycler to the desired number of cycles (e.g., 30 cycles).
5. Purify the labeled DNA by precipitation (as described in the previous protocol) or by use of a spin column (Qiagen).

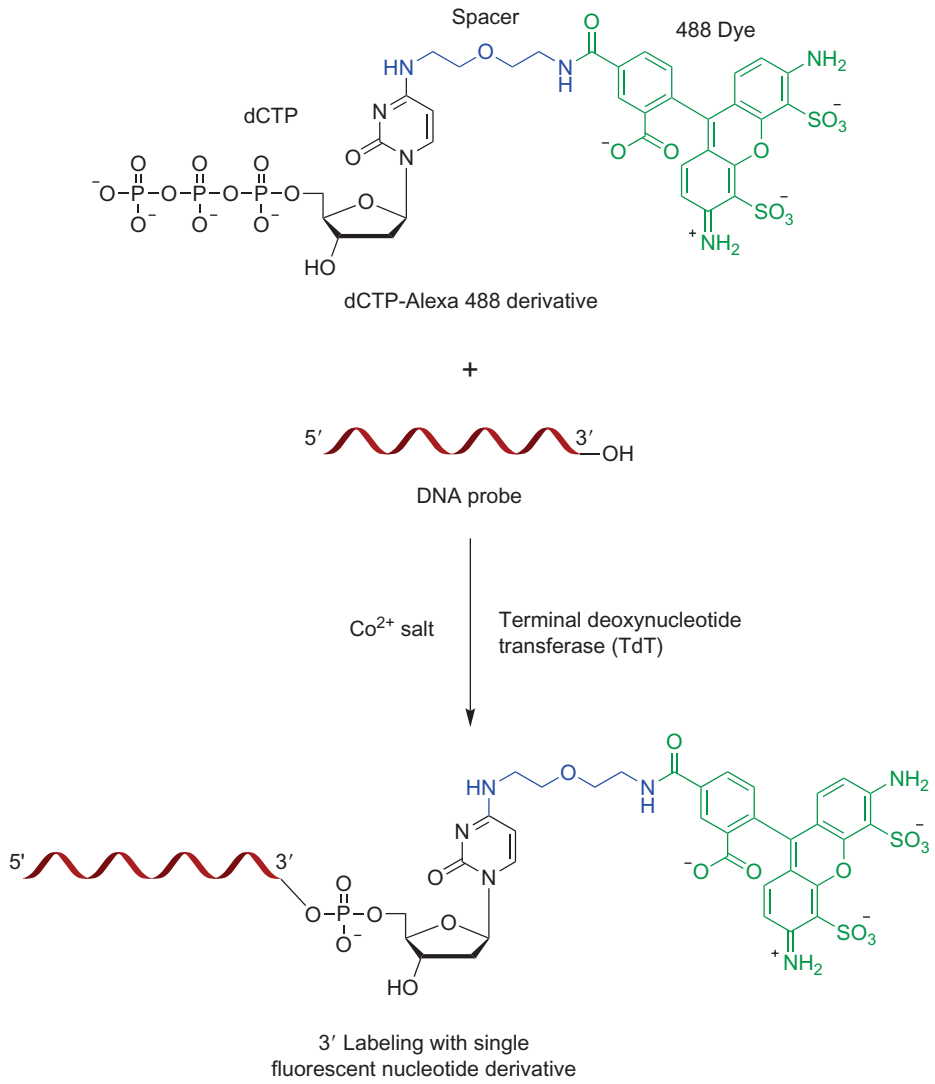

FIGURE 23.4 Oligonucleotide labeling by terminal transferase. Under controlled conditions, a single labeled nucleotide can be added to an existing DNA strand at its 3′ OH end without the need for a template. The Alexa 488 fluorescent dCTP derivative provides a bright green emission dye at the end of every oligo probe for detection purposes in hybridization assays. Other fluorescent dye derivatives may be used in similar labeling reactions.

1.4. Terminal Transferase Labeling

Enzymatic labeling using any of the polymerase-mediated methods (except when using labeled primers during PCR) results in derivatized dNTPs being incorporated at numerous locations within an oligonucleotide strand. These modifications can potentially interfere with the hybridization of a probe to a complementary sequence, especially if the level of labeling is high. Enzymatic labeling using terminal transferase is a way to avoid derivatization in the middle of a strand, and thus preserve sequence or targeting specificity. Terminal deoxynucleotidyl transferase (TdT) is a DNA polymerase enzyme commonly found in some lymphoid cell types. Under normal circumstances, TdT adds multiple dNTPs to the 3′ end of a DNA molecule. However, under the right conditions (in the presence of a Co^{2+} salt) the enzyme will add only a single base to the 3′ OH end (Horáková *et al.*, 2011) (Figure 23.4). It is also able to add the labeled nucleotide to the DNA without the need for a complementary template, thus making it capable of adding a labeled nucleotide to an existing single-stranded oligo probe. Since modification is limited to the end of the oligonucleotide and only one labeled nucleotide is added per strand, the main probe sequence is not disturbed by modifications that could possibly prevent hydrogen bonding interactions between base pairs. This process also is ideal for labeling a detection oligo at its 3′ end with biotin to detect hybridization events on oligo arrays. This discrete modification strategy ensures

that each detection oligo can interact with a streptavidin conjugate at its 3′ end, which can be designed in the assay to be pointing up from the array surface.

Terminal transferase labeling was originally developed using radiolabeled (typically ^{32}P) nucleoside triphosphates (Roychoudhury *et al.*, 1979; Tu and Cohen, 1980). Later, the technique was extended to the use of nonradioactive nucleotide derivatives (Kumar *et al.*, 1988). The technique is especially convenient for adding a single biotin affinity tag to the 3′ end of an oligo probe to facilitate the interaction of streptavidin detection conjugates at a position that will not interfere with oligo probe binding to a target sequence (Leduc *et al.*, 2011).

Protocol for Labeling DNA at the 3′ End Using Terminal Transferase

1. Prepare 1 µg of purified DNA probe, either by restriction digestion or by synthetic means.
2. Add to the purified probe: (a) 20 µl of 0.5-*M* potassium cacodylate, 5-m*M* $CoCl_2$, 1-m*M* dithiothreitol (DTT), pH 7.0; (b) 100 µ*M* of a modified deoxynucleoside triphosphate, 4 µl of 5-m*M* dCTP, and 100 µl of water. Mix.
3. Add terminal transferase to a final concentration of 50 units in the reaction mixture.
4. React for 45 min at 37°C.
5. Isolate the labeled probe by alcohol precipitation as described previously for nick translation.

1.5. T4 RNA Ligase 1 Labeling

The labeling of the 3′ hydroxyl end of RNA using T4 RNA ligase 1 is another way of adding a single nucleotide derivative to an oligonucleotide probe, similar to the use of terminal transferase with a DNA probe (described previously). It was originally developed to incorporate a radiolabeled (^{32}P) *bis*-phosphoryl–cytidine derivative onto an RNA probe (England *et al.*, 1977; England and Uhlenbeck, 1978). However, other derivatives of cytidine bases formed by modification of the C-5 site can be used with the T4 RNA ligase enzyme with success (Opperman *et al.*, 2011; Paredes *et al.*, 2011). For example, biotinylated or fluorescently labeled *bis*-phosphoryl–cytosine derivatives have been synthesized and used to create highly sensitive oligo probes (Kore *et al.*, 2009). In addition, T4 RNA ligase can be used with N-6-labeled *bis*-phosphoryl–adenosine derivatives to add a single labeled adenosine nucleotide to the 3′ end of RNA (Richardson and Gumport, 1983). The enzymatic techniques for end labeling of DNA and RNA have an advantage over the PCR methods, because they add only a single label to each oligo probe at a position that will not affect hybridization efficiency with DNA or RNA targets.

Unlike the polymerase-based labeling methods described previously that use nucleotide triphosphate derivatives, the type of labeled nucleotide required for T4 RNA ligase labeling is a *bis*-phosphoryl derivative, wherein the 3′ and 5′ hydroxyl groups both have a single phosphate group on them. The *bis*-phosphoryl derivative is required for ligase recognition and incorporation onto the 3′ end of an existing RNA strand. This reaction is illustrated in Figure 23.5.

Protocol for Labeling DNA at the 3′ End Using T4 RNA Ligase

The following protocol is based on the method described by Thermo Fisher for their RNA 3′ end biotinylation kit.

1. Prepare an RNA probe to be labeled at a concentration of 125 nM in water.
2. Add to a small centrifuge tube 3 µl of nuclease-free water and 3 µl of 10× reaction buffer (0.5-*M* Tris, 0.1-*M* $MgCl_2$, 0.1-*M* DTT, 10-m*M* ATP, pH 7.8).
3. Add 1 µl of an RNase inhibitor to this solution to prevent RNA digestion (use the recommended final concentration of the particular inhibitor chosen).
4. Add 5 µl of the unlabeled RNA probe from step 1 to the reaction mixture to obtain a final concentration of 50 p*M*.
5. Prepare a labeled cytidine *bis*-phosphate derivative wherein the label is attached to the C-5 carbon atom (e.g., biotin labeled) at a concentration of 1 m*M* in water. Add 1 µl of this labeled nucleotide to the reaction solution with mixing.
6. Add to the reaction mixture 2 µl of a 20,000-U/ml solution of T4 RNA ligase to obtain a final activity of 40 U.
7. Add 300 µl of a 30% PEG solution to obtain a final concentration of 15% PEG in the reaction mixture.
8. Incubate the reaction for at least 2 h at 16°C. The reaction may be carried out overnight to increase the yield if necessary.
9. Add 70 µl of additional nuclease-free water to the reaction with mixing.
10. Extract and remove the RNA ligase enzyme from the reaction by the addition of 100 µl of chloroform : isoamyl alcohol and vortex mix thoroughly. Centrifuge the mixture to separate the phases and recover the top aqueous phase carefully from the tube.
11. Add to the aqueous phase 10 µl of 5-*M* NaCl followed by 1 µl of 20 mg/ml glycogen and 300 µl of ice-cold ethanol (100%).
12. Allow the labeled RNA to precipitate for 1 h at −20°C and centrifuge at 13,000 *g* for 15 min to pellet the precipitated oligo. Remove the supernatant and wash the pellet with an additional 300-µl quantity of ice-cold ethanol, then centrifuge a nd remove the ethanol. Allow the pellet to dry and redissolve the labeled RNA in nuclease-free water or a buffer for use.

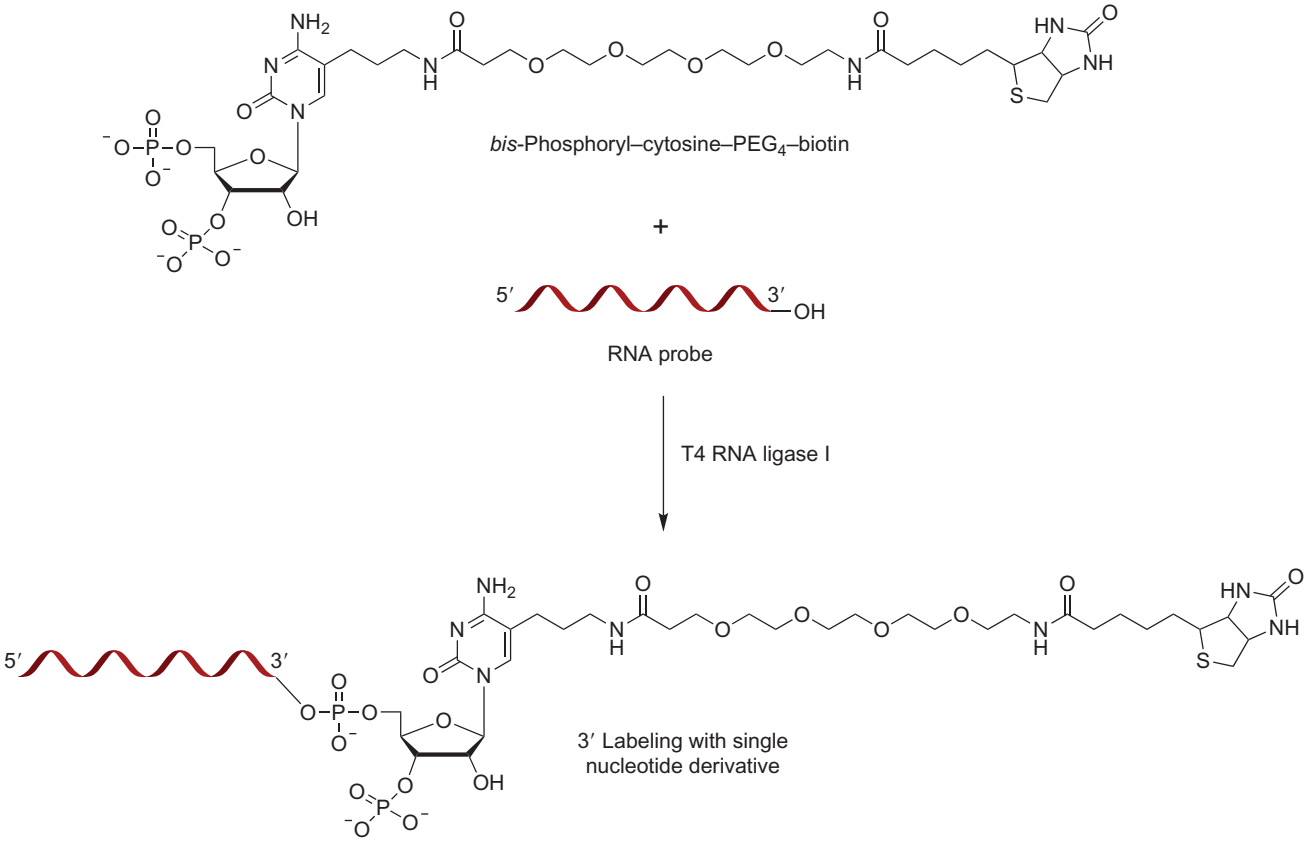

FIGURE 23.5 Labeling of an oligo probe can be done at the 3′ end of an existing RNA molecule by the use of T4 RNA ligase. The reaction attaches a single labeled *bis*-phosphoryl nucleotide to the 3′ OH without the need for a template. The *bis*-phosphoryl–cytosine–biotin derivative provides a biotinylated oligo probe that can be detected using streptavidin conjugates.

Regardless of the type of enzymatic labeling being done, it is important that the label be incorporated into the nucleotides or primers in a way that does not affect enzyme recognition and activity. Thus, every enzymatic labeling procedure for modifying RNA or DNA probes must start with chemical derivatization of individual nucleotides. Of the many chemical approaches that can be used to modify a nucleotide monomer, there are only a few that will result in a derivative still able to be enzymatically added to an existing oligonucleotide strand.

Of the purine nucleotides, dATP may be derivatized at its N-6 position using a long linker arm terminating in a detectable group without losing the ability to be enzymatically incorporated into DNA probes. By contrast, if modification is performed at the C-8 position of purine bases, DNA polymerase cannot be used to add the labeled monomer to an existing strand. C-8 derivatives of purines, however, can be added at the 3′ terminal using terminal transferase or T4 RNA ligase enzymes.

The pyrimidine nucleosides dUTP or dCTP can be modified at their C-5 position with a spacer arm containing a tag, such as a biotin group or a fluorescent molecule, and still remain good substrates for DNA polymerase. Enzymatic labeling with a biotin-modified pyrimidine-based dNTP is one of the most common methods of adding a detectable group to an existing DNA strand.

Figure 23.6 illustrates some of the common nucleoside triphosphate derivatives that can be used in enzymatic labeling processes. For a review of these methods in greater detail, see Gottfried and Weinhold (2011), Horakova *et al.* (2011), Kricka (1992), or Keller and Manak (1989). See Section 2 for a discussion of the chemical methods that can be used to label individual nucleic acids for incorporation into oligonucleotides by enzymatic means.

2. CHEMICAL MODIFICATION OF NUCLEIC ACIDS AND OLIGONUCLEOTIDES

The chemical modification of nucleic acids at specific sites within individual nucleotides or within

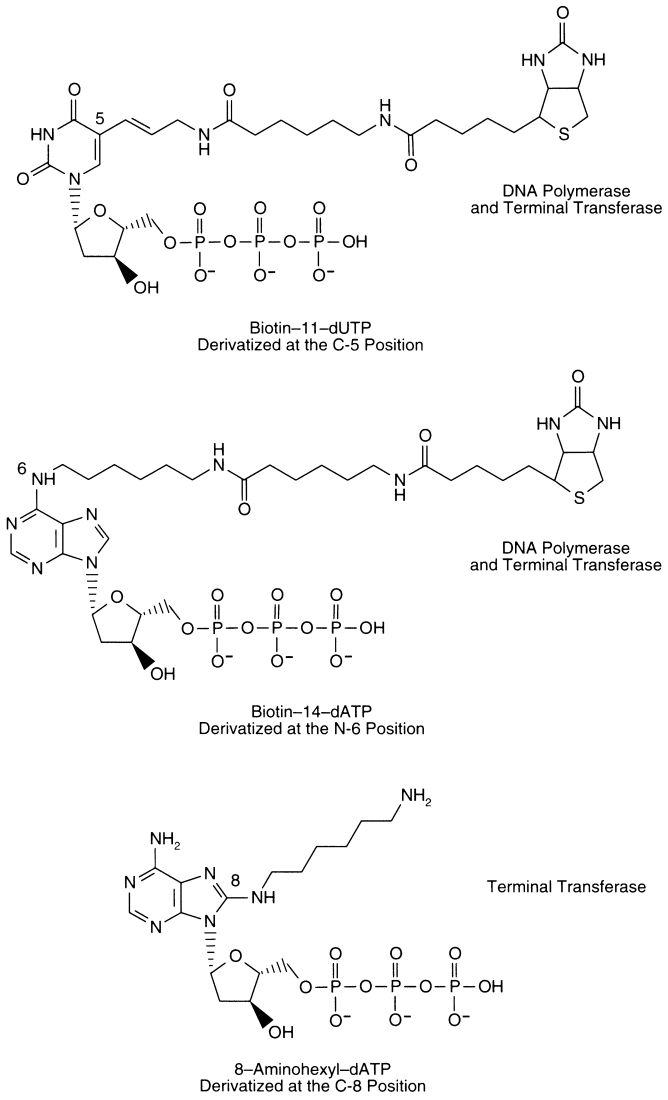

FIGURE 23.6 Three common nucleoside triphosphate derivatives that can be incorporated into oligonucleotides by enzymatic means. The first two are biotin derivatives of pyrimidine and purine bases, respectively, that can be added to an existing DNA strand using either polymerase or terminal transferase enzymes. Modification of DNA with these nucleosides results in a probe detectable with labeled avidin or streptavidin conjugates. The third nucleoside triphosphate derivative contains an amine group that can be added to DNA using terminal transferase. The modified oligonucleotide can then be labeled with amine-reactive bioconjugation reagents to create a detectable probe.

oligonucleotides allows various labels to be incorporated into DNA or RNA probes. This labeling process can produce conjugates having sensitive detection properties for the localization or quantification of oligo binding to a complementary strand using hybridization assays.

Some form of chemical labeling process must be used regardless of whether the final oligo conjugate is created by enzymatic or strictly chemical means. If enzymatic modification is to be performed, the initial label still must be incorporated into an individual nucleoside triphosphate, which is then polymerized into an existing oligonucleotide strand (Section 1). Fortunately, many useful modified nucleoside triphosphates are now available from commercial sources, often eliminating the need for custom derivatization of individual nucleotides.

Chemical modification may also be used to directly label an oligonucleotide, eliminating the enzymatic step altogether. The chemical modification of nucleic acids can encompass several strategies, ranging from creating intermediate derivatives containing a functional group needed for subsequent conjugation, producing a reactive group that can spontaneously couple to a desired biomolecule, or forming a final covalent linkage to a surface, such as a particle or planar array. The initial derivatization might only be done to add a spacer arm to a particular site on the nucleotide structure. The spacer typically contains a terminal functional group, such as an amine, that can be used to couple with another molecule. Another modification built upon this amine derivative might be to add a fluorescent probe to the end of the spacer, thus creating a detectable complex. The spacer may also be used to react with a crosslinking agent, such as a heterobifunctional compound (Chapter 6), which can facilitate the conjugation of a protein or another molecule to the modified nucleotide. It should be noted that if enzymatic methods are used to incorporate a small spacer into an oligonucleotide, subsequent chemical conjugation steps still will be needed to label the oligo at this site or link it with another molecule.

In some cases, if an oligonucleotide contains the appropriate functional group, a label may be directly incorporated into it using chemical methods. For instance, certain fluorescent molecules or biotin tags can be used to modify nucleotides without going through an initial derivatization step with a spacer arm. Such labels usually contain nucleophilic or photoreactive groups that can couple directly to the oligo using an intermediate activating agent or by exposure to UV light, respectively.

Many of the chemical derivatization methods employed in these strategies involve the use of an activation step that produces a reactive intermediary. The activated species can then be used to couple a molecule containing a nucleophile, such as a primary amine or a thiol group. The following sections describe the chemical modification methods suitable for derivatizing individual nucleic acids as well as oligonucleotide polymers.

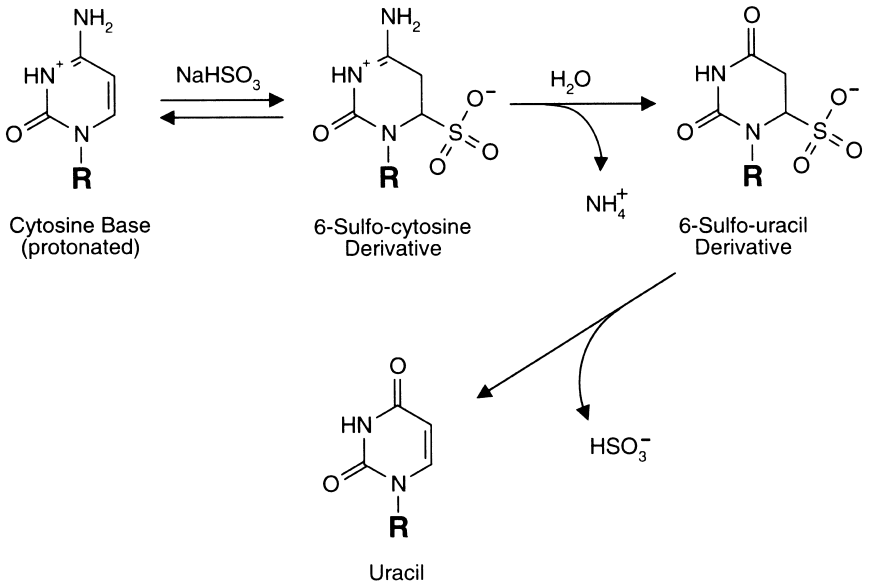

FIGURE 23.7 Treatment of cytosine bases with bisulfite results in a multistep deamination reaction, ultimately leading to uracil formation.

2.1. Diamine or *bis*-Hydrazide Modification of DNA

One of the more useful chemical modifications that can be performed on nucleic acids or oligonucleotides is to add an amine-terminal spacer arm using a diamine compound. The resultant amine derivative can be targeted by numerous amine-reactive crosslinkers or modification reagents to create a detectable conjugate. A similar approach can be used to modify a DNA probe with a *bis*-hydrazide compound (Chapter 5, Section 8) to produce terminal hydrazide group. The oligonucleotide derivative can then be coupled with aldehyde-containing molecules to form conjugates. The following methods utilize activation reagents which transform a particular site on nucleic acids into an amine-reactive or hydrazide-reactive intermediate. Coupling a diamine or *bis*-hydrazide compound to these activated species results in the formation of an alkyl spacer arm terminating in a primary amine group or a hydrazide functional group, respectively.

Conjugation via *Bisulfite Activation of Cytosine*

Single-stranded DNA molecules can react with sodium bisulfite, adding a sulfonate group across the 5,6-double bond of cytidine bases and creating 6-sulfocytosine derivatives. The reaction also catalyzes the deamination of cytosine to uracil by loss of the 4-amino group, which is the first step in assays that determine DNA methylation (Cheung *et al.*, 2012). Subsequent loss of HSO_3^- effectively forms the uracil base (Figure 23.7). This reaction sequence was recognized in the early 1970s as potential evidence for the mutagenicity of bisulfite (Shapiro *et al.*, 1973, 1974). Shapiro and Weisgras (1970) demonstrated that the bisulfite reaction also can cause transamination to occur at the N-4 position of cytosine. In the presence of an amine-containing molecule, such as a diamine, sodium bisulfite will cause the exchange of the N-4 amine for another amine-containing compound, effectively forming a new covalent linkage with release of ammonium ion (Figure 23.8). Draper and Gold (1980) used this reaction to produce primary amine groups on a poly(C) oligonucleotide by coupling 1,3-diaminopropane to a limited number of the cytosine residues. The amine derivative subsequently could be used to couple a fluorescent probe to the polymer, allowing sensitive studies of messenger RNA.

Bisulfite-catalyzed transamination can also be used to label oligonucleotide probes for application in non-radioisotopic hybridization assays. Viscidi *et al.* (1986) described a method for derivatizing cytosine groups in DNA probes using the short spacer, ethylenediamine. Other diamine molecules may also be used, such as 1,3-diaminopropane, 1,6-diaminohexane, or 3,3′-iminobispropylamine. The use of the long, hydrophilic Jeffamine molecules (Huntsman International; see Chapter 2, Section 4.3, and Chapter 15, Section 2.8) may be especially well suited for this type of modification due to the presence of a hydrophilic polyethylene glycol (PEG)-based spacer. Longer spacer arms may provide better steric accommodation for larger detection components without interfering substantially in the probe's ability to hybridize to a complementary DNA strand.

If an amine-containing fluorescent probe or hydrazide-containing compound is transaminated onto

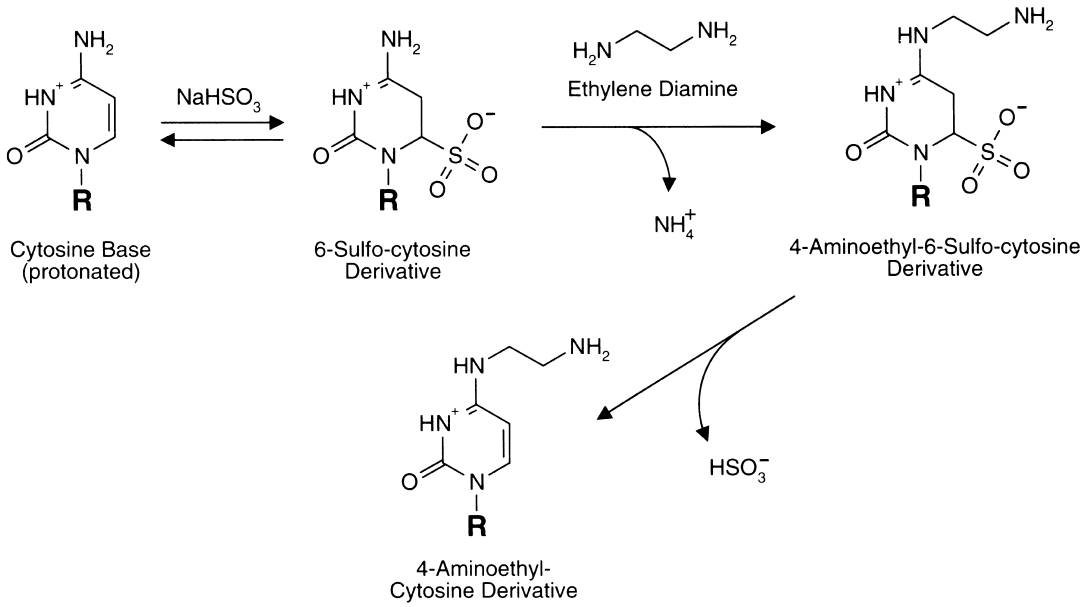

FIGURE 23.8 The reaction of cytosine with bisulfite in the presence of an excess of an amine nucleophile (such as a diamine compound) leads to transamination at the N-4 position. This process is a route to adding an amine functional group to cytosine residues in oligonucleotides.

an oligonucleotide using bisulfite, the labeling of nucleic acids can be done in a single step. An example of this approach is the coupling of biotin hydrazide (Chapter 11, Section 6.4) to cytosine residues, resulting in a biotinylated oligonucleotide suitable for (strept) avidin-based detection systems (Reisfeld *et al.*, 1987) (Chapter 11, Section 2).

Since the site of modification on cytosine bases is at a hydrogen bonding position in double-helix formation, the degree of bisulfite derivatization should be carefully controlled. Reaction conditions such as pH, diamine concentration, and incubation time and temperature affect the yield and type of products formed during the transamination process. At low concentrations of diamine, deamination and uracil formation dramatically exceed transamination. At high concentrations of diamine (3-*M*), transamination can approach 100% yield (Draper and Gold, 1980). Ideally, only about 30 to 40 bases should be modified per 1000 bases to ensure hybridization ability after derivatization.

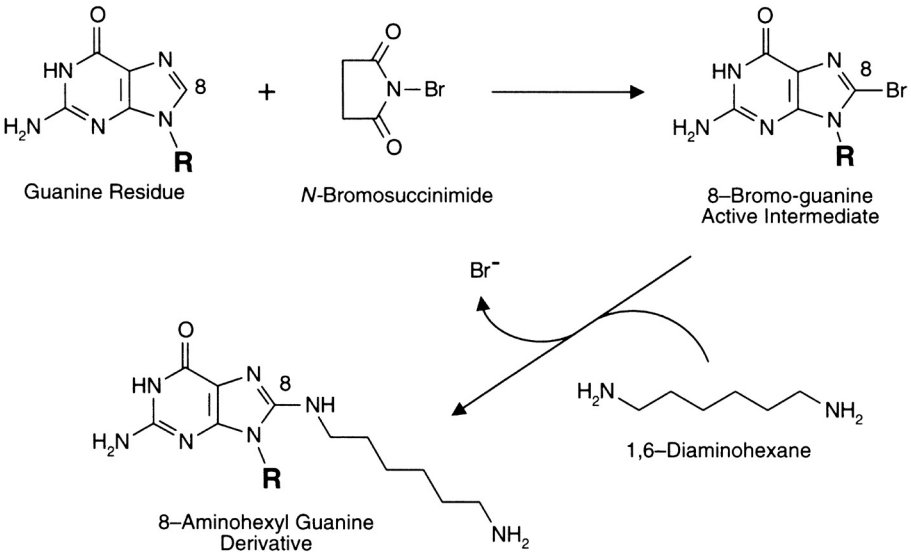
Bisulfite modification of cytosine residues also can be used to permanently add a sulfone group to the C-6 position. In this scheme, the sulfone functions as a hapten recognizable by specific anti-sulfone antibodies. At high concentrations of bisulfite and in the presence of methylhydroxylamine, cytosines are transformed into N^4-methoxy-5,6-dihydrocytosine-6-sulphonate derivatives (Herzberg, 1984; Nur *et al.*, 1989). Labeled antibodies can then be used to detect the hybridization of such probes.

Protocol for Labeling Nucleic Acids by Bisulfite-Catalyzed Transamination

1. Prepare single-stranded DNA (denatured) at a concentration of 1 mg/ml.
2. Prepare bisulfite modification solution consisting of: 3-*M* concentration of a diamine (i.e., ethylenediamine), 1-*M* sodium bisulfite, pH 6. The use of the dihydrochloride form of the diamine avoids having to adjust the pH down from the severe alkaline pH of the free-base form. Note: The optimum pH is 4.5 for the transamination of biotin–hydrazide to cytosine residues using bisulfite (see Section 2.3).
3. Add 20 µl of the DNA to 180 µl of bisulfite modification solution. Mix well.
4. React for 3 h at 42°C.
5. Dialyze the solution against water overnight at 4°C to remove excess reactants.
6. The modified DNA may be recovered by alcohol precipitation according to the method in Section 1 described previously for nick-translation modification. Alternatively, dialysis or gel filtration may be carried out to remove excess reactants.

Conjugation via Bromine Activation of Thymine, Guanine, and Cytosine

The nucleotide bases of DNA and RNA can be activated with bromine to produce reactive intermediates capable of coupling to nucleophiles (Traincard *et al.*, 1983; Sakamoto *et al.*, 1987; Keller *et al.*, 1988;



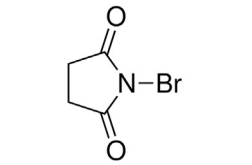


FIGURE 23.9 Reaction of guanine bases with N-bromosuccinimide causes bromination at the C-8 position of the ring. Amine nucleophiles can be coupled to this active derivative by nucleophilic displacement. Reaction of diamine compounds results in amine terminal spacers that can be further modified to contain detectable components.

Litosh *et al.*, 2011). Bromination occurs at the C-8 position of guanine residues and the C-5 of cytosine, yielding reactive derivatives which can be used to couple diamine spacer molecules by nucleophilic substitution (Figure 23.9). Other pyrimidine derivatives are also reactive to bromine compounds, but adenine residues are more resistant. However, even AMP can be immobilized through the introduction of an aminohexyl spacer at the C-8 position using bromination (Lowe, 1979). Either an aqueous solution of bromine or the compound *N*-bromosuccinimide can be used for this reaction. The alkaline modification proceeds rapidly but may be too severe for RNA molecules. Coupling of amine-containing molecules is done at elevated temperatures (50°C) to ensure good incorporation. Both amine-bearing spacers and probes may be coupled using this strategy. Moreover, the sites of derivatization using bromine activation are not involved in hydrogen bonding during base pairing, thus maintaining hybridization ability in the final conjugate.

N-Bromosuccinimide
MW 177.98

Optimal bromination of a DNA probe is in the range of 30 to 35 bases per 1000 bases, a level which can be controlled by the amount of *N*-bromosuccinimide added. Over-labeling can prevent specific interactions with target DNA, even if the point of initial modification is not a hydrogen bonding site.

The major disadvantage with bromination is the extreme toxicity of bromine. Use a fume hood for all operations. Avoid the breathing of fumes or contact with skin or eyes. Protective clothing and gloves are recommended.

Protocol for Labeling Nucleic Acids by N-Bromosuccinimide Activation

(A) BROMINATION

1. Mix in a microfuge tube 20 µg of the DNA probe to be labeled, 20 µl of 1-*M* sodium bicarbonate, pH 9.6, and 196 µl of water. Chill on ice.
2. In a fume hood, dissolve *N*-bromosuccinimide (Thermo Fisher) in water at a concentration of 1.42 mg/ml.
3. Add 4 µl of the *N*-bromosuccinimide solution to the DNA solution (makes an 8-m*M* final concentration of brominating reagent). Mix well.
4. React on ice for 10 min. Use the bromine-activated DNA immediately.

(B) COUPLING A DIAMINE-CONTAINING SPACER OR PROBE

1. Dissolve a diamine spacer (i.e., ethylenediamine or 1,6-diaminohexane—Thermo Fisher) in water at a concentration of 80 to 100-m*M*. Caution: Amine-containing molecules such as diamines are highly corrosive if they are in the free-base form (not the

dihydrochloride). Work in a fume hood and wear gloves and other protective clothing. The pH of an aqueous solution of free-base diamine will be >pH 12 and may fume, especially during neutralization. The solution will also generate heat upon dissolution of the amine. Keeping it in an ice bath will help maintain a cool solution with less fuming. Using a dihydrochloride form of a diamine, if available, will avoid the problems associated with corrosiveness, heat, and fuming.

2. Add 25 µl of the diamine solution to the bromine-activated DNA solution prepared in protocol (A), above.
3. React for 1 h at 50°C.
4. The diamine-modified DNA may be isolated from excess reactants by ethanol precipitation according to steps 4 to 7 of the protocol described earlier for nick translation (Section 1). Alternatively, dialysis or gel filtration may be done to remove excess reactants.

Conjugation via Carbodiimide Reaction with the 5′ Phosphate of DNA (Phosphoramidate Formation)

The water soluble carbodiimide EDC (Chapter 4, Section 1.1) rapidly reacts with carboxylates or phosphates to form an active complex able to couple with amine-containing compounds. The carbodiimide activates an alkyl phosphate group to a highly reactive phosphodiester intermediate. Diamine spacer molecules or amine-containing probes then may react with this active species to form a stable phosphoramidate bond. Alternatively, *bis*-hydrazide compounds (Chapter 5, Section 8) may be coupled to DNA using this protocol to result in terminal hydrazide groups able to react with aldehyde-containing molecules (Ghosh *et al.*, 1989). Specific labeling of DNA probes only at the 5′ end is possible using these techniques.

Carbodiimide modification of the phosphomonoester end groups on DNA molecules was first used in Khorana's lab to determine nucleotide sequences (Ralph *et al.*, 1962). That early work used the water-insoluble reagent N,N′-dicyclohexylcarbodiimide (DCC) (Chapter 4, Section 1.4) in an organic/aqueous solvent system to effect the conjugations.

Chu *et al.* (1983, 1986) and Ghosh *et al.* (1990) described modified carbodiimide protocols using the water soluble reagent EDC instead of DCC. They also incorporate a second reactive intermediate, a phosphorimidazolide, created from the reaction of the phosphomonoester at the 5′-terminus of DNA with EDC in the presence of imidazole. A reactive phosphorimidazolide will rapidly couple to amine-containing molecules to form a phosphoramidate linkage (Figure 23.10). The chemistry had been used previously to cause the formation of phosphodiester linkages between short DNA strands (Shabarova *et al.*, 1983).

The formation of a phosphorimidazolide intermediate provides better reactivity toward amine nucleophiles than the EDC phosphodiester intermediate if EDC is used without added imidazole. The EDC phosphodiester intermediate also has a shorter half-life than the phosphorimidazolide in aqueous conditions due to hydrolysis. Although EDC alone will create nucleotide phosphoramidate conjugates with amine-containing molecules (Shabarova, 1988), the result of forming the secondary phosphorimidazolide-activated species is increased conjugation yield over carbodiimide-only reactions.

The downside of EDC conjugation with oligonucleotides is the potential for reaction of the carbodiimide at the guanosine N-1 site or with thymidine residues (von der Haar *et al.*, 1971). In practice, however, this cross-reactivity appears to be low enough to maintain complete biological activity and hybridization efficiency in the final conjugate, indicating most of the derivatization occurs at the 5′ phosphate group (Chu *et al.*, 1983).

Carbodiimide-mediated labeling of DNA or RNA probes at the 5′-phosphate end has been used as a general method of end-labeling RNA (Paredes *et al.*, 2011), to fabricate DNA-polymer brush arrays (Barbee *et al.*, 2011), for fluorescent tagging of small mRNAs (Vogel and Richert, 2012), and to fix siRNA molecules in cells by crosslinking to any nearby amines for subsequent probing by hybridization using the tyramide signal amplification (TSA) process (Shi *et al.*, 2011).

The following protocol describes the modification of DNA or RNA probes at their 5′-phosphate ends with a *bis*-hydrazide compound, such as adipic acid dihydrazide or carbohydrazide. A similar procedure for coupling the diamine compound cystamine can be found in Section 2.2.

Protocol

1. Weigh out 1.25 mg of the carbodiimide EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride; Thermo Fisher) into a microfuge tube.
2. Add to the tube 7.5 µl of RNA or DNA containing a 5′ phosphate group. The concentration of the oligonucleotide should be 7.5 to 15 nmol or total of about 57 to 115.5 µg. Also immediately add 5 µl of 0.25-*M bis*-hydrazide compound dissolved in 0.1-*M* imidazole, pH 6.0. Because EDC is labile in aqueous solutions, the addition of the oligo and *bis*-hydrazide/imidazole solutions should be performed quickly.
3. Mix by vortexing, then place the tube in a microcentrifuge and spin for 5 min at maximal rpm.

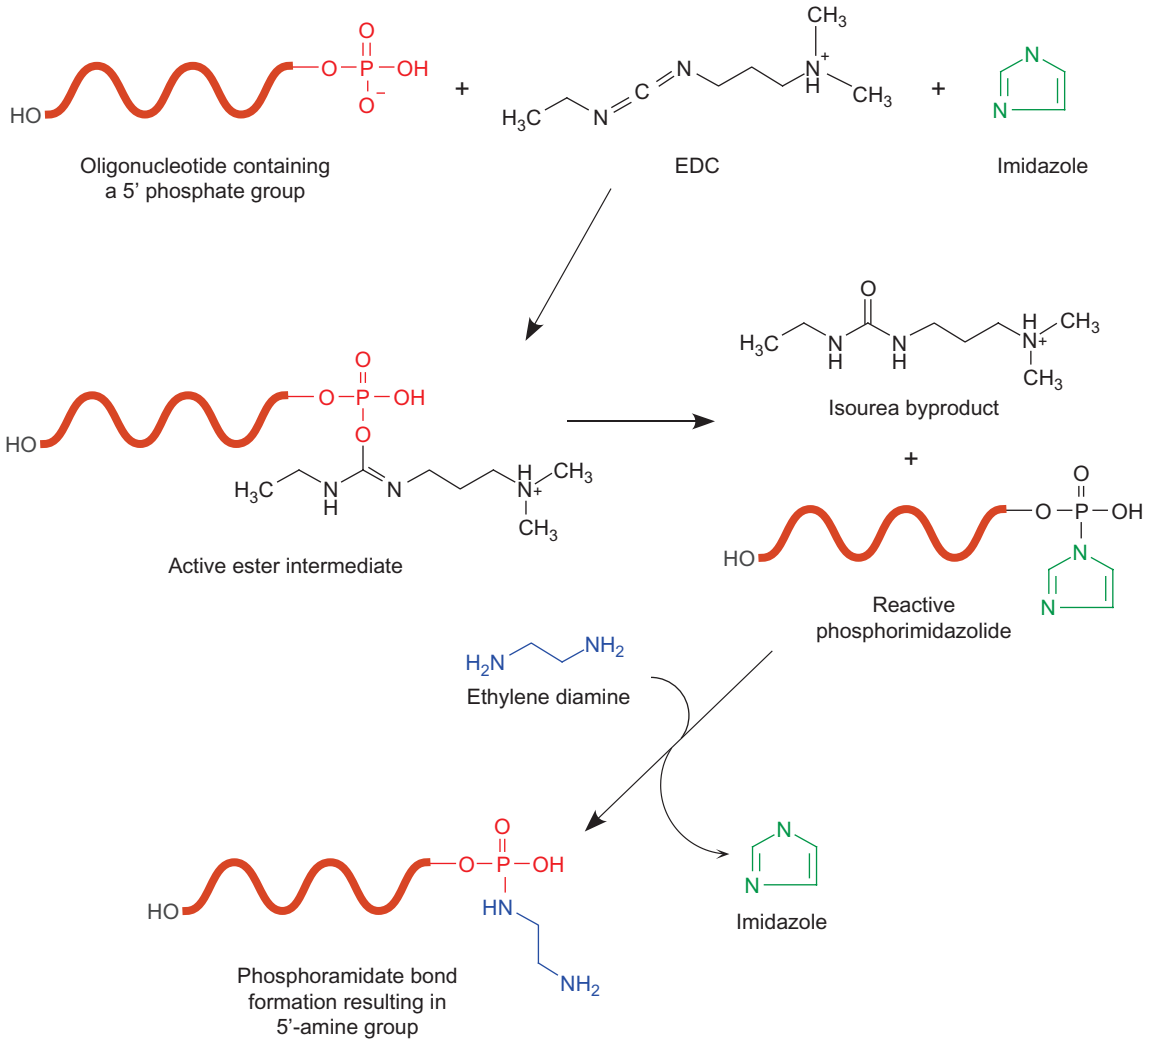

FIGURE 23.10 Oligonucleotides containing a 5′-phosphate group can be reacted with EDC in the presence of imidazole to form an active phosphorimidazolide intermediate. This derivative is highly reactive with amine nucleophiles, forming a phosphoramidate linkage. Diamines reacted with the phosphorimidazolide result in amine terminal spacers that can be modified with detectable components.

4. Add an additional 20 µl of 0.1-*M* imidazole, pH 6.0. Mix and react for 30 min at room temperature.
5. Purify the hydrazide-labeled oligo by gel filtration on desalting resin using 10-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2. The probe may now be used to conjugate with an aldehyde-containing molecule.

2.2. Sulfhydryl Modification of DNA

Creating a sulfhydryl group on nucleic acid probes allows conjugation reactions to be performed with sulfhydryl-reactive heterobifunctional crosslinkers (Chapter 6), providing increased control over the derivatization process. Proteins can be activated with a crosslinking agent containing an amine-reactive and a sulfhydryl-reactive end, such as *N*-succinimidyl 3-(2-pyridyldithio)propionate (SPDP) (Chapter 6, Section 1.1), leaving the sulfhydryl-reactive portion free to couple with the modified DNA probe. Having a sulfhydryl group on the probe directs the coupling reaction to a discrete site on the nucleotide strand, thus better preserving hybridization ability in the final conjugate. In addition, heterobifunctional crosslinkers of this type allow two- or three-step conjugation procedures to be carried out, which result in better yield of the desired conjugate than when using homobifunctional reagents.

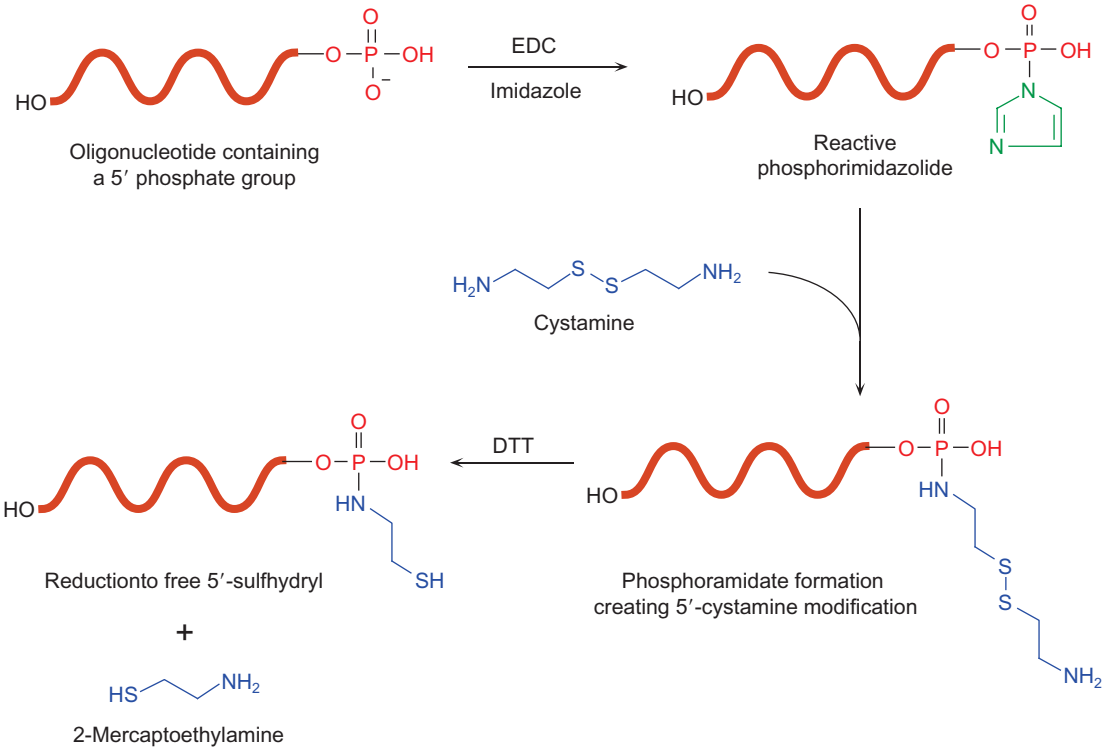

FIGURE 23.11 The 5′-phosphate group of oligonucleotides may be labeled with cystamine using the EDC/imidazole reaction. This results in the formation of an amine terminal spacer containing an internal disulfide group. Reduction of the disulfide provides a route for creating a free thiol for further derivatization.

Cystamine Modification of 5′ Phosphate Groups Using EDC

DNA or RNA may be modified with cystamine at the 5′ phosphate group using a carbodiimide reaction identical to that described previously (Section 2.1). In some procedures, the reaction is carried out in a two-step process by first forming a reactive phosphorimidazolide by EDC conjugation in an imidazole buffer. Next, cystamine is reacted with the activated oligonucleotide, causing the imidazole to be replaced by the amine and creating a phosphoramidate linkage (Chu *et al.*, 1986). An easier protocol was described by Ghosh *et al.* (1990) in which the oligo, cystamine, and EDC were all reacted together in an imidazole buffer. A modification of this method developed by Zanocco *et al.* (1993) is described below.

Reduction of the cystamine-labeled oligo using a disulfide reducing agent releases 2-mercaptoethylamine and creates a thiol group for conjugation (Figure 23.11). DNA probes labeled in this manner have been successfully coupled with SPDP-activated alkaline phosphatase (Chapter 22, Sections 1.2 and 2.5), maleimide-activated horseradish peroxidase (Chapter 22, Section 1.1), NHS–LC-biotin (Chapter 11, Section 6.2, and Section 2.3, this chapter), and the fluorescent tag AMCA–HPDP (Chapter 10, Section 3, and Section 2.5, this chapter).

Protocol

1. Weigh out 1.25 mg of the carbodiimide EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride; Thermo Fisher) into a microfuge tube.
2. Add to the tube 7.5 µl of RNA or DNA containing a 5′ phosphate group. The concentration of the oligonucleotide should be 7.5 to 15 nmol/µl or total of about 57 to 115.5 µg. Also immediately add 5 µl of 0.25-*M* cystamine in 0.1-*M* imidazole, pH 6.0. Because EDC is labile in aqueous solutions, the addition of the oligo and cystamine/imidazole solutions should be done quickly.
3. Mix by vortexing, then place the tube in a microcentrifuge and spin for 5 min at maximal rpm.
4. Add an additional 20 µl of 0.1-*M* imidazole, pH 6.0. Mix and react for 30 min at room temperature.
5. For reduction of the cystamine disulfides, add 20 µl of 1.0-*M* DTT and incubate at room temperature for 15 min. This will release 2-mercaptoethylamine from the cystamine modification site and create the free sulfhydryl on the 5′ terminus of the oligonucleotide.

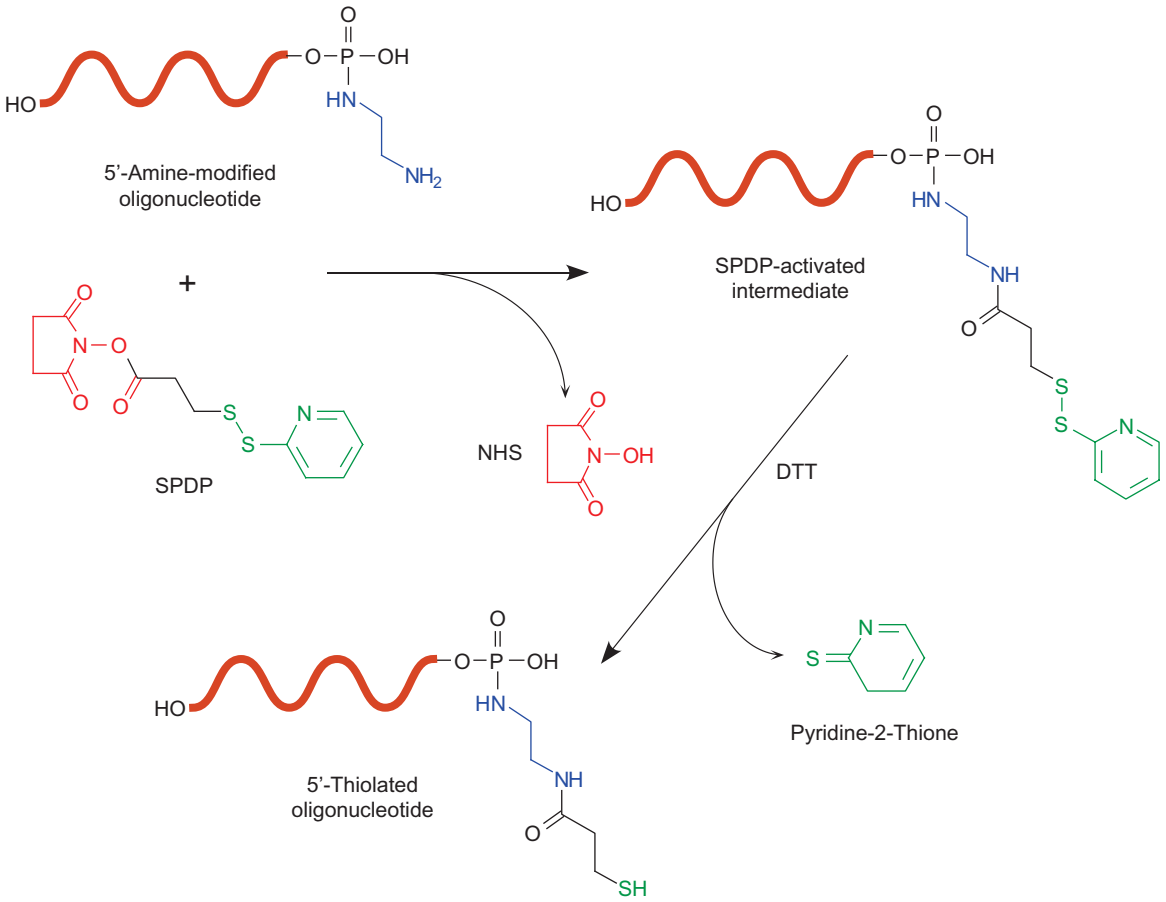

FIGURE 23.12 An oligonucleotide modified at its 5′-phosphate with a diamine compound may be reacted with SPDP and subsequently reduced to create a free sulfhydryl.

6. Purify the SH-labeled oligo by gel filtration on a desalting resin using 10-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2. The probe now may be used to conjugate with an activated enzyme, biotin, fluorescent tag, or other molecules containing a sulfhydryl-reactive group.

SPDP Modification of Amines on Nucleotides

Oligonucleotide probes that have been modified with an amine-terminal spacer arm using any of the methods discussed in Sections 1 and 2 of this chapter may be thiolated to contain a sulfhydryl residue. Theoretically, any of the amine-reactive thiolation reagents described in Chapter 2, Section 4.1, may be used to convert an amino group on a DNA molecule into a thiol. One of the more common choices, both for crosslinking and for thiolation reactions, is the heterobifunctional reagent SPDP (Chapter 6, Section 1.1). The NHS ester end of SPDP reacts with primary amine groups to produce stable amide bonds. The other end of the crosslinker contains a thiol-reactive pyridyl disulfide group that also can be reduced with DTT to create a free sulfhydryl.

The reaction of a 5′-diamine-modified oligonucleotide probe with SPDP proceeds under mildly alkaline conditions (optimal pH 7–9) to give the pyridyl disulfide-activated intermediate (Figure 23.12). This derivative has dual functionality. It can be used to couple directly with sulfhydryl-containing detection reagents or enzymes, or it may be converted into a free sulfhydryl for coupling to thiol-reactive compounds (Gaur *et al.*, 1989; Gaur, 1991). In an alternative approach, Chu and Orgel (1988) used 2,2′-dipyridyldisulfide (Chapter 2, Section 5.2) to create reactive pyridyl disulfide groups on a reduced 5′-cystamine-labeled oligonucleotide probe. This derivative can then be used to couple with sulfhydryl-containing molecules, forming a disulfide bond.

Reduction of the pyridyl disulfide end after SPDP modification releases the pyridine-2-thione leaving group and generates a terminal–SH group. This procedure allows sulfhydryl-reactive derivatives such as maleimide-activated enzymes (Chapter 22, Section 2.3) to be conjugated with DNA probes for use in hybridization assays (Malcolm and Nicolas, 1984).

Protocol

1. Dissolve the amine-modified oligonucleotide to be thiolated in 250 µl of 50-m*M* sodium phosphate, pH 7.5.
2. Dissolve SPDP (Thermo Fisher) at a concentration of 6.2 mg/ml in DMSO (makes a 20-m*M* stock solution). Alternatively, LC-SPDP may be used and dissolved at a concentration of 8.5 mg/ml in DMSO (also makes a 20-m*M* solution). The 'LC' form of the crosslinker provides a longer spacer arm that often results in better probe activity after modification. If the water soluble sulfo-LC-SPDP is used, a stock solution in water may be prepared just prior to adding an aliquot to the thiolation reaction. In this case, prepare a 10-m*M* solution of sulfo-LC-SPDP by dissolving 5.2 mg/ml in water. Since an aqueous solution of the crosslinker will degrade by hydrolysis of the sulfo-NHS ester, it should be used quickly to prevent significant loss of activity.
3. Add 50 µl of the SPDP (or LC-SPDP) solution to the oligo solution. Add 100 µl of the sulfo-LC-SPDP solution, if the water soluble crosslinker is used. Mix.
4. React for 1 h at room temperature.
5. Remove excess reagents from the modified oligo by gel filtration on a desalting resin. The modified probe now may be used to conjugate with a sulfhydryl-containing molecule, or it may be reduced to create a thiol for conjugation with sulfhydryl-reactive molecules.
6. To release the pyridine-2-thione leaving group and form the free sulfhydryl, add 20 µl of 1.0-*M* DTT and incubate at room temperature for 15 min. If present in sufficient quantity, the release of pyridine-2-thione can be followed by its characteristic absorbance at 343 nm ($\varepsilon = 8.08 \times 10^3\,M^{-1}\,cm^{-1}$). For many oligonucleotide modification applications, however, the leaving group will be present in too low a concentration to be detectable.
7. Purify the thiolated oligonucleotide from excess DTT by dialysis or gel filtration using 50-m*M* sodium phosphate, 1-m*M* EDTA, pH 7.2. The modified probe should be used immediately in a conjugation reaction to prevent sulfhydryl oxidation and formation of disulfide crosslinks.

SATA Modification of Amines on Nucleotides

Oligonucleotides containing amine groups introduced by enzymatic or chemical means may be modified with *N*-succinimidyl *S*-acetylthioacetate (SATA) (Chapter 2, Section 4.1), to produce protected sulfhydryl derivatives. The NHS ester end of SATA reacts with a primary amine to form a stable amide bond. After modification, the acetyl protecting group can be removed as needed by treatment with hydroxylamine under mildly alkaline conditions (Figure 23.13). The result is terminal sulfhydryl groups that can be used for subsequent labeling with thiol-reactive probes or activated-enzyme derivatives (Kumar and Malhotra, 1992).

The advantage of using SATA over disulfide-containing thiolation reagents such as SPDP (previous section) is that the introduction of sulfhydryl residues does not include the use of a disulfide reducing agent. Typically, the pyridyl dithiol group resulting from an SPDP thiolation must be reduced with a sulfhydryl-containing disulfide reducing compound like DTT to free the- SH group. With SATA, the sulfhydryl is freed by hydroxylamine cleavage, thus eliminating the need for removal of sulfhydryl reductants prior to a conjugation reaction.

Protocol

1. Dissolve the amine-modified oligonucleotide to be thiolated in 250 µl of 50-m*M* sodium phosphate, pH 8.0.
2. Dissolve SATA in DMF at a concentration of 8 mg/ml.
3. Add 250 µl of the SATA solution to the oligo solution. Mix.
4. React for 3 h at 37°C.
5. Remove excess reagents from the modified oligo by gel filtration.
6. To deprotect the acetylated thiol group, add 100 µl of 50-m*M* hydroxylamine hydrochloride, 2.5-m*M* EDTA, pH 7.5.
7. React for 2 h.
8. The sulfhydryl-containing oligonucleotide may be used immediately to conjugate with a sulfhydryl-reactive label, or it can be purified from excess hydroxylamine by gel filtration.

2.3. Biotin Labeling of DNA

Biotinylation of oligonucleotide probes provides a highly specific biological recognition site for detection of DNA using (strept)avidin conjugates. The preparation of biotin-labeled DNA can be performed by either enzymatic or chemical means. Enzyme-catalyzed reactions utilize biotinylated nucleoside triphosphates that can be incorporated into an oligonucleotide randomly or at the 3′ terminus (Section 1). Chemical derivatization methods make use of certain reactive biotin compounds that can couple to functionally modified probes or react with DNA with the use of an activating reagent. For a description of the wide range of biotinylation compounds available, see Chapter 11, Section 6. The preparation and use of avidin and streptavidin conjugates is discussed in Sections 1 to 5 of that chapter.

Biotin–LC-dUTP

Perhaps the most common method of DNA biotinylation is through enzymatic incorporation with the use of a biotin-labeled deoxynucleoside triphosphate. First reported by Langer *et al.* in 1981, the procedure

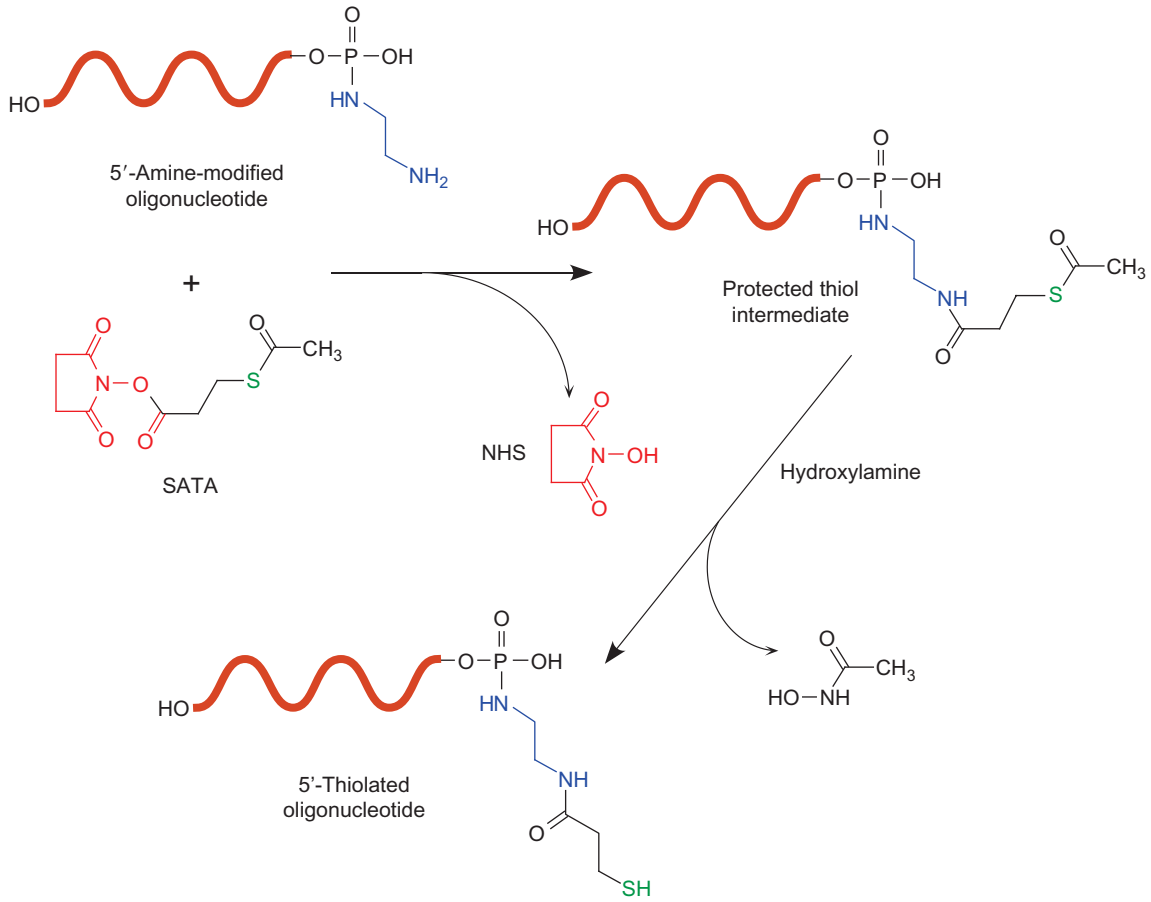

FIGURE 23.13 SATA can be used to modify a 5′-amine derivative of an oligonucleotide, forming a protected sulfhydryl. Deprotection with hydroxylamine results in generation of a free thiol.

is probably the most popular nonradioactive labeling technique reported for oligonucleotide probes. Although biotinylated derivatives of dCTP and dATP are reported in the literature, by far the most frequently employed derivative is biotin–dUTP prepared from the reaction of an amine-modified dUTP with an amine-reactive biotinylation reagent, such as NHS–LC-biotin (Li *et al.*, 2011; Kim *et al.*, 2012) (Chapter 11, Section 6.2).

Biotin–dUTP derivatives are formed by modification of the C-5 position of uridine. This location is not involved in hydrogen bonding activity with complementary DNA strands, thus hybridization efficiency is not immediately compromised. By contrast, biotin–dCTP or biotin–dATP derivatives involve modification of the bases at the N-4 position of cytosine and the N-6 position of adenine, locations directly involved in hydrogen bond formation with complementary bases. Thus, DNA biotinylation through the use of modified deoxynucleoside triphosphates to be incorporated into existing DNA strands may result in better activity of the probe if dUTP is used over dATP or dCTP.

The length of the spacer arm between the C-5 position of uridine and the biotin group is another important parameter for activity of the resulting conjugate. The spacer affects the incorporation efficiency into existing probes using DNA polymerases, and it also affects the ability of an (strept)avidin conjugate to effectively bind the biotinylated probe. Designation of spacer length is usually expressed as the number of atoms separating the nucleotide base from the biotin component. Thus, biotin–*n*–dUTP would describe a biotinylated deoxynucleoside triphosphate having a spacer arm *n* atoms long. The shorter the spacer arm, the better the derivative is able to be recognized and incorporated into DNA polymers using polymerase enzymes. Conversely, the longer the spacer arm, the better the biotinylated probe is able to hybridize to its target and still maintain the capacity to have a streptavidin conjugate be complexed with it. Thus, there is an optimal trade-off in spacer length between enzymatic incorporation efficiency and labeled-probe detectability. Studies have determined that this optimal range is

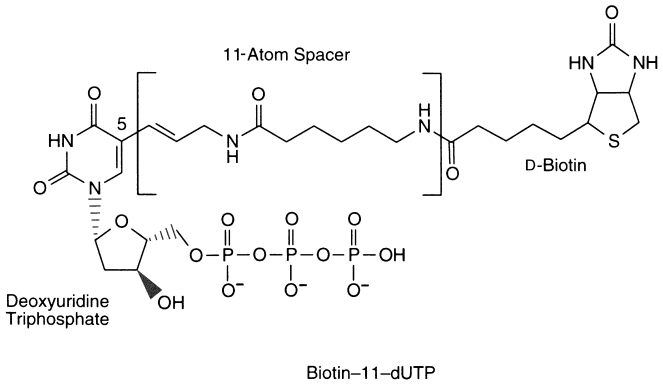

FIGURE 23.14 Biotin–11–dUTP is perhaps one of the most popular nucleotide derivatives used for enzymatic biotinylation of oligonucleotides. The "11" designation refers to the number of atoms in its spacer arm.

rather broad—between 7 atoms and 21 atoms in length. Perhaps the most common derivative is biotin–11–dUTP, wherein an 11-atom spacer is employed (Figure 23.14).

General protocols for the enzymatic incorporation of biotin–11–dUTP into DNA probes can be found in Section 1. A particularly interesting modification of the typical enzymatic incorporation protocol for biotin is described by Didenko (1993). The single-strand template is immobilized by adsorption onto membranes before synthesis of the biotinylated probe. After polymerase incorporation of biotin–11–dUTP, the labeled probe is removed by brief heating to 90°C in water. The result is highly pure probe with no contaminating complementary DNA strands.

Photobiotin Modification of DNA

The photoreactive biotin derivative, *N*-(4-azido-2-nitrophenyl)-aminopropyl-*N′*-(*N*-d-biotinyl-3-aminopropyl)-*N′*-methyl-1,3-propanediamine, simply called photoactivatable biotin or photobiotin (Forster *et al.*, 1985) contains a 9-atom diamine spacer group on the biotin valeric acid side chain on one end, while the other end of the spacer terminates in an phenyl azide group. The phenyl azide group can be photolyzed with UV light (350 nm) resulting in the formation of a highly reactive nitrene intermediate. In most instances, this nitrene rapidly reacts via ring expansion to form a dehydroazepine that is reactive with nucleophiles, such as amine groups (Chapter 6, Section 3).

When photobiotin is irradiated in the presence of DNA the reaction process nonselectively couples a biotin label to every 100 to 200 base residues (Saito *et al.*, 2012). The result is an oligonucleotide probe detectable by the use of (strept)avidin conjugates. The use of photobiotin for DNA or RNA modification is summarized in Chapter 11, Section 6.5. Refer also to the same section of Chapter 11 for use of the compound psoralen–PEO_3–biotin for an alternative option in the photoreactive labeling of, in this case, double stranded DNA or RNA molecules.

The following protocol is based on the method of Forster *et al.* (1985). Some optimization may be necessary to obtain the best signal and activity for particular probes in hybridization assays.

Protocol for Labeling DNA Probes with Photobiotin

1. In subdued lighting conditions, dissolve photobiotin in water at a concentration of 1 µg/µl. Protect from light.
2. Dissolve the oligonucleotide probe in water or 0.1-m*M* EDTA, pH 7.0, at a concentration of 1 µg/µl.
3. Mix an equal volume of the photobiotin solution with the DNA probe solution.
4. Place the solution in an ice bath and irradiate from above (about 10 cm away) for 15 min using a sunlamp (such as Philips Ultrapnil MLU 300 W, General Electric sunlamp RSM 275 W, or National Self-Ballasted BHRF 240–250 V 250 W W-P lamp).
5. Add 50 µl of 0.1-*M* Tris, pH 9, and increase the total volume of the solution to 100 µl (if it is less than this amount).
6. To extract excess photobiotin, add 100 µl of 2-butanol. Mix well and centrifuge. Discard the upper phase. Repeat this process two more times.
7. To recover the biotinylated DNA, add 75 µl of 4-*M* NaCl and mix.
8. Add 100 µl of ethanol and cool the sample in dry ice (CO_2) for 15 min.
9. Centrifuge to collect the precipitated, biotinylated DNA.

Reaction of NHS–LC-Biotin with Diamine-Modified DNA Probes

NHS–LC-biotin is an extended spacer arm derivative of biotin containing an amine-reactive NHS ester (Chapter 11, Section 6.2). The compound is a popular choice for biotinylating a wide range of molecules containing primary amine groups, especially proteins. Oligonucleotides modified to contain amine-terminal spacer arms also can be modified with NHS–LC-biotin to create stable amide bond derivatives. Alternatively, a hydrophilic biotinylation compound containing a PEG spacer arm can be used to form a biotin–oligo derivative without the hydrophobic character of the alkyl chain within NHS–LC-biotin. Chapter 18, Section 1.3, describes the amine-reactive NHS–PEG_n–biotin compounds suitable for this purpose.

Whether an amine is incorporated into an oligo by enzymatic means or chemical derivatization, an NHS-ester-containing biotinylation reagent can be used to label the derivative in high yield. If an amine group is

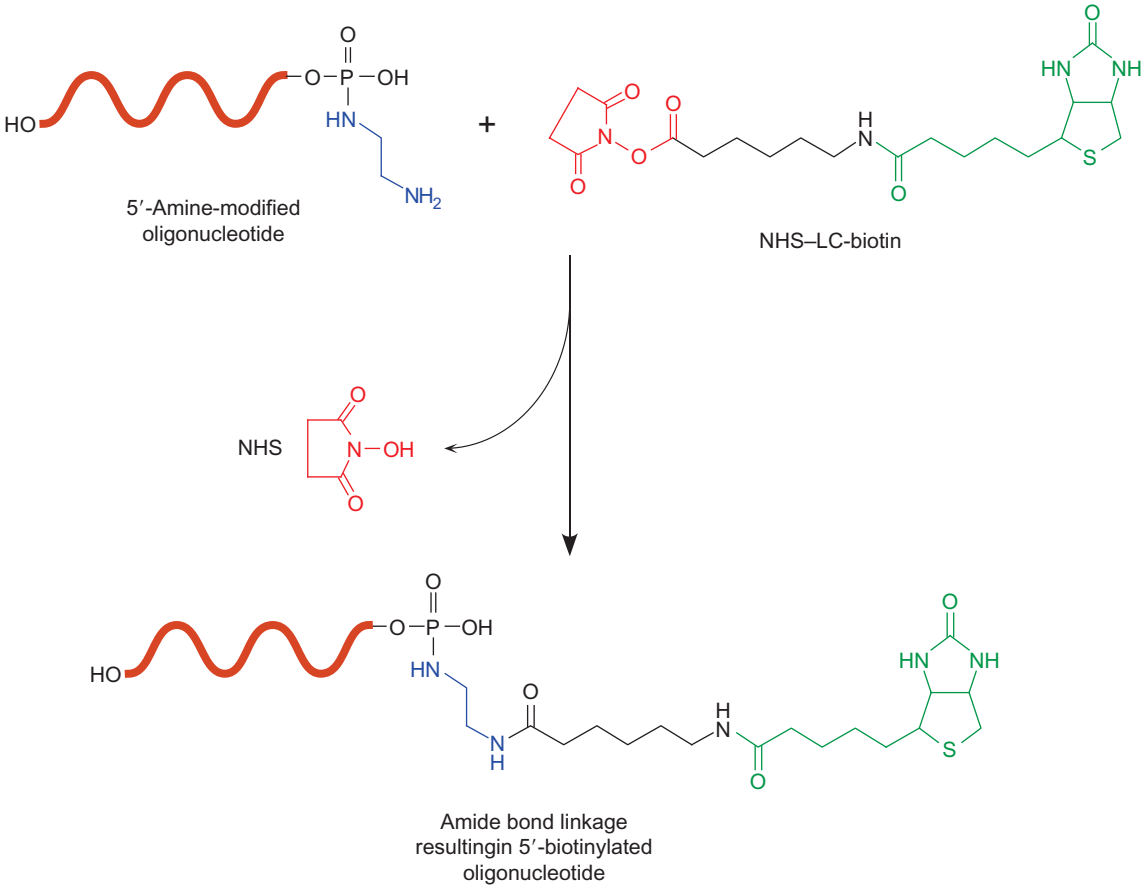

FIGURE 23.15 Biotinylation of oligonucleotides may be performed at the 5′-phosphate end using a diamine derivative and reacting with NHS–LC-biotin.

added to the 5′ end of a DNA probe by phosphoramidate formation (Section 2.1), then biotinylation of such molecules directs the label to a region totally removed from interfering in subsequent hybridization with a target DNA strand (Figure 23.15).

The following protocol assumes that the amine-containing oligo has already been synthesized by any of the methods discussed in Section 2.1.

Protocol

1. Prepare 10 to 20 µg of amine-containing oligonucleotide in 200 µl of water. Add to this solution, 20 µl of 1-*M* sodium bicarbonate, pH 9.0.
2. Dissolve NHS–LC-biotin (Thermo Fisher) in DMSO at a concentration of 10 mg/ml. Add 50 µl of the biotinylation solution to the oligo solution. Mix well.
3. React for 2 h at room temperature.
4. Isolate the biotinylated probe by ethanol/salt precipitation as described in Section 1 for nick-translation modification of DNA probes. Alternatively, dialysis, gel filtration, or *n*-butanol extraction may be used to remove excess reagents.

Biotin–Diazonium Modification of DNA

Diazonium groups are able to couple at the C-8 position of adenosine or guanosine residues, forming diazo bonds. *p*-Aminobenzoyl biocytin can be used in this reaction to add a biotin handle to purine bases within oligonucleotides (Chapter 11, Section 6.6). This biotinylation reagent contains a 4-aminobenzoic acid amide derivative off the α-amino group of biocytin's lysine residue (Thermo Fisher). The aromatic amine can be treated with sodium nitrite in dilute HCl to form a highly reactive diazonium derivative, which is able to couple with active hydrogen-containing compounds. A diazonium reacts rapidly with histidine or tyrosine residues within proteins, forming covalent diazo bonds (Wilchek *et al.*, 1986). It also can react with purine residues within DNA at position 8 of the bases (Lowe, 1979; Rothenberg and Wilchek, 1988) (Figure 23.16).

Protocol

1. Prepare diazotized *p*-aminobenzoyl biocytin by using the protocol outlined in Chapter 11, Section 6.6, but instead of starting with 2 mg the biotinylation reagent dissolved in 40 µl of 1-*N* HCl, use 9 mg in

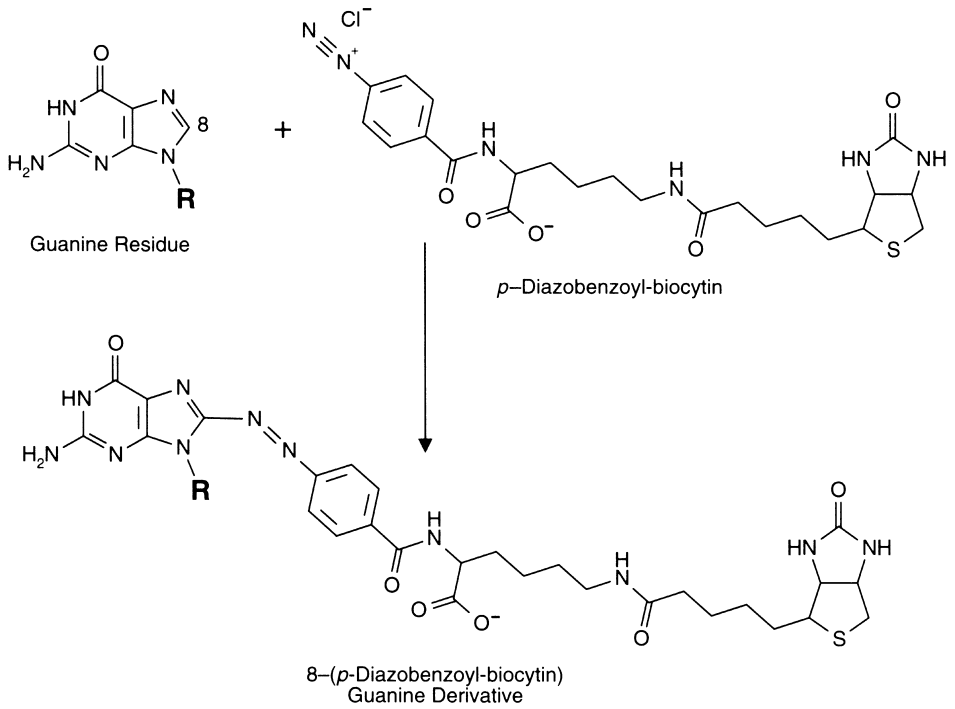

FIGURE 23.16 This diazo derivative of biocytin may be used to modify guanine bases at the C-8 position.

180 µl of 1-*N* HCl. Proportionally scale up the other reactant quantities used in the protocol. After the reaction is complete, immediately adjust the pH of the final solution to 9.
2. Add 1 µg of single-stranded DNA to the above solution.
3. React for 30 min at room temperature.
4. Purify the biotinylated DNA probe by ethanol precipitation, gel filtration, *n*-butanol extraction, or dialysis as discussed in previous sections.

Reaction of Biotin–BMCC with Sulfhydryl-Modified DNA

Biotin–BMCC is a sulfhydryl-reactive biotinylation reagent containing a maleimide group at the end of an extended spacer arm. The long spacer (32.6 Å) provides enough distance between modified oligonucleotides and the bicyclic biotin end to allow efficient binding of (strept) avidin probes, even when hybridized to target sequences. The reagent may be used to add a biotin label to DNA or RNA molecules after they have been modified to contain thiol groups. For instance, cystamine labeling at the 5′ phosphate group of DNA via carbodiimide-mediated phosphoramidate formation followed by disulfide reduction (Section 2.2) can create the required sulfhydryl groups. Subsequent reaction with biotin–BMCC results in a derivative labeled only at an end of the DNA probe (Figure 23.17), thus avoiding the potential for hydrogen bonding interference in hybridization assays.

Since maleimide groups are highly specific for coupling to thiols in the pH range of 6.5 to 7.5, side reaction products can be reasonably avoided. The reaction is complete within 2 h at room temperature.

Protocol

1. Prepare 10 to 20 µg of a sulfhydryl-containing oligonucleotide in 200 µl of 50-m*M* sodium phosphate, 10-m*M* EDTA, pH 7.2 (the methods outlined in Section 2.2 can be used to form the thiol group).
2. Dissolve biotin–BMCC in DMSO at a concentration of 5 mg/ml. Prepare fresh.
3. Add 50 µl of the biotinylation solution to the oligo. Mix well.
4. React for 2 h at room temperature.
5. Isolate the biotinylated probe by ethanol/salt precipitation as described in Section 1 for nick translation (this chapter).

Biotin–Hydrazide Modification of Bisulfite-Activated Cytosine Groups

Biotin–hydrazide is the hydrazine derivative of D-biotin prepared using its valeric acid carboxylate (Chapter 11, Section 6.4). The hydrazide group is typically used to react with aldehyde and ketone groups to give hydrazone linkages. However, the hydrazide compound can also undergo transamination reactions with cytosine residues *via* catalysis with bisulfite (Section 2.1)

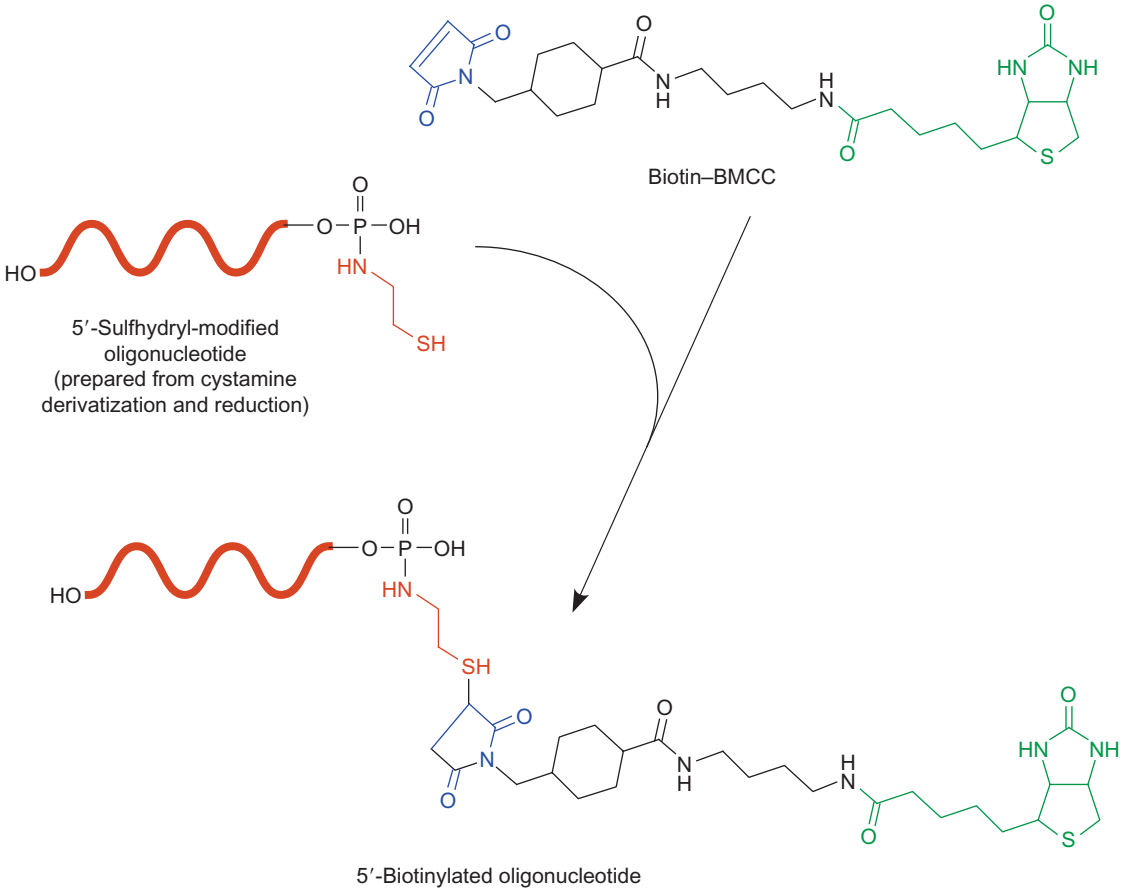

FIGURE 23.17 Biotin–BMCC can be used to modify a reduced, cystamine derivative of DNA, forming a thioether linkage.

(Figure 23.18). DNA or RNA probes containing cytosine groups may be modified to contain biotin labels using a simple, one-step procedure (Reisfeld *et al.*, 1987). The detection limit of DNA probes biotinylated using this technique can be less than 1 pg on blots, when analyzed using a streptavidin–HRP conjugate with chemiluminescent detection. A longer-chain analog of biotin–hydrazide, biotin–LC-hydrazide, may be used to create an extended spacer between the oligonucleotide and the bicyclic biotin group, thus increasing the binding efficiency of avidin or streptavidin conjugates. Alternatively, a hydrophilic biotin–PEG_n–hydrazide compound may be used in this reaction to provide greater water solubility for the label (Chapter 18, Section 1.3). Leary *et al.* (1983) reported that increasing the spacer arm length from 4 to 11 atoms when biotinylating DNA probes can increase the detectability of the target DNA approximately 4-fold.

The following method is adapted from Reisfeld *et al.* (1987).

Protocol

1. Prepare 50 µg of a single-stranded DNA probe in 300 µl of 50-m*M* sodium acetate, pH 4.5.
2. Dissolve biotin–hydrazide in water at a concentration of 10 mg/ml.
3. Add 300 µl of the biotin–hydrazide solution to the DNA solution.
4. Add sodium bisulfite to obtain a final concentration of 1-*M* in the reaction medium.
5. React for 24 h at 37°C.
6. Remove excess reactants by dialysis against water at 4°C.

2.4. Enzyme Conjugation to DNA

Enzymes useful for detection purposes in ELISA techniques (Chapter 22) can also be employed in the creation of highly sensitive DNA probes for hybridization assays. The attached enzyme molecule provides

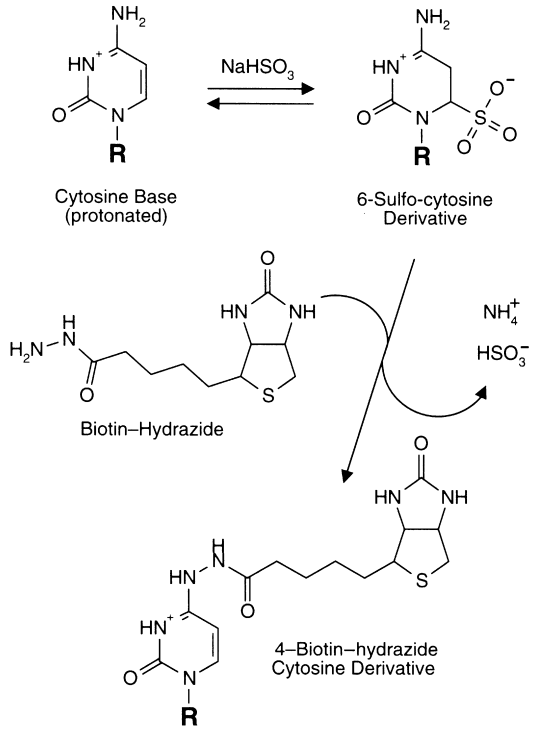

FIGURE 23.18 Biotin–hydrazide may be incorporated into cytosine bases using a bisulfite-catalyzed transamination reaction.

detectability for the oligonucleotide through turnover of substrates that can produce chromogenic or fluorescent products. Enzyme-based hybridization assays are perhaps the most common method of nonradioactive detection used in nucleic acid chemistry today. The sensitivity of enzyme-labeled probes can equal or exceed that of radiolabeled nucleic acids, thus eliminating the need for radioactivity in most assay systems.

The conjugation reactions involved in DNA–enzyme crosslinking are not unlike the methods used to form antibody–enzyme conjugates (Chapter 20, Section 1). Bifunctional crosslinkers can be used to couple a modified oligonucleotide to an enzyme molecule using the same basic principles effective in protein–protein conjugation. The only requirement is that the DNA molecule be modified to contain one or more suitable functional groups, such as nucleophiles like amines or sulfhydryls. The modification process used to create these functional groups can use enzymatic (Section 1, this chapter) or chemical (Section 2, this chapter) means and it can result in random incorporation of modification sites or be directed exclusively at one end of the DNA molecule, such as in 5′ phosphate coupling.

The following sections describe some of the more common procedures of preparing DNA–enzyme conjugates.

Alkaline Phosphatase Conjugation to Cystamine-Modified DNA Using Amine- and Sulfhydryl-Reactive Heterobifunctional Crosslinkers

A cystamine group added to the 5′ phosphate of DNA molecules using a carbodiimide reaction (Section 2.2) can be used in a heterobifunctional crosslinking scheme to conjugate with alkaline phosphatase. Crosslinking agents containing an amine-reactive portion and a sulfhydryl-reactive part work best in forming this type of conjugate. Perhaps one of the most common heterobifunctional reagents used for DNA–enzyme formation is SPDP (Chapter 6, Section 1.1). SPDP contains an NHS ester on one end able to create an amide bond linkage with amino groups on protein molecules. After modification of alkaline phosphatase with this crosslinker, the enzyme is activated to contain pyridyl disulfide groups for coupling to the sulfhydryls on a cystamine-modified DNA probe (Figure 23.19). The reaction forms disulfide bonds between the oligonucleotide and the alkaline phosphatase enzyme. Since the crosslink occurs only at the 5′ end of the DNA strand, the presence of an enzyme molecule does not adversely affect the ability of base pairing and hybridization to a target sequence.

The following protocol assumes that the labeling process used to create a sulfhydryl-modified DNA probe already has been done according to the method of Section 2.2 (this chapter). The modification procedure for activating alkaline phosphatase with SPDP may be done according to the protocol described in Chapter 6, Section 1.1 (see also Chapter 22, Section 1.2). To obtain efficient labeling of all the alkaline phosphatase added to the reaction medium, the modified oligo is reacted in a 10-fold molar excess. Reaction of the DNA probe in excess allows easy separation of not-coupled oligo from conjugated probe, thus eliminating any potential interference in hybridization assays due to unlabeled oligonucleotide.

Protocol

1. Dissolve a 5′-sulfhydryl-modified oligonucleotide in water or 10-m*M* EDTA at a concentration of 0.05 to 25 µg/µl. Calculate the total nanomoles of oligo present based upon its molecular weight.
2. Prepare SPDP-activated alkaline phosphatase in 50-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2. Add to the oligo solution, an amount of the activated enzyme representing a 10-fold molar excess over the calculated amount of DNA present.
3. React at room temperature for 30 min with gentle mixing.
4. The alkaline phosphatase–DNA conjugate may be purified away from excess oligo by dialysis, gel filtration, or through the use of centrifugal concentrators. A simple way of removing unreacted

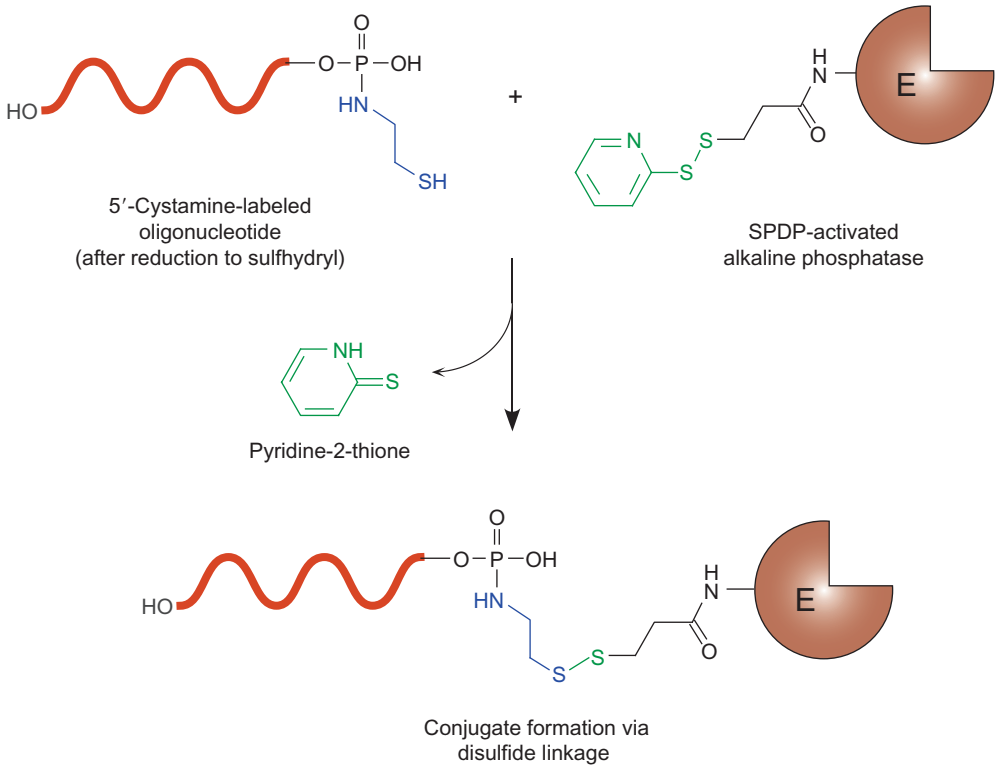

FIGURE 23.19 An oligonucleotide modified with cystamine and reduced to generate a free sulfhydryl may be conjugated with an SPDP-modified enzyme, forming a disulfide linkage.

oligo is to use Centricon-30 concentrators (Amicon) which have a molecular weight cutoff of 30,000. Since the enzyme molecular weight is approximately 140,000 and the conjugate is even higher, a relatively small DNA probe will pass through the membranes of these units while the conjugate will not. To purify the conjugate using Centricon-30s, add 2 ml of the phosphate buffer from step 2 to one concentrator unit, then add the reaction mixture to the buffer and mix. Centrifuge at 1000 *g* for 15 min or until the retentate volume is about 50 µl. Add another 2 ml of buffer and centrifuge again until the retentate is 50 µl. Invert the Centricon-30 unit and centrifuge to collect the retentate in the collection tube provided by the manufacturer.

Alkaline Phosphatase Conjugation to Diamine-Modified DNA Using DSS

Disuccinimidyl suberate (DSS) is a homobifunctional crosslinker containing an amine-reactive NHS ester at both ends (Chapter 5, Section 1.2). Reaction of the reagent in excess with diamine-modified DNA probes creates an activated intermediate able to conjugate with enzyme molecules through their available amine groups (Figure 23.20) (Jablonski *et al.*, 1986). The coupling reaction produces stable amide linkages under mildly alkaline conditions. Although the following protocol has been used to label oligonucleotides with success, it may be less efficient than the previous protocol at forming the desired conjugate due to the homobifunctional nature of the crosslinker. During the activation step, the modified DNA must be purified away from excess DSS. Since this is carried out under aqueous conditions, hydrolysis of the free NHS ester at the other end of the crosslinker takes place at the same time. Activity losses can be severe if the separation step is not done rapidly. In fact, the original protocol called for several hours of gel filtration chromatography and concentration before the conjugation reaction was performed. Farmer and Castaneda (1991) made a significant improvement to this procedure by including a faster separation step using alcohol extraction after activation of the oligo with DSS. The purification time decreased to minutes instead of hours. This does help to limit hydrolysis, but cannot completely avoid it.

The following protocol is based on the methods of Farmer and Castaneda (1991), Kiyama *et al.* (1992), and Ruth (1993).

Protocol

1. Prepare an amine-modified oligonucleotide according to any of the protocols discussed in Section 2.1. Dissolve or buffer-exchange the oligo into 0.1-*M* sodium borate, 2-m*M* EDTA, pH 8.25, at a concentration of 9 nmol (2.0 $A_{260\,nm}$ units) in 15 µl.

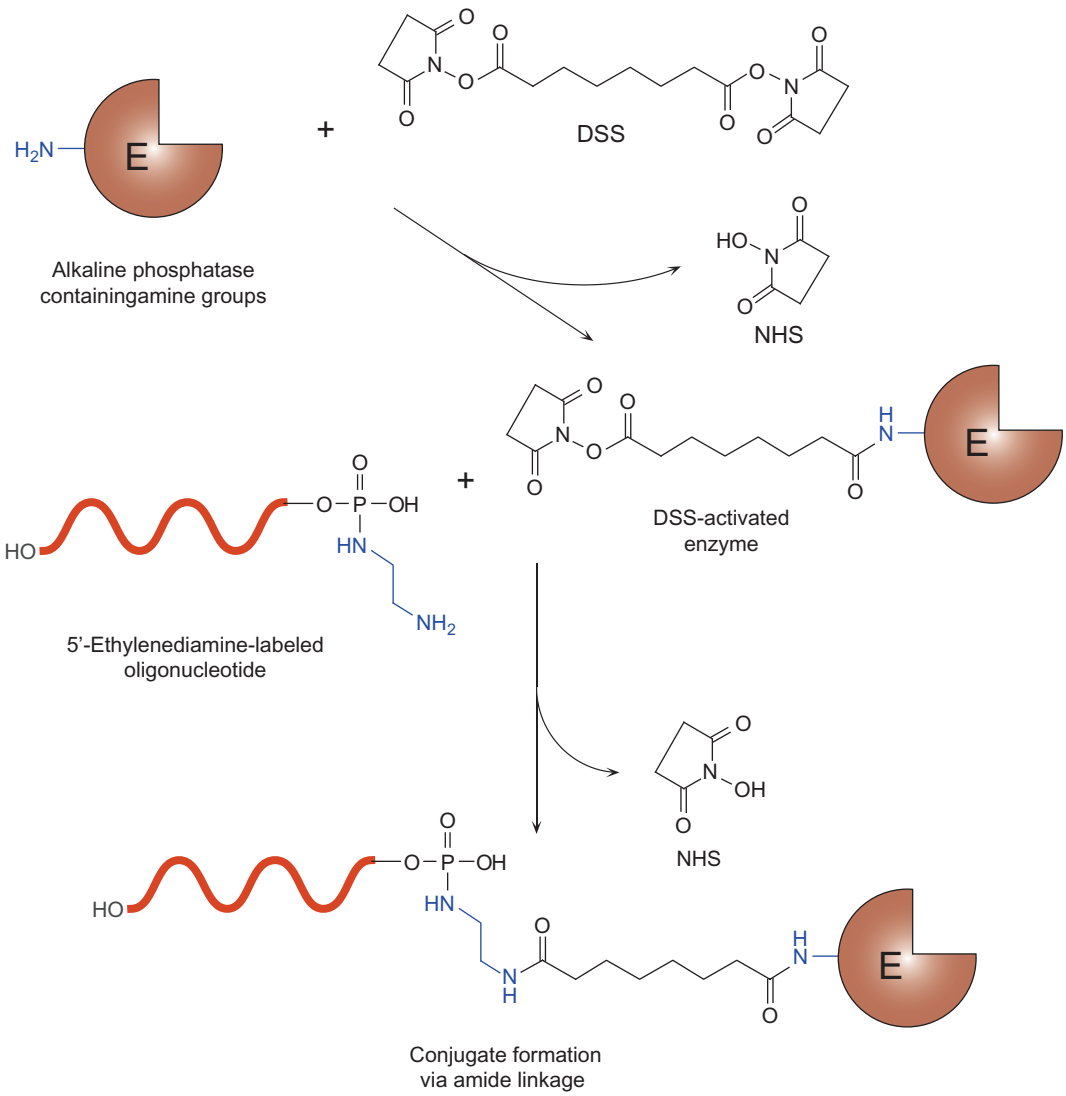

FIGURE 23.20 The homobifunctional crosslinker DSS may be used to conjugate an enzyme to a 5′-diamine-modified oligonucleotide. The NHS ester groups on DSS react with the amines to form amide bonds.

2. Dissolve DSS in dry DMSO at a concentration of 1 mg/100 µl. Prepare fresh.
3. Add 30 µl of the DSS solution to the oligo. Mix well.
4. React for 15 min at room temperature in the dark.
5. Immediately extract excess DSS and reaction by-products by the addition of 0.5 ml of *n*-butanol. Mix vigorously by vortexing and centrifuge (1 min, 15,000 rpm) to separate the two phases. Carefully remove the upper layer and discard. Extract two more times with *n*-butanol.
6. Chill the remaining sample on dry ice and lyophilize to remove the last traces of liquid. The drying period will only take 15 to 30 min. The dried, DSS-activated DNA is stable under anhydrous conditions.
7. Dissolve or dialyze alkaline phosphatase into 3-*M* NaCl, 30-m*M* triethanolamine, 1-m*M* $MgCl_2$, pH 7.6, at a concentration of 20 mg/ml.
8. Add 70 µl of the alkaline phosphatase to the dried, DSS-activated DNA. Mix gently to dissolve.
9. React overnight at 4°C in the dark.
10. Remove unconjugated oligo by using a Centricon-30 centrifugal concentrator according to step 4 of the protocol described in the previous section. Unconjugated enzyme may be removed by ion-exchange chromatography using a MonoQ-10 (0.5 × 5 cm) FPLC column (GE Healthcare) or the equivalent. Binding buffer is 20-m*M* Tris, pH 8. Elute using a linear gradient of 0–100% 20-m*M* Tris, 1-*M* NaCl, pH 8. Free enzyme will elute before the more negatively charged oligo–enzyme conjugate.

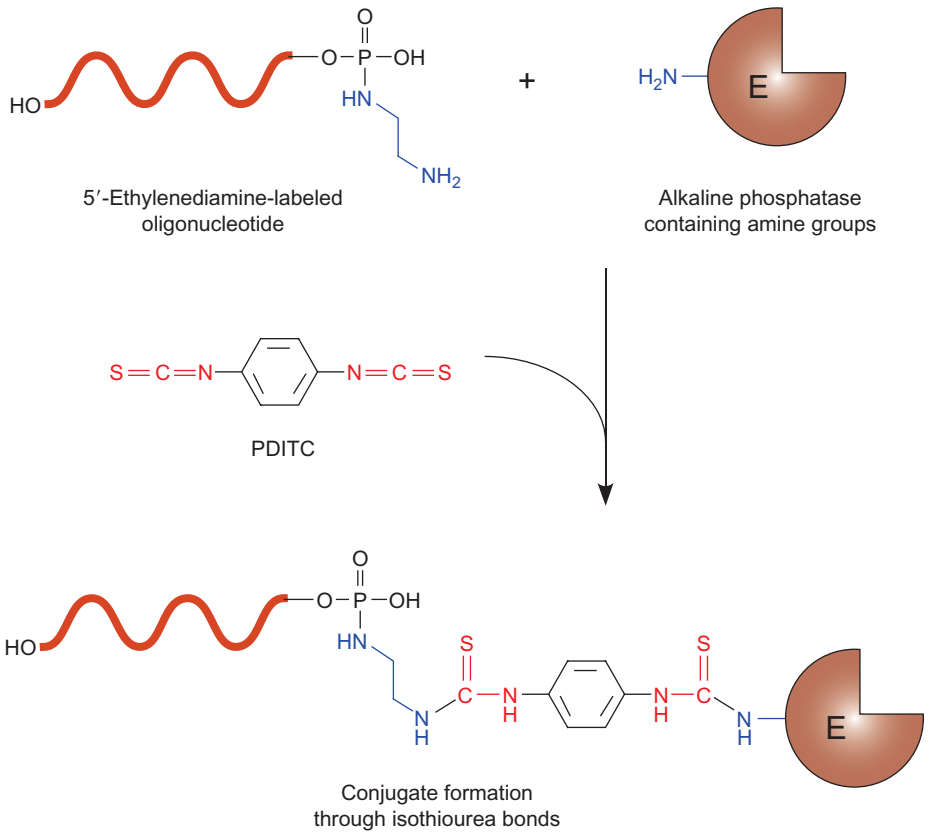

FIGURE 23.21 The homobifunctional crosslinker PDITC may be used to conjugate an enzyme to a 5′-diamine-modified oligonucleotide, creating isothiourea linkages.

Enzyme Conjugation to Diamine-Modified DNA Using PDITC

PDITC, 1,4-phenylene diisothiocyanate, is a homobifunctional crosslinker containing two amine-reactive isothiocyanate groups on a phenyl ring. Reaction in excess with an amine-modified oligonucleotide results in the formation of a thiourea linkage, leaving the second isothiocyanate group free to couple with amine-containing enzymes or other molecules (Urdea *et al.*, 1988) (Figure 23.21).

The following protocol is adapted from Keller and Manak (1989).

Protocol

1. Prepare an amine-modified oligonucleotide using any of the methods of Section 1 or 2.1. Dissolve or buffer exchange 70 µg of the oligo into 25 µl of 0.1-*M* sodium borate, pH 9.3.
2. Dissolve 10 mg of PDITC (Aldrich) in 500 µl of DMF. Add this solution to the oligo prepared in step 1.
3. React for 2 h at room temperature in the dark.
4. To extract excess reactant, add to the reaction medium, 3 ml of *n*-butanol and 3 ml of water. Mix well. Centrifuge the mixture to separate the two phases. Discard the upper yellow layer. Repeat the extraction process several times, and then dry the remaining solution containing activated oligo using lyophilization or a rotary evaporator. The PDITC-activated DNA is stable in a dried state.
5. Dissolve HRP (Chapter 22) in 200 µl 0.1-*M* sodium borate, pH 9.3, at a concentration of 10 mg/ml. If the HRP is supplied as an ammonium sulfate suspension, all ammonium ions must be removed by extensive dialysis prior to the conjugation reaction. Add the HRP solution to the activated oligo.
6. React overnight at room temperature in the dark.
7. Excess enzyme may be removed through isolation of the oligo–enzyme conjugate using electrophoresis separation under nondenaturing conditions. The reaction solution is applied to a 7% polyacrylamide gel using 90-m*M* Tris, 90-m*M* boric acid, 2.7-m*M* EDTA, pH 8.3, as the running buffer. The conjugate appears as a brown band in the middle of the gel.

Conjugation of SFB-Modified Alkaline Phosphatase to bis-Hydrazide-Modified Oligonucleotides

DNA probes modified to contain a 5′-terminal hydrazide group (Section 2.1) can be conjugated to aldehyde-containing molecules, resulting in the formation of a hydrazone bond. The crosslinking agent succinimidyl *p*-formylbenzoate (SFB; Chapter 17, Section 2) can be used to add aldehyde groups to proteins and other molecules that do not naturally contain them (Chapter 2, Section 4.4). Reaction of SFB-modified alkaline phosphatase with a hydrazide–DNA derivative can produce a conjugate having excellent sensitivity for use as a hybridization probe (Figure 23.22). Other enzymes and detection molecules modified to contain aldehydes may be coupled to hydrazide–DNA probes using similar methods. Using an SFB-modified HRP (or periodate-oxidized HRP) that contains aldehyde groups to prepare the DNA conjugate gives about a 40-fold less sensitivity in hybridization assays when compared to an alkaline phosphatase conjugate in this procedure (Ghosh *et al.*, 1989). However, this result may change if chemiluminescent detection using an HRP conjugate is used, as this method can result in femtogram detection limits.

The following protocol assumes the prior derivatization of an oligonucleotide at the 5′ end using a *bis*-hydrazide compound according to the protocol of Section 2.1 using a carbodiimide-mediated reaction.

Protocol

1. Dissolve alkaline phosphatase at a concentration of 10 mg/ml in 0.1-*M* sodium bicarbonate, 3-*M* NaCl, pH 8.5. Dialyze against this solution if the enzyme is already dissolved in another buffer. This protocol requires at least 0.4 ml of the enzyme solution.
2. Dissolve SFB in acetonitrile at a concentration of 50-m*M* (12.35 mg/ml). Make at least 100 µl.
3. Add 40 µl of the SFB solution to the 0.4-ml alkaline phosphatase solution with mixing.
4. React for 30 min at room temperature.
5. Remove excess reactants by dialysis against 50-m*M* MOPS, 0.1-*M* NaCl, pH 7.5.
6. Add the aldehyde-derivatized alkaline phosphatase to 8 nmol of a 5′-hydrazide oligonucleotide preparation made according to Section 2.1 using a carbodiimide coupling protocol.
7. React overnight at room temperature.
8. Remove unconjugated oligonucleotide using gel filtration on a column of Bio-Rad P-100 (1.5 × 65 cm). Use 50-m*M* Tris, pH 8.5, as the chromatography buffer. Pool the enzyme fractions and apply the sample to a 1 × 7 cm column of DEAE–cellulose equilibrated with the same buffer. After washing the column with 0.1-*M* Tris, pH 8.5, a salt gradient from 0- to 0.2-*M* NaCl in the same buffer is used to remove unconjugated enzyme. The enzyme–DNA conjugate is then eluted with 0.1-*M* Tris, 0.5-*M* NaCl, pH 8.5.

2.5. Fluorescent Labeling of DNA

Oligonucleotide probes may be labeled with small fluorescent molecules for detection of hybridization by luminescence. Fluorescent probes are widely used in assay systems involving biospecific interactions (Chapter 10). Receptors for ligands may be localized in tissues or cells by modification of the ligand with the appropriate fluorophore. Targeted molecules may be quantified through measurement or modulation of a fluorescent signal upon binding of a tagged ligand. The sensitivity of fluorescent assays can exceed that obtained using radiolabels, but enzyme assays typically are more sensitive than fluorescent detection without catalytic enhancement.

Fluorescently labeled DNA probes can be used for detection, localization, or quantification of target DNA sequences. *In situ* hybridization mapping of genomic DNA sequences can be carried out using fluorescent probes to target particular regions within chromosomes. Called FISH for fluorescent *in situ* hybridization, the technique is used extensively to identify marker chromosomes or chromosomal rearrangements. Since many genomic sequences are repeated, usually occurring in multiple copies within isolated regions of the chromosome, the fluorescent label on the DNA probe allows localization of targeted genes with high sensitivity. For a review of FISH, see Meyne (1993) and also refer to Chapter 1 for a discussion of current fluorescent DNA probe-based conjugates and methods.

Fluorescently labeled DNA probes also can be used in homogeneous assay systems to detect and quantify target complementary sequences. The majority of these systems use a process of energy transfer and fluorescent quenching to detect hybridization phenomena. The principle of these assays involves the labeling of two binding components that can specifically interact with a target DNA. One or both of the labels may be a luminescent compound. The luminescent quality of the first label may consist of a chemiluminescent probe that can be excited through specific chemical processes, producing light emission. Alternatively, the label may be a fluorescent probe that can absorb light of a particular wavelength and subsequently emit light at another wavelength.

The second label may also be a fluorescent compound, but does not necessarily have to be. As long as the second label can absorb the emission of the first label and modulate its signal, binding events can be

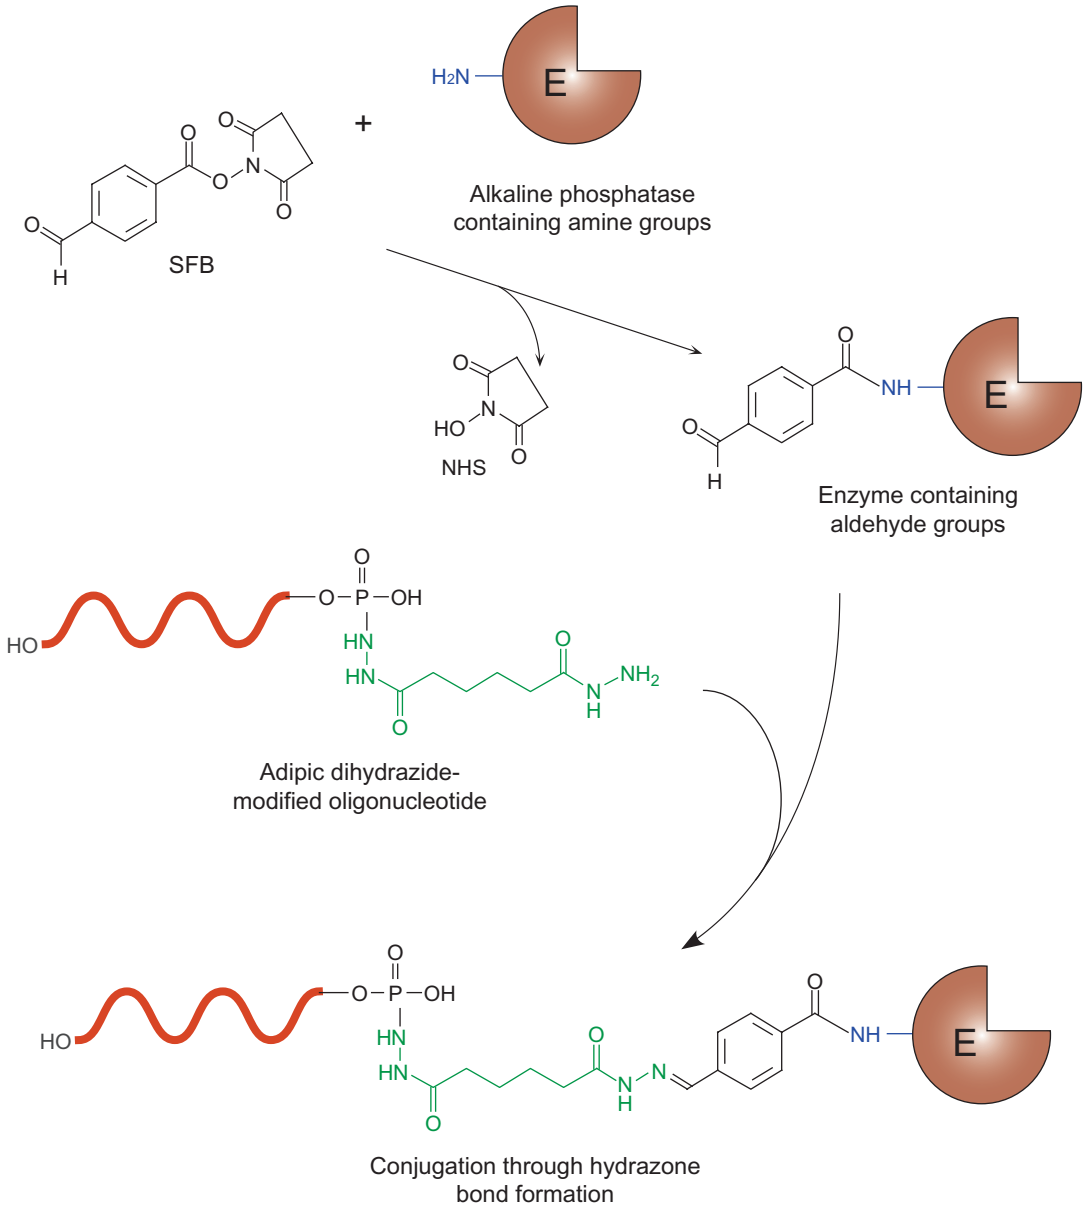

FIGURE 23.22 SFB may be used to create aldehyde groups on enzyme molecules for subsequent conjugation to a 5′-bishydrazide-modified oligonucleotide, forming hydrazone bonds.

observed. Thus, the two labeled DNA probes interact with each other to produce fluorescence modulation only after both have bound target DNA and are in enough proximity to initiate fluorescence resonance energy transfer (FRET). Common labels utilized in such assay techniques include the chemiluminescent probe *N*-(4-aminobutyl)-*N*-ethylisoluminol, and reactive fluorescent derivatives of fluorescein, rhodamine, and the cyanine dyes (Chapter 10). For a review of these techniques, see Morrison (1992) and Chapter 1.

To prepare labeled DNA molecules for use in fluorescent assays, the oligo must first be derivatized to contain a functional group. Any of the methods of Sections 2.1 and 2.2 (this chapter) may be used to add an amine or sulfhydryl residue to specific regions of the DNA polymer. Once modified in this manner, the oligo may be further reacted with a fluorescent probe to create the final derivative. However, many of the fluorescent quenching formats exclusively specify either 3′ or 5′ labeled DNA molecules. This is because discrete modification at just one end of the oligo ensures that the label on a hybridized probe will be near enough to a second hybridized-and-labeled DNA molecule to effect the luminescent modulation necessary to make the system viable. Multiple fluorescent labels on nucleotides within the DNA probe would not be affected to the

same degree by a second label attached to another oligo hybridized some distance away on the target strand. Therefore, use of the terminal transferase method of adding a modified nucleoside triphosphate to the 3′ end (Section 1) or 5′-phosphate modification using a carbodiimide-mediated reaction (Section 2.1) work best for creating functionalized DNA derivatives for fluorescent modulation techniques.

Another method of fluorescent detection of DNA or RNA targets involves the modification of a targeting oligo at both ends. In this approach, one end is modified with a fluorescent molecule and the other end is modified with another label that can be a quencher of fluorescence or another fluorescent probe able to accept energy from the first label. These "molecular beacons," as they are called, contain terminal sequences that are able to hybridize the ends together in solution in the absence of target. Thus, if a fluorescent molecule is at one end of the molecular beacon and a quencher is at the other end, in solution without a target DNA present the fluorescent signal would be completely quenched. In the presence of the target DNA, the molecular beacon would hybridize to the target and open up the stem-and-loop structure of the probe, thus forcing the fluorophore and quencher too far away from each other to cause fluorescent quenching. The result is that specific target binding of the molecular beacon causes the generation of a fluorescent signal. The more fluorescence that occurs the more target is present in solution. For a review of molecular beacon technology, see Bratu (2006).

The following sections describe two methods of coupling fluorescent labels to functionalized DNA probes. Other fluorophores or quenching molecules may be attached using similar procedures with careful reference to the properties and reactivities of such labels as discussed in Chapter 10.

Conjugation of Amine-Reactive Fluorescent Probes to Diamine-Modified DNA

DNA modified with a diamine compound to contain terminal primary amines may be coupled with amine-reactive fluorescent labels. The most common fluorophores used for oligonucleotide labeling are the cyanine dyes and derivatives of fluorescein and rhodamine. However, any of the amine-reactive labels discussed throughout Chapter 10 are valid candidates for DNA applications.

Some fluorescent probes are relatively water insoluble and must be dissolved in an organic solvent prior to addition to an aqueous reaction medium containing the DNA to be labeled. Even water soluble fluorescent probes may be dissolved first in an organic solvent to permit easy addition to an aqueous reaction medium without hydrolysis of the reactive group. Suitable solvents are identified for each fluorophore, but mainly DMF, DMAC, or DMSO are used to prepare a stock solution. Some protocols utilize acetone when labeling DNA. However, avoid the use of DMSO for sulfonyl chloride compounds as this group reacts with the solvent. For oligonucleotide labeling, the amount of solvent added to the reaction mixture should not exceed more than 20% (although at least one protocol calls for a 50% acetone addition; see Nicolas *et al.*, 1992).

The following protocol is a generalized method for labeling amine-modified oligonucleotides with a fluorescent probe, such as FITC. It is based on the method of Morrison (1992).

Protocol

1. Prepare 10 nmol of a diamine-modified DNA probe using the chemical methods discussed in Section 2.1 or through enzymatic derivatization using an amine-containing nucleoside triphosphate (Section 1). Dissolve or buffer exchange the oligo into 1.0 ml of a suitable coupling buffer for the type of amine-reactive fluorophore utilized (see recommended reaction conditions for the particular fluorescent label in Chapter 10). For FITC, the appropriate buffer condition for the oligo is 0.1-*M* sodium carbonate, pH 9.0.
2. Dissolve the fluorophore in DMF or another suitable solvent at a concentration of 0.01-*M*. For FITC, this translates into a concentration of 3.89 mg/ml.
3. Add 50 µl of the FITC solution to the oligo solution and mix. For the use of NHS ester or sulfonyl chloride fluorescent probes, add up to 150 µl of the fluorophore solution to the DNA.
4. React overnight at room temperature.
5. Remove excess fluorophore from the labeled oligo using gel filtration on a desalting resin, dialysis, or a centrifugal concentrator.

Conjugation of Sulfhydryl-Reactive Fluorescent Probes to Sulfhydryl-Modified DNA

Fluorescent probes containing sulfhydryl-reactive groups can be coupled to DNA molecules containing thiol modification sites. The chemical derivatization methods outlined in Section 2.2 may be used to thiolate the oligo for subsequent modification with a fluorophore. Appropriate fluorescent compounds and their reaction conditions may be found in Chapter 10. The protocol discussed in the previous section can be used as a general guide for labeling DNA molecules.

CHAPTER

24

Bioconjugation in the Study of Protein Interactions

The study of protein interactions has become a vital research effort as a result of the sequencing of the human genome and the genomes of other organisms. The next great challenge beyond merely having knowledge of gene sequences is to understand the complex interplay of the resultant protein molecules within cells as they bind, interact, and affect cellular processes. From the many research papers that have appeared on this subject, it is becoming clear that each protein molecule interacts with other proteins and molecules not in isolated obscurity, but in a highly complex web of interactions, which can have far reaching effects on overall biological function (Braun and Gingras, 2012).

Protein interactions mediate virtually every cellular process. They are involved with transcription, translation, transport, cell cycle control, the determination of cell type and function, protein folding, post-translational modifications, signal transduction, metabolism and energy production, cell structure and motility, the formation of biological machines, cell and organism defense, and apoptosis (Katz *et al.*, 2011; Khan *et al.*, 2011). Genetic mutations or damaging modifications resulting in abnormal protein interactions are often the root cause of many diseases, especially tumorogenesis.

The general types of protein–protein interactions that occur in cells include receptor–ligand, enzyme–substrate, multimeric complex formation, structural scaffolds, and chaperones. However, proteins interact with more targets than just other proteins. Protein interactions can include protein–protein or protein–peptide, protein–DNA/RNA or protein–nucleic acid, protein–glycan or protein–carbohydrate, protein–lipid or protein–membrane, and protein–small molecule or protein–ligand. It is likely that every molecule within a cell has some kind of specific interaction with a protein (Roldos *et al.*, 2011; Smith, 2012).

The consequences of protein interactions in effecting cellular biochemistry include the synthesis, destruction, or recycling of biomolecules; the supply of energy for cellular processes; the generation of chemical signals; activation or inhibition of proteins and enzymes; changes in protein conformation and structure; the creation of new binding sites or active centers in proteins; the motility of cells, tissues, and organisms; transport of molecules within cells or into/out of cells; and the formation of cellular structures and compartments.

Protein interactions can be described in relative ways related to the strength of the binding that takes place between the two molecules and the time that the interaction lasts. Any interacting molecules can be characterized as having (1) either high affinity (strong) or low affinity (weak) binding, and (2) either stable (long lasting) or transient (short-lived) binding. Thus, a given protein interaction may be described in one of four possible ways: strong and stable, strong and transient, weak and stable, or weak and transient. Interactions of the weak and stable type may at first seem like an oxymoron, but often multiple weak interactions can take place simultaneously with a target and the combined "avidity" makes the resultant complex stable.

Of the large number of protein interactions that take place in cells, perhaps the vast majority may be described as transient. Most proteins that modify other molecules do so very rapidly and so interact only briefly with their substrates or binding partners (i.e., enzymes). In addition, since proteins within cells are highly compartmentalized, the affinity of most interactions does not have to be very great, because each potential binding partner is within short diffusion distances and the relative concentration of molecules within these small volumes is high.

Of course, the designations of strong, weak, stable, or transient are all subjective terms. They mainly result from the outcome of affinity capture experiments of binding partners on insoluble supports or the analytical determination of the kinetic parameters of specific

binding interactions. In general, if the affinity constant of a protein interaction is strong enough to allow a binding partner to be captured and purified using an immobilized affinity ligand, then the interaction can be described as being reasonably strong. This usually correlates to an affinity constant of $>10^6$ or a dissociation constant of $<10^{-6}$ (with units dependent upon the number of molecules interacting and the resultant equilibrium equation). Conversely, interactions having affinity constants of $\leq 10^6$/M are often too weak to survive the washing steps needed to isolate the interacting protein on a solid phase affinity support. Quantitative measurement of the affinity constant between interacting proteins and the half-life of the interaction may be performed using surface plasmon resonance (SPR) techniques (Homola *et al.*, 1995, 1999).

The vast network of protein–protein interactions that have been deciphered in recent years has grown to include literally thousands of proteins in a sometimes chaotic dance of complexity. Using the two-hybrid method, for instance, which involves the use of split transcription factor fusion proteins that allows detection of interacting proteins by activation of reporter gene expression, many putative protein–protein interaction partners have been identified in yeast (Fields and Song, 1989; Chien *et al.*, 1991; Criekinge and Beyaert, 1999). A map of these interactions looks a lot like a picture of the myriad nodes of addresses on a vast network of computers, such as the interconnections that make up the Internet (Jeong *et al.*, 2001). Although most of the proteins in an organism have only a few partners that interact with them, major hubs in protein "interactomes" can have up to 10 to 20 links with other proteins, indicating that these key proteins are critical players in cell vitality. Many of these sentinel proteins are enzymes, such as kinases, that act on a variety of different protein substrates in turning on or turning off pathways within cells in response to metabolic or external stimuli. Figure 24.1 shows a small segment of the yeast interactome.

Through the growing knowledge of protein–protein interactions and their corresponding gene sequences major interaction domains on protein surfaces are being identified. These relatively conserved amino acid sequences create structural motifs that are designed to bind with certain targeted sequences in other proteins or molecules (Pawson and Nash, 2003; Ingham *et al.*, 2005; Ibrahim *et al.*, 2011). Using this information, many common binding regions on proteins can be identified just through their gene sequences. The role of protein interaction domains has been an important topic in identifying disease mechanisms (Ibrahim *et al.*, 2011).

However, it is much more difficult to characterize the interactions of proteins with no known interaction domains. The traditional "lock and key" approach to

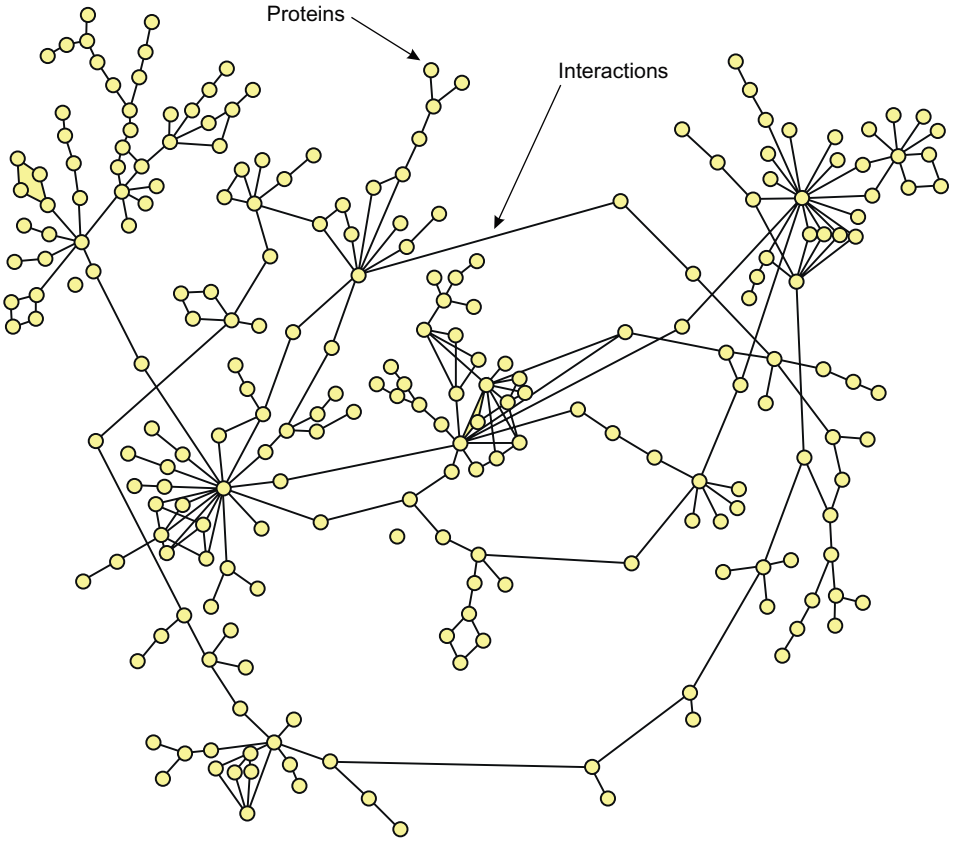

FIGURE 24.1 A small segment of the yeast interactome. The spheres represent proteins and the interconnecting lines are identified protein interactions. Many proteins are seen to interact with one or two other proteins, but some can have over a dozen other interacting partners.

conceptualizing binding pairs is far too simplistic to allow easy visual identification of interacting surfaces on the complex three-dimensional space making up the topology of protein molecules. Even in those instances where protein interacting partners have been crystallized together and their three-dimensional structures determined, it is obvious from the molecular models that it would be difficult or impossible to visually identify the site of interaction without having such structural data in place beforehand. For this reason, experimental schemes are needed that are more elaborate than just knowledge of genetic sequences or interaction domains to characterize the majority of specific interactions proteins undergo. Even when two-hybrid studies indicate the probability of a protein interaction occurring, it still does not provide information on the nature of the interaction, the binding sites, or its function.

The techniques developed to study protein interactions can be divided into a number of major categories (Table 24.1), including bioconjugation, protein interaction mapping, affinity capture, fusion protein labeling, protein probing, and instrumental analysis (i.e., NMR, crystallography, mass spectrometry, and surface plasmon resonance). Many of these methods are dependent on the use of an initial bioconjugation step to discern key information on protein interaction partners. For a review of the major methods used in the study of protein interactions, see Perrakis *et al.* (2011).

TABLE 24.1 Common Reagents and Techniques Used to Investigate Protein Interactions

Category	Technique
Bioconjugation	• Bifunctional crosslinking agents • Trifunctional label-transfer agents • Oxidative cross-linking • Photoreactive amino acids
Protein Interaction Mapping	• Mutagenesis • Site-directed modification • Chemical cutting agents • Enzymatic digestion
Affinity Capture	• Co-Immunoprecipitation • Pull-down assays • Streptavidin–biotin • Antibody & protein arrays • Tandem tag isolation • Affinity arrays
Fusion Protein Labeling	• Yeast two-hybrid techniques • Protein complementation assays • Fluorescent protein FRET assays • BRET assays
Protein Probing	• Far-western blot analysis • Labeled protein probes • Antibody probing of epitopes • Substrate or ligand inhibitors • Spin labels and photoaffinity probes • Fluorescent probes • Proximity ligation assays
NMR, Crystallography, Mass Spectrometry, SPR	• Mass tags and heavy atom labels • Molecular modeling of interacting pairs • Label-free detection

Many of the methods developed to study protein interactions use the bait/prey model to detect interacting partners (Phizicky and Fields, 1995; Archakov *et al.*, 2003; Piehler, 2005). The bait protein is a purified protein (often recombinant) that is used to lure and capture a putative interacting protein or biomolecule. The bait protein may be immobilized to a solid phase for affinity separations or used in solution. It may also be fusion tagged (i.e., GST or 6xHis) or labeled with a detectable molecule, such as a fluorescent probe. It is often the case that there exists an antibody specific for the bait protein to use for detection or in recovery of the interacting complexes.

The prey is a protein, protein complex, or other biomolecule that interacts with the bait protein. It can be captured by its specific affinity interaction with the bait. Since many protein interactions may involve low affinity binding events or are transient, the use of chemical crosslinking techniques can greatly facilitate analysis of an interacting prey protein. In fact, the use of bioconjugation to "fix" interacting proteins is a powerful route to capturing weak affinity or transiently interacting molecules, as the crosslinked complexes can be isolated and analyzed without loss of some components.

The following sections describe the use of bioconjugation reagents for the study of protein interactions. These reagents and techniques can be used to crosslink and capture interacting proteins, to investigate the binding sites involved with interactions, and to identify which peptide regions or amino acids participate in the binding event. In addition to the bioconjugation reagents described in this section, the reader is also referred to Chapter 12, Section 3, entitled Mass Tags and Isotope Tags, wherein some of those reagents can also be used to investigate interacting proteins.

1. HOMOBIFUNCTIONAL CROSSLINKING AGENTS

One of the first applications of bioconjugate techniques was the use of simple homobifunctional compounds (see Chapter 5) to capture interacting proteins in biological samples. As the name of this type of reagent implies, the compounds have reactive groups on each end of a spacer arm that are identical and react with the same type of functionality on different proteins. For instance, early development of crosslinking compounds resulted in the creation of homobifunctional amine-reactive reagents using either imidoesters or NHS esters as the reactive groups. Both of these reagent types could be reacted with

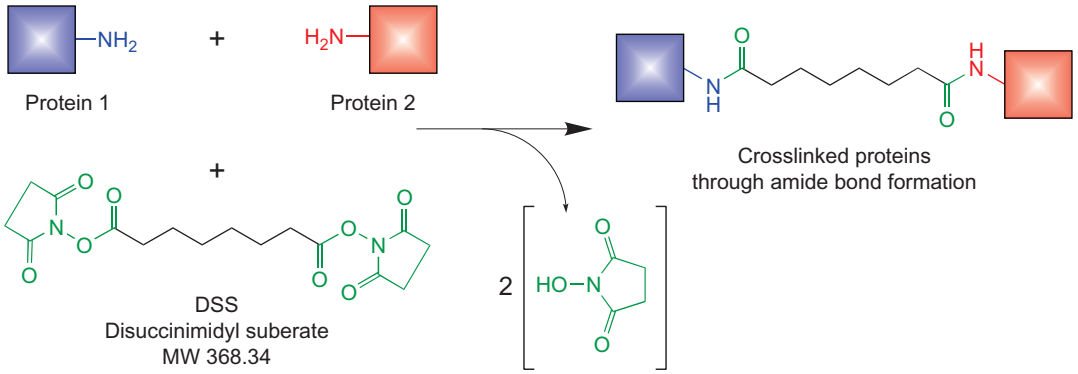

FIGURE 24.2 DSS can capture protein interacting partners through amide bond crosslinks.

a complex protein sample mixture to result in efficient conjugation of proteins through their available amine groups. The reactive groups on these compounds survive long enough in a physiological pH environment to effectively capture and covalently link proteins in proximity to one another. In this way, any proteins undergoing specific biological interactions can be "fixed" by chemical conjugation and thus link together permanently interacting complexes for analysis.

However, as one might expect, this strategy is more or less a crude "shotgun" approach, wherein every protein in the sample has the potential to be crosslinked with other proteins regardless of whether they are undergoing specific interactions or not. The use of homobifunctional reagents to study protein interactions may therefore result in high noise levels or many false positives, because of their non-selective crosslinking characteristics. The end result often makes it difficult to identify conjugated proteins that are specifically interacting from those proteins crosslinked just due to random collisions.

However, even acknowledging their disadvantages, homobifunctional crosslinkers have been used successfully to investigate many protein–protein interactions, within cells and within lysates or protein solutions. The key to capturing true interacting proteins while limiting the degree of nonspecific conjugation is to optimize the amount of crosslinker at the lowest possible concentration. Using too high a concentration will extensively conjugate all proteins, even those that are not specifically interacting at the moment. Using too low a concentration will not effectively conjugate even interacting proteins. Therefore, optimization is typically needed to determine the best concentration of homobifunctional crosslinker for a particular application.

1.1. DSS and BS^3

Two crosslinking agents that have been used extensively to study protein interactions are disuccinimidyl suberate (DSS) and *bis*-sulfosuccinimidyl suberate (BS^3) (see Chapter 5, Section 1.2). Both reagents contain an 8-carbon spacer arm built from suberate core and have reactive esters at each end that couple with amines to form amide bonds. They differ, however, in the fact that DSS contains NHS esters and BS^3 contains negatively charged sulfo-NHS esters. BS^3 therefore is water soluble and will not penetrate cell membranes, whereas DSS is hydrophobic, water insoluble, and membrane permeable. For this reason, BS^3 can be used to study cell surface–protein interactions (Friedrichson and Kurzchalia, 1998; Simons *et al.*, 1999), while DSS can be used to study intracellular protein interactions (Ishmael *et al.*, 2005). The reaction of DSS to capture and crosslink interacting proteins is shown in Figure 24.2.

The following protocol represents a generalized strategy for crosslinking interacting proteins using either DSS or BS^3. The buffer conditions and reagent amounts are gleamed from published procedures, but the exact quantities should be optimized for each protein interaction studied.

Protocol

1. Suspend cells at ~25 × 10^6cells/ml in PBS (pH 8.0).
2. Wash cells three times with ice-cold PBS (pH 8.0) to remove amine-containing culture media and extracellular proteins from the cells.
3. For cell–surface interaction studies, add ligands to the cells and incubate for 1 h at 4°C.
4. Dissolve DSS or BS^3 in dry DMSO at a concentration of 25-m*M*. Note: BS^3 may be added directly to PBS buffer or dissolved as a stock solution in DMSO.
5. Add an aliquot of the DSS or BS^3 solution to the reaction medium to obtain a final concentration of 0.5 to 5-m*M*. Note: Simons *et al.* (1999) successfully used a concentration of 0.5-m*M* BS^3 with Madin–Darby canine kidney (MDCK) cells permanently expressing a GPI-anchored form of growth hormone decay accelerating factor (GH-DAF) to crosslink the protein interaction complexes on the cell surfaces.

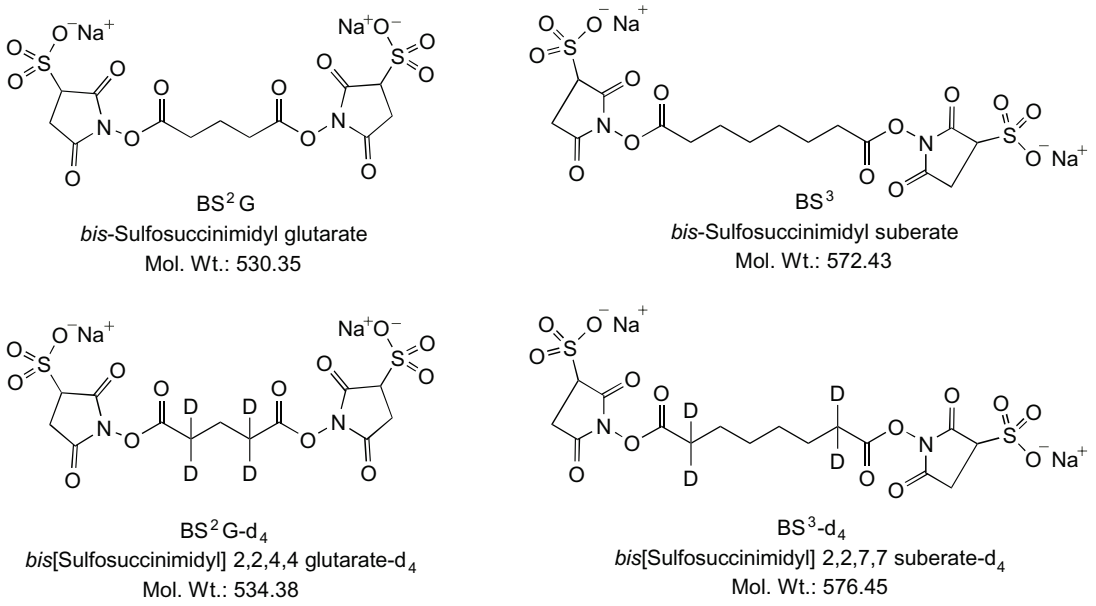

FIGURE 24.3 The homobifunctional crosslinkers BS^2G and BS^3 can be used to capture protein interactions through amide bond formation. The deuterium-labeled analogs of these reagents can be used to differentiate samples by mass spectrometry.

6. Incubate the reaction mixture for 30 min at room temperature. To reduce active internalization of BS^3 into cells, this incubation may be performed at 4°C.
7. Quench the reaction by adding an aliquot of 1-*M* Tris, pH 7.5, to give a final concentration of 10 to 20-m*M*.
8. Incubate the quenching reaction for 15 min at room temperature.
9. Lyse cells and analyze the protein interactions by electrophoresis, western blotting, and mass spectrometry.

1.2. Heavy Atom, Deuterated Crosslinking Agents

Another approach to the study of protein interactions using homobifunctional crosslinkers uses the incorporation of isotopes, such as deuterium, into the reagent structure to produce a heavy atom analog suitable for mass spectrometry analysis. In this technique, the normal or light H (hydrogen) version of a crosslinker is used in an equal molar ratio to a heavy D (deuterium) version to capture interacting proteins through covalent conjugation. The heavy and light analogs are reacted with a sample at the same time, so that each form of the reagent will have an equal chance of reacting with an interaction complex. Subsequent proteolytic digestion of the sample (i.e., with trypsin) creates peptide fragments, some of which will contain covalent crosslinks from the heavy or light crosslinkers. In addition, these crosslinked peptides will have an equal chance of having either a light atom linker or a heavy atom linker holding them together.

Mass spectrometer analysis of the peptide fragments formed by this process yields pairs of MS peaks differing only by the mass change caused by the substitution of deuterium atoms for hydrogen atoms in half of the crosslinks. Thus, searching for MS peaks in the data that differ by the number of deuterium substitutions will immediately identify peptides from the interacting proteins that have been captured by the crosslinking process.

Using this approach, homobifunctional crosslinking agents containing sulfo-NHS esters have been developed based on the core structures of glutaric and suberic acids. The suberate-based crosslinker is also known as BS^3 and has been described previously (Section 1.1, this chapter). These two standard amine-reactive reagents are then modified at two carbons of their respective cross-bridge structures to contain two pairs of deuterium atoms, increasing their molecular mass by exactly four from the normal hydrogen atom analogs.

These heavy atom reagent pairs are termed $BS^2G\text{-}d_4$ (*bis*[sulfosuccinimidyl] 2,2,4,4 glutarate-d_4) and $BS^3\text{-}d_4$ (*bis*[sulfosuccinimidyl] 2,2,7,7 suberate-d_4), and their light atom analogs are called $BS^2G\text{-}d_0$ (*bis*[sulfosuccinimidyl] glutarate-d_0) and $BS^3\text{-}d_0$ (*bis*[sulfosuccinimidyl] suberate-d_0) (Thermo Fisher) (Figure 24.3). The sulfo-NHS esters of these four compounds all react equally well with amine groups on proteins to form amide bonds. Therefore, there are virtually no differences in properties or reactivities between the heavy and light versions of these reagents.

The conjugation of interacting proteins with heavy/light crosslinkers potentially can result in a number of derivatives having unique atomic mass units (amu) observed by mass spectrometry. For instance, any of

TABLE 24.2 Potential Atomic Mass Unit Contributions Associated with the Heavy/Light Crosslinkers

Reagent	Both Ends Amide Bond Linked	One End Hydrolyzed to Carboxylate
BS^3-d_0	138.068 amu	157.079 amu
BS^3-d_4	142.090 amu	161.102 amu
BS^2G-d_0	98.102 amu	116.113 amu
BS^2G-d_4	102.124 amu	120.135 amu

these crosslinkers might react with amines on interacting proteins at both ends to form amide bonds. Alternatively, one end of these homobifunctional compounds may react with a protein to form an amide bond while the other end hydrolyzes, resulting in loss of the sulfo-NHS group to form a carboxylate. Thus, the heavy/light crosslinking pairs may have two potential amu results when peptides are analyzed by mass spectrometry. Table 24.2 shows the potential amu contributions for each of the possible products formed by the reactions of the heavy/light crosslinkers with proteins.

This technique has been described as a general method of studying protein–protein interactions as well as a method for investigating the three-dimensional structure of individual proteins (Muller *et al.*, 2001; Back *et al.*, 2003; Dihazi and Sinz, 2003; Sinz, 2003, 2006). It has also been used for the study of the interactions of cytochrome *c* and ribonuclease A (Pearson *et al.*, 2002), to investigate the interaction of calmodulin with a specific peptide binder (Kalkhof *et al.*, 2005a; Schmidt *et al.*, 2005) and for probing laminin self-interaction (Kalkhof *et al.*, 2005b).

In practice, sample concentrations are typically kept in the micromolar range to limit the widespread conjugation of molecules not specifically interacting or to limit intermolecular conjugation when studying the structure of a single protein. Therefore, most protein concentrations will be in the microgram/milliliter range prior to the addition of crosslinkers. Even in cases wherein a single purified protein is crosslinked to study its three-dimensional structure, limiting the amount of crosslinker in the reaction mixture will help to limit polymerization of the protein. However, successful results have been obtained by this method using up to a 200-fold excess of crosslinker over the concentration of protein in solution.

The following protocol is based on the published methods as well as the specific instructions provided with the heavy atom crosslinkers from Thermo Fisher Scientific. For new applications, the amount of crosslinkers added to the sample will have to be optimized to obtain useful information about the interactions.

Protocol

1. Dissolve the protein(s) to be studied in 20-m*M* HEPES buffer, pH 7.5, at a concentration of 5 to 10 μ*M*.
2. Dissolve together in one solution the desired heavy and light crosslinker analogs in dry DMSO at an equal concentration of up to 100-m*M*. Use either the pair BS^2G-d_4/BS^2G-d_0 or BS^3G-d_4/BS^3G-d_0, but do not mix the different sized crosslinkers together. The heavy and light analogs of the same type should always be dissolved at equivalent concentrations in DMSO to prepare the stock solution.
3. Add a quantity of the crosslinker solution to the protein solution to obtain at least a 10-fold molar excess of the crosslinkers over the concentration of the protein. Studies should be performed at several levels of crosslinker addition to determine the optimal conjugation conditions (e.g., 10-, 50-, 100-, and 200-fold excess).
4. Quench the reaction by the addition of NH_4HCO_3 to a final concentration of 20-m*M*. The optimal time course for the reaction should be determined by removing portions of the solution at different points, starting at about 5 to 10 min and extending out to 2 h in length.
5. Analyze the quenched reaction by SDS electrophoresis, western blotting, and mass spectrometer analysis.

1.3. Formaldehyde

By far the simplest bifunctional crosslinking agent is formaldehyde. Although structurally it appears to be a mono-functional aldehyde compound, formaldehyde reacts with proteins via a two-step reaction to yield a methylene bridge crosslink between two amines on proteins and other molecules, thus it behaves as though it is bifunctional in nature (Figure 24.4). The reaction of formaldehyde with proteins is rapid and efficient, and it has long been used to fix cells and tissue samples for preservation, staining, and probing. Formaldehyde quickly penetrates cells and at the right concentration, results in locking biomolecules in place, preventing diffusion, morphological changes, or loss of proteins through solubilization. It has long been used to inactivate viruses in the production of vaccines (Eckels and Putnak, 2003).

Formaldehyde can also be used at limiting concentrations to crosslink interacting proteins, while avoiding the extensive global crosslinking typically obtained when fixing cells. At relatively low concentrations, formaldehyde will link together only those proteins and other amine-containing molecules within proximity to one another and presumably, therefore, undergoing specific biological interactions (Prossnitz *et al.*, 1988;

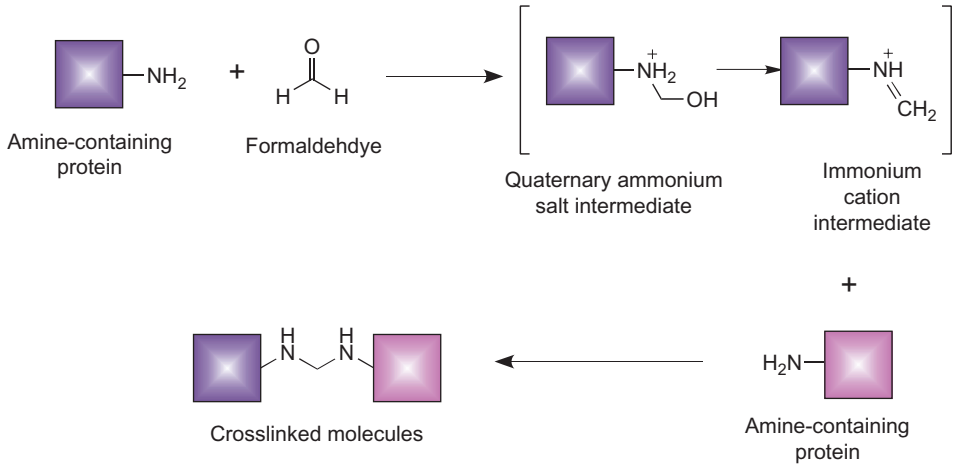

FIGURE 24.4 Formaldehyde can be used to capture protein interactions if it is used at low concentrations. The reaction proceeds through modification of a protein to create an intermediate immonium cation, which then goes on to react with a neighboring protein to form the crosslinked product via secondary amine bonds.

Skare *et al.*, 1993; Derouiche *et al.*, 1995; Orlando *et al.*, 1997; Orlando, 2000; Hall and Struhl, 2002; Vasilescu *et al.*, 2004).

Guerrero *et al.* (2006) used this technique along with the quantitative mass spectrometry strategy called SILAC (stable isotope labeling of amino acids in cell culture) (Ong *et al.*, 2002) to identify the yeast proteins that interact with the 26S proteasome. Formaldehyde has particular compatibility with mass spectrometry analysis, because the crosslinks have the option of being reversed by heating. A specific interaction complex from a sample can be isolated using co-immunoprecipitation (co-IP) by allowing a biotinylated antibody directed against one of the interacting proteins to interact with a lysed cell sample along with subsequent capture of the complex on an immobilized streptavidin column (Chapter 15, Section 2.5). The general process of immunoprecipitation (IP) is illustrated in Chapter 1, Figure 1.6. In a co-IP procedure, the protein pulled down by the antibody would have putative interacting partners crosslinked to it by glutaraldehyde (or by use of another crosslinker). Recombinant fusion tags have also been used with immobilized affinity ligands (Chapter 15 and Chapter 1, Table 1.2) for purification of protein–protein interaction complexes after crosslinking (Young *et al.*, 2012). The protein complexes thus isolated can be analyzed using mass spectrometry with or without reversing the crosslinks holding the complexes together. Without reversing the glutaraldehyde crosslinks, the peptide segments making up the interacting protein complex may be analyzed after proteolytic digestion to determine the exact sites of crosslinking.

The use of mass spectrometry has also aided in identifying the products of formaldehyde crosslinking with proteins, which potentially involves initial reactions with the N-terminal amines on peptide chains, the ε-amine of lysine side chains, the secondary amine of proline (if available), and tryptophan's ring nitrogen. These primary sites of glutaraldehyde reaction create a methylol imine at the modified nitrogens. The major reaction product occurs with lysine side-chain amines. In a second step, these initially modified amino acids can go on to react with one of several amino acids: a histidine side-chain nitrogen, an asparagine or glutamine side-chain amide nitrogen, addition to a tyrosine phenolic ring in the *ortho* position to the –OH group, a tryptophan side-chain nitrogen, or an arginine guanidinyl group (Sutherland *et al.*, 2008). If the formaldehyde crosslinks from this process are reversed prior to MS analysis, then the original peptides can be analyzed to determine the proteins from which they originated. A review of co-IP techniques was published by Geva and Sharan (2011).

Formaldehyde crosslinking can also be used to study the interactions of proteins with DNA or RNA molecules. This technique is typically called chromatin immunoprecipitation (ChIP) and the experiments can be performed using several methods (Bortz and Wamhoff, 2011; Truax and Greer, 2012). ChIP-based assays can be performed similarly to co-IP assays in that cell samples can be treated and fixed with dilute glutaraldehyde, lysed, and the targeted protein that may be interacting with the DNA or RNA segment isolated by affinity chromatography and then analyzed by use of a gel-shift assay (Yakhnin *et al.*, 2012) or by mass spectrometry. The ChIP approach can also be performed using immobilized oligonucleotides in an array (ChIP-on-chip) to probe for interacting proteins from lysed cell samples (Qin *et al.*, 2011). These methods are illustrated in Figures 1.20 and 1.21 in Chapter 1.

The following protocol is a generalized method that summarizes the publications on the use of formaldehyde for capturing interaction proteins. The concentration ranges indicated for the reactants and the time of the reaction need to be optimized for each protein interaction studied.

Protocol

1. Grow cells and wash into ice-cold 10-m*M* PBS buffer, pH 6.8.
2. Add formaldehyde to a final concentration of 0.125 to 1% (w/w) (optimize to find the best concentration level for the particular protein being studied).
3. React at room temperature to 37°C for 5 to 60 min (optimize to find the best reaction time for the protein being studied).
4. Wash cells and solubilize pellet in SDS-PAGE sample buffer.
5. Heat at 37°C for 10 min to fully solubilize and maintain crosslinked proteins, and then enrich specific complexes by immunoprecipitation using an immobilized antibody specific for the bait protein that was used. Alternatively, heat at 96°C for 20 min to solubilize and break all crosslinks (this may be used as a control).
6. Analyze interacting proteins by electrophoresis, western blotting, and mass spectrometry.

1.4. Protein Interaction Reporters

Standard homobifunctional crosslinkers, such as those described in the previous sections, can capture protein interactions effectively through covalent linkages, but they create severe challenges for analyzing exactly what proteins have been conjugated. This is not just the result of the large number of protein interacting partners that get crosslinked; it is also a result of the wide variety of products that can form from the process, including side reactions, nonspecific conjugations, and crosslinkers that only reacted with one protein. Attempting to deconvolute the identity of true protein interacting complexes created by large-scale crosslinking of complex samples is the major problem of most conjugation techniques used to study protein interactions.

A new type of crosslinking strategy may overcome this problem, as it takes advantage of definitive mass spectrometry identification after the chemical crosslinking of interacting proteins. The protein interaction reporter (PIR) reagent as described by Tang *et al.* (2005) is based on a bifunctional crosslinker concept, but having the additional feature of containing two mass spectrometry cleavable bonds within a specially designed spacer arm. The cleavable parts of the molecule consist of two RINK groups, which are amide-releasing, acid-cleavable components based on the solid-phase peptide synthesis resin first described by Rink (1987), and containing the 4-(2′,4′-dimethoxyphenylaminomethyl)phenoxy linker on each side of a central mass reporter tag (Figure 24.5). On both ends of the PIR compound, NHS esters provide amine reactivity to capture any interacting proteins in a complex sample, such as within a cell or lysate. In use, the PIR crosslinker is first reacted with a sample to form conjugates and then the proteins are subjected to proteolysis to create peptides. Some of the peptides that are formed will be conjugated together through the PIR crosslinks. This complex mixture of peptides is then subjected to mass spectrometry analysis using a mass spectometry capable of MS^2 or MS^3 separations.

Second-generation PIR reagents have been designed to include an affinity handle branching off from the central reporter group's free carboxylate. In one such design, a biotin group is built at the end of a

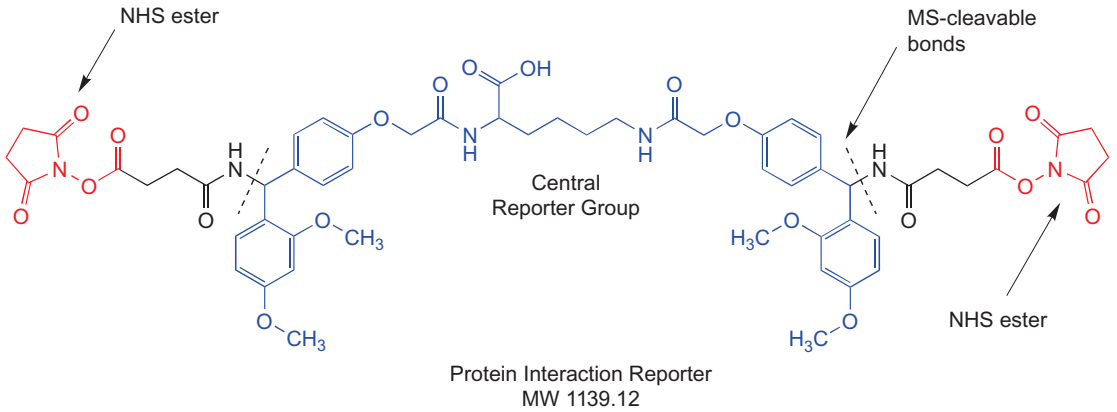

FIGURE 24.5 This PIR compound contains NHS esters at both ends to capture interacting proteins through amide bond formation. It also contains MS-cleavable bonds that release a central reporter group, which can be used to identify crosslinked peptides by mass spectrometry.

hydrophilic PEG spacer (Figure 24.6). The PEG arm provides increased water solubility to the overall reagent, which is otherwise rather hydrophobic. The biotin group can be used to detect or capture crosslinked interacting proteins out of complex solutions. For instance, immobilized streptavidin can be used to pull down any proteins modified with the biotin–PIR reagent. Alternatively, a complex solution may be separated by electrophoresis and the modified proteins identified after western blotting through the use of a streptavidin conjugate detection complex.

The use of a crosslinker containing MS labile bonds along with a mass reporter group can significantly reduce the complexity of finding and identifying coupled peptides in a huge amount of mass spectrometry data. In the first dimension of a MS separation, the overall mass of the PIR crosslinked peptides can be accurately determined as a single peak in the MS spectrum. The resultant mass correlates to the sum of the two crosslinked peptides plus the intervening PIR spacer, which links them together.

With bifunctional NHS ester reagents, one of three modification products can occur with proteins: (1) a dead-end linkage wherein one end of the crosslinker has attached to an amine group within a protein and the other end has hydrolyzed and not formed an attachment; (2) an intra-protein crosslink wherein the PIR reagent has been coupled at both ends to amines within the same protein; or (3) an inter-protein crosslink wherein both ends of the PIR reagent have been coupled with amines on two different protein molecules (Figure 24.7).

The second stage of an MS^2 analysis can be performed to bombard with more energy the mass products of the first stage separation in order to fragment the proteolytically digested complexes. At this point, the mass reporter group within the PIR crosslink is released due to breakdown of the two labile RINK bonds within the reagent structure (see Figure 24.5). Mass spectrometry cleavage of these groups and release of the reporter results in one of two potential mass signatures depending on if both ends of the PIR reagent have reacted (which gives a reporter mass = m/z 711) or if only one end has reacted (a dead-end; reporter mass = m/z 828). The resulting mass spectrum then shows either two or three peaks, depending on the type of modification formed from the initial PIR reaction. This process also releases the crosslinked peptides without disrupting the peptide backbone and thus leaves a small part of the PIR compound attached to each peptide fragment, minus the reporter group.

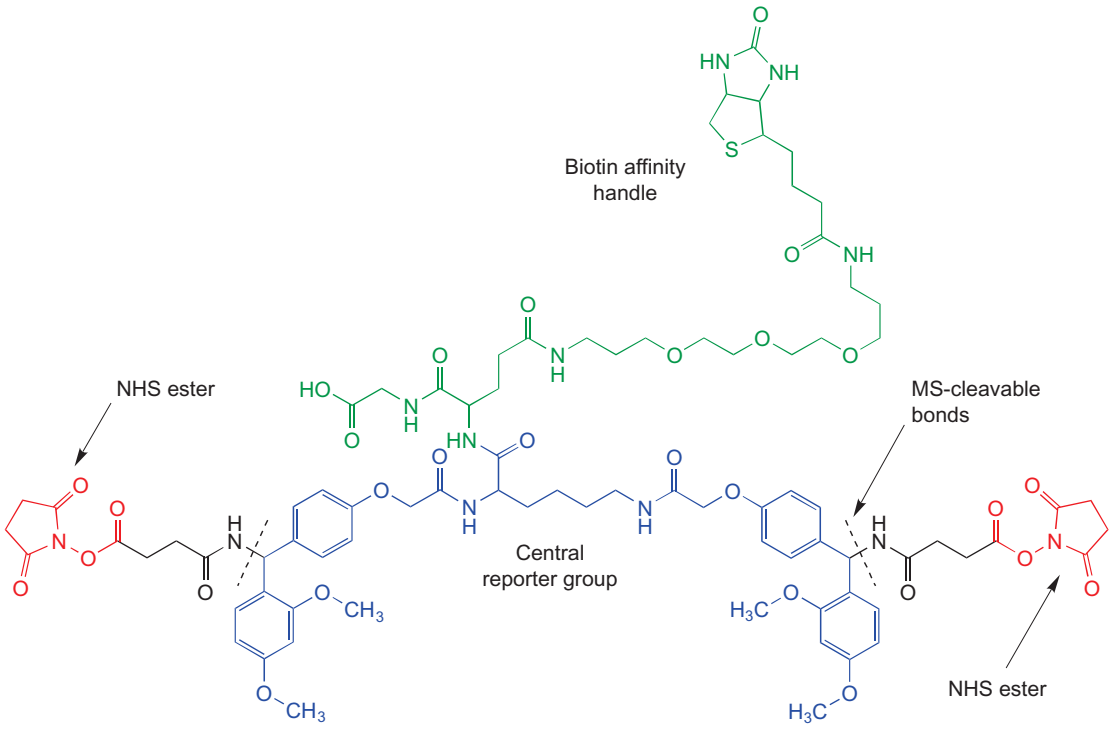

FIGURE 24.6 A trifunctional PIR compound that contains two NHS esters to capture interacting proteins through amide bond formation and a PEG–biotin arm to permit isolation of crosslinked proteins on (strept)avidin supports.

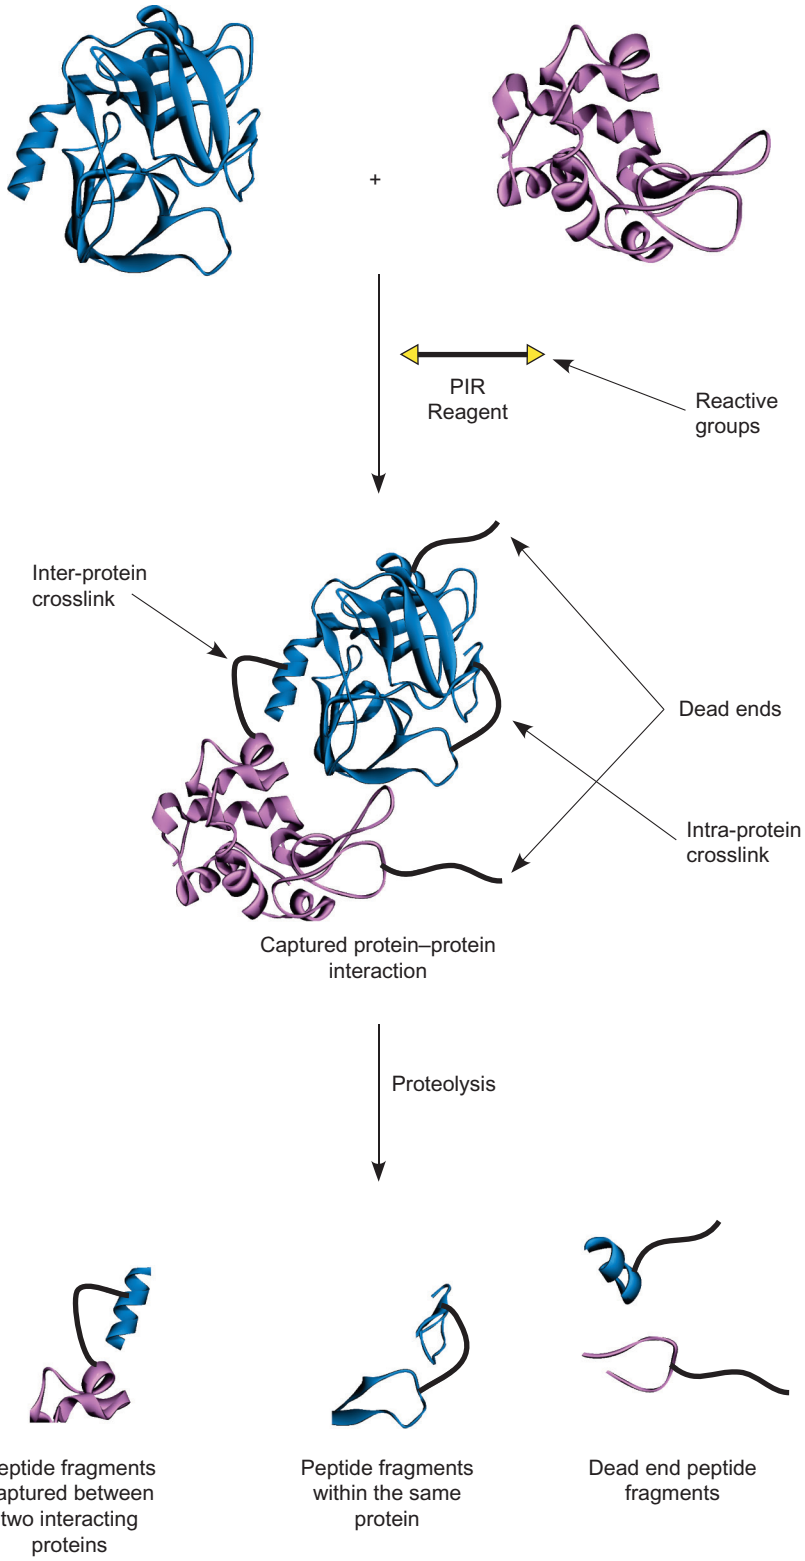

FIGURE 24.7 Reaction of a PIR compound with a protein sample can result in several products, all of which can be identified by mass spectrometer analysis. A true inter-protein crosslink can occur that links two interacting proteins together, which is the desired product. However, the crosslinking process may also result in intra-protein crosslinks or dead ends wherein only one end of the PIR reagent has coupled to a protein.

The specific fragmentation pattern observed at this stage distinguishes the kind of crosslink or modification that was initially formed. In this regard, a single modified peptide peak plus a reporter peak of mass *m/z* 828 indicates a dead-end modification with no value in determining protein interactions. Alternatively, a single peptide fragment peak plus a reporter group peak of mass *m/z* 711 indicates an intra-molecular crosslink made between regions of the same protein, which is also not of interest. However, a fragmentation pattern containing two labeled peptide peaks plus a reporter peak of mass *m/z* 711 indicates a successful conjugation between two protein molecules, which may be indicative of a true protein–protein interaction. Note that alternative designs of a PIR-type reagent containing other reporter structures, including those with a biotin handle and a PEG spacer, will result in different reporter fragmentation mass values than those stated here.

The use of PIR compounds to study protein interactions is a significant advance over the use of standard homobifunctional crosslinkers (Bruce, 2011; Yang *et al.*, 2012). The unique design of the PIR reagent facilitates deconvolution of putative protein interaction complexes through a simplified mass spectrometry analysis. The software can ignore all irrelevant peak data and just focus analysis on the two labeled peptide peaks, which accompany the reporter signal of appropriate mass. This greatly simplifies the bioinformatics of data analysis and provides definitive conformation of protein–protein crosslinks.

Finally, knowledge of the peptide masses that resulted from the PIR conjugation provides information to identify the parent proteins from which they originated. Peptide mass and sequence databases are now sufficiently developed to provide rapid confirmation of protein–protein interaction partners.

The following protocol is designed for treating cells with the PIR reagent to study protein interactions *in vivo*. It is based on the method of Tang *et al.* (2005). The use of the PIR compound to treat intact cells will result in the crosslinking of proteins both on the cell surface and within the cell, which indicates that the reagent is able to cross the cell membrane.

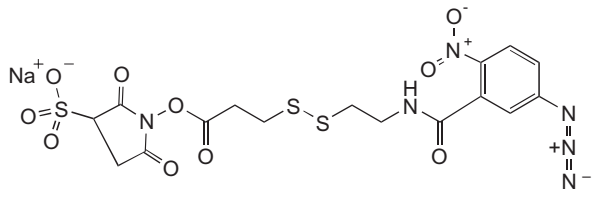
Protocol

1. Dissolve the PIR compound in dry DMSO to make a 100-m*M* stock solution.
2. Grow cells in media to a density of about $OD_{600\,nm}$ = 1.2 and harvest in mid-log phase. Centrifuge cells at 3200 rpm to pellet them and wash three times with ice-cold PBS (150-m*M* sodium phosphate, 100-m*M* NaCl, pH 7.5).
3. Suspend the cells in 1 ml of PBS and add an aliquot of the dissolved PIR compound to bring the final concentration to 1-m*M*.
4. React at room temperature with gentle shaking for 5 min.
5. Quench the reaction by the addition of 50 µl of 1-*M* Tris, pH 7.5.
6. Wash the cells five times by centrifugation with cold PBS to remove excess PIR reagent and any secreted proteins.
7. Lyse the cells using a detergent lysis buffer suitable for the cell type being treated. Centrifuge the lysate at 15,000 rpm for 40 min at 4°C to remove insoluble material. Collect the supernatant and discard the pellet. At this point, the soluble protein fraction may be analyzed by electrophoresis, if desired.
8. Remove unreacted PIR reagent and reaction byproducts by gel filtration or dialysis.
9. Precipitate the protein with TCA to further remove any remaining salts and detergent, centrifuge to pellet the precipitated protein, wash the pellet with TCA, and centrifuge again. Re-dissolve the washed pellet in 100 µl of 100-m*M* NH_4HCO_3, pH 7.8, containing 8-*M* urea.
10. Reduce protein disulfides by adding dithiothreitol (DTT) to a final concentration of 5-m*M* and incubate for 30 min at 60°C. Add iodoacetamide to a final concentration of 25-m*M* to alkylate the thiols. React for 1 h in the dark.
11. Dilute the solution 4-fold with 100-m*M* 25-m*M* NH_4HCO_3, and then add 20 µg trypsin to digest the proteins. Incubate at 37°C for 4 h or overnight at 30°C with shaking.
12. Purify the tryptic peptides by chromatography on a C18 column to remove salts (follow the manufacturer's directions for peptide purification). Dry the eluent and re-dissolve the peptides in 20 µl 0.1% formic acid.
13. Analyze the purified peptides using 2D-LC/MS/MS.

2. USE OF PHOTOREACTIVE CROSSLINKERS TO STUDY PROTEIN INTERACTIONS

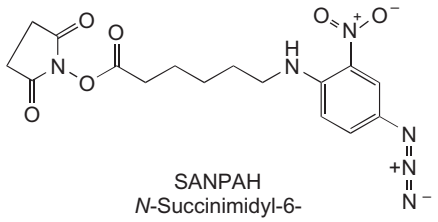
The use of crosslinking agents containing at least one photoreactive group provides reagents that can be activated at a desired point after bait proteins have been allowed to interact and bind to prey proteins. The availability of the first photoreactive homobifunctional or heterobifunctional compounds permitted protein interactions to be studied at a new level of specificity. Unlike the use of spontaneously reactive homobifunctional reagents, the incorporation of a photoreactive group helps to prevent nonselective crosslinking and uncontrolled polymerization of proteins that may or may not be specifically interacting.

In use, a bait protein is first modified with the spontaneously reactive (thermoreactive) end of a



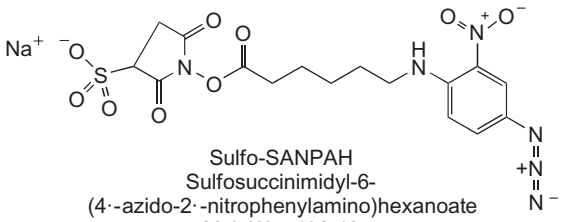
photoreactive heterobifunctional compound, while protecting the solution from light exposure. The modified bait protein is then allowed to interact with a sample containing other proteins and biomolecules, which may contain prey proteins able to interact with it. Finally, the sample mixture is exposed to UV light to activate the photoreactive end of the crosslinker, causing conjugation of this group with any nearby interacting molecules (Leitner, 2012). The rapid reaction rate of the activated photoreactive intermediates assures that they do not survive long enough to cause much conjugation to proteins just due to random collisions. However, interacting proteins that are in proximity to the modified bait protein are more likely to be captured through reaction with the activated photoreactive group.

The following sections discuss the application of several photoreactive heterobifunctional crosslinkers to the study of protein interactions.



2.1. Sulfo-SAND, SANPAH, and Sulfo-SANPAH

These three photoreactive crosslinkers are described in terms of their properties and reactivities in Chapter 6, Section 3, Amine-Reactive and Photoreactive Crosslinkers. They represent early examples of the use of standard phenyl azide photoreactive compounds for the study of protein interactions. All of them contain either an amine-reactive NHS ester or the charged and water soluble analog, a sulfo-NHS ester (Figure 24.8). SANPAH is uncharged and hydrophobic and thus provides membrane permeability for studying intracellular protein interactions in whole cells (Mikhailov *et al.*, 2001; Kota and Ljungdahl, 2005). Sulfo-SAND and sulfo-SANPAH, however, possess a negatively charged sulfonate group, which prevents them from passing through cell membranes, and thus are membrane impermeable (Uckun *et al.*, 1995; Tiberi *et al.*, 1996; Gaudet *et al.*, 2003). The sulfonated compounds may be used with whole cells to study cell surface protein interactions, although, in use, their concentration should be limited to prevent internalization by active transport into cells.



Sulfo-SAND, SANPAH, and sulfo-SANPAH all contain a nitrated phenyl azide photoreactive group. The presence of the nitro group shifts the optimal wavelength for photoactivation to higher wavelengths, thus avoiding the potential for biomolecule damage due to UV irradiation (photoactivation occurs at 320-350 nm). Sulfo-SAND provides one further option for studying interacting proteins. It has a cleavable disulfide-containing cross-bridge that permits recovery of any prey proteins that have been captured by the photo-coupling process (McMahan and Burgess, 1994; Uchiyama *et al.*, 2002). Finally, each of these

FIGURE 24.8 The heterobifunctional crosslinkers sulfo-SAND, SANPAH, and sulfo-SANPAH contain an amine-reactive (sulfo)NHS ester on one end and a photoreactive phenyl azide group on the other end. Sulfo-SAND allows release of conjugates by reduction of its internal disulfide bridge.

photoreactive crosslinkers has phenyl azide rings that undergo ring expansion to the 7-membered ring, dehydroazepine intermediate, which reacts primarily with amines on target molecules. Thus, the proteins that are captured by these crosslinkers are typically coupled through secondary amine linkages to the photoreactive end of the reagents. A general protocol for the use of these compounds to study protein interactions is given at the end of the next section.

2.2. Sulfo-SFAD

Sulfo-SFAD is sulfosuccinimidyl-[perfluoroazidobenzamido]-ethyl- 1,3′-dithiopropionate, an amine-reactive and photoreactive crosslinker with more advanced properties than the photoreactive reagents discussed above. This reagent contains a sulfo-NHS ester to provide increased water solubility prior to conjugation,

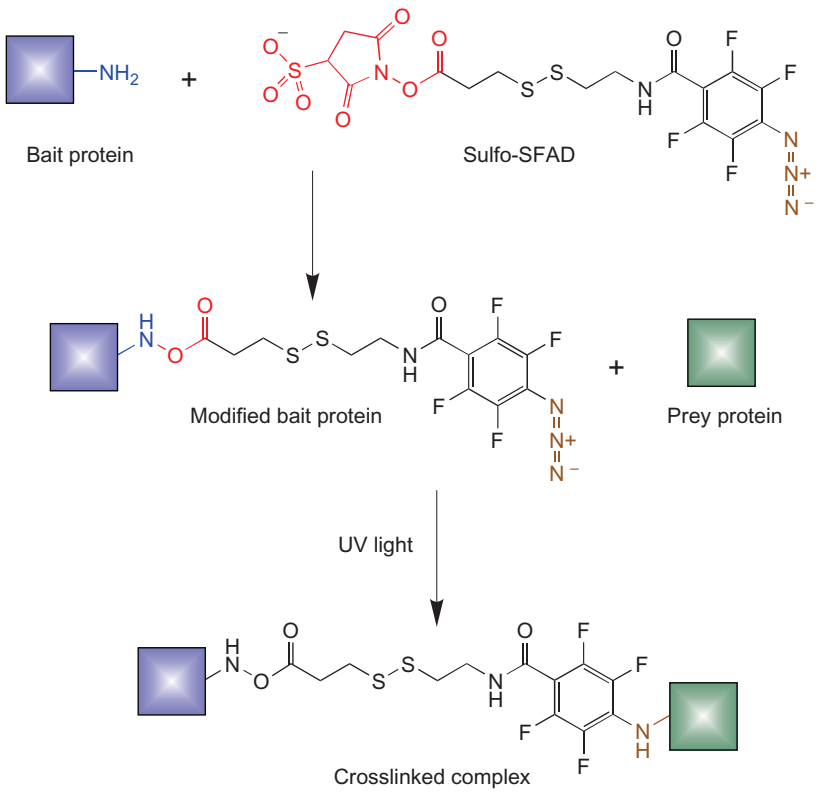

FIGURE 24.9 Sulfo-SFAD is an advanced heterobifunctional photoreactive crosslinker that contains an amine-reactive sulfo-NHS ester on one end and a tetrafluorophenyl azide group on the other end. The fluorine substitutions on the phenyl ring prevent the photoactivated nitrene from reacting with the ring, thereby providing greater yields in capturing interacting proteins. The disulfide-containing cross-bridge allows cleavage of conjugated molecules by reduction with DTT.

and this group will react with an amine on proteins and other biomolecules to form an amide linkage. Sulfo-SFAD also contains a perfluorophenyl azide group that has better photo-insertion capability than the original unsubstituted phenyl azide group. The reason for this enhanced yield is that, after photoactivation, the nitrene intermediate cannot react with the phenyl ring itself and undergo ring expansion to a dehydroazepine as happens with typical unsubstituted phenyl azides. The result is that the nitrene survives long enough to react with neighboring molecules in the immediate molecular vicinity, such as proteins that are interacting with the modified bait protein. Perfluorophenyl azides thus have higher yields of conjugation, and they can react by insertion into C–H bonds, N–H, unsaturated carbon–carbon bonds, and other structures in target molecules. By contrast, unsubstituted phenyl azides ring expand and react mainly with amines, and even then at low yield. The perfluorophenyl azide may be activated with UV light at 320 nm.

Sulfo-SFAD also contains a disulfide bond in its cross-bridge, which provides subsequent cleavability of any crosslinks formed. Thus, prey proteins can be recovered from complexes for analysis by simple reduction of the conjugate with DTT. Once reduced, the perfluorophenyl ring group of sulfo-SFAD is transferred to the interacting prey protein. This group can be identified by ^{19}F NMR, and it also provides a traceable label for identification of peptide fragments by mass spectrometry. Figure 24.9 illustrates the reactions of sulfo-SFAD in capturing a bait–prey complex.

The following references provide further information on the use of sulfo-SFAD and perfluorophenyl azide photoreactive groups: Camperchioli *et al.* (2011); Pandurangi *et al.* (1995a,b, 1996, 1997a,b, 1998); Yan *et al.* (1994).

A general protocol that can serve as a guide for the use of heterobifunctional crosslinkers in the study of protein interactions is given below. Some optimization of concentrations may have to be performed depending on the particular type and properties of proteins being studied.

Protocol

1. Dissolve the photoreactive crosslinker in DMF or DMSO at a concentration of 10 to 25-m*M* (protect from light). Water soluble crosslinkers can be added to water or buffer, but should be used immediately.
2. Modify a purified bait protein by adding an aliquot of crosslinker to achieve a molar excess of 2 to 10 moles per mole of protein (protect from light). For NHS ester-containing reagents, react in 0.1-*M* sodium phosphate buffer at pH 7.2 to 7.4. Avoid using any other amine containing buffer components, such as Tris or imidazole, which will interfere with the reaction.

3. React for 30 to 60 min in the dark (room temperature or 4°C).
4. Remove excess crosslinker from the modified bait protein by gel filtration or dialysis in the dark.
5. Add the modified bait protein to a sample containing potentially interacting prey proteins and incubate for 1 h protected from light. The sample may be cells (for cell surface interaction studies), cell lysate, or various extracts from cells, tissues, or biological fluids.
6. Expose the sample to UV light to crosslink and capture interacting proteins via the photoreactive group.
7. Recover interaction complexes by affinity chromatography. This is typically performed using immobilized antibodies to the bait protein or using fusion tag binders, if the bait protein contains a fusion partner (e.g., immobilized glutathione for binding GST-labeled bait proteins).
8. Analyze the purified complexes by SDS-PAGE, western blotting, and mass spectrometry.

3. TRIFUNCTIONAL LABEL TRANSFER REAGENTS

The earliest examples of label transfer reagents were cleavable heterobifunctional compounds that incorporated a phenyl azide group, which also had a phenolic modification on the ring. The phenolic hydroxyl activates the ring for substitution reactions to occur *ortho* or *para* to its position. These compounds thus can be radioiodinated using typical oxidation reagents such as chloramine T or Iodobeads. Iodination of the crosslinker with ^{125}I prior to its use will result in a radioactive label transfer reagent that can tag an unknown interacting protein with a radiolabel after cleavage of the crosslinker's spacer arm.

Subsequent designs of label transfer reagents used non-radioactive labels to avoid the safety and regulatory issues posed by ^{125}I. Fluorescent constituents designed into cleavable photoreactive crosslinkers make possible transfer of a fluorescent label to an unknown interacting protein. An example of this type of reagent that incorporates a coumarin group is SAED, which has been derivatized with an azido group on the aromatic ring. The reagent is non-fluorescent prior to exposure to UV light, but upon photo-activation and coupling to interacting proteins, it becomes highly fluorescent. The reagent also has a disulfide bond that can be reduced, resulting in cleavage of the crosslinked proteins and transfer of the label to the unknown interacting species. In this case, the fluorescently labeled interacting proteins can be followed in cells to determine the site of interactions or the fate of the proteins after interacting.

The most advanced type of bioconjugation reagent that is designed to study interacting proteins is a trifunctional label transfer reagent, and it has become an important component in the reagent toolbox to capture protein complexes (Rutkowska and Schultz, 2012). These compounds are a special category of trifunctional crosslinkers (see Chapter 7), which possess two reactive groups and a third arm containing a label. Typically, one of the reactive groups is thermoreactive and can be used to label a bait protein, while the second reactive group is usually photoreactive for selective activation and coupling upon UV irradiation. The third arm of the reagent can be designed to have a fluorescent group for detection or terminate in a biotin group for both detection and purification (Figure 24.10).

An important feature of trifunctional label transfer reagents is the presence of a cleavable cross-bridge on the arm containing the thermoreactive group. After a bait protein has been conjugated with an interacting prey protein using this type of reagent, the complex can then be cleaved, which releases the interacting proteins and transfers the label over to the prey protein. The label can be used to detect prey proteins on a western blot or to purify them from the sample solution. Unlike the heterobifunctional compounds discussed previously for studying protein interactions, label transfer reagents allow specific detection and purification of unknown interacting prey proteins for subsequent analysis.

The use of trifunctional label transfer crosslinkers has involved the study of the glycolytic enzyme

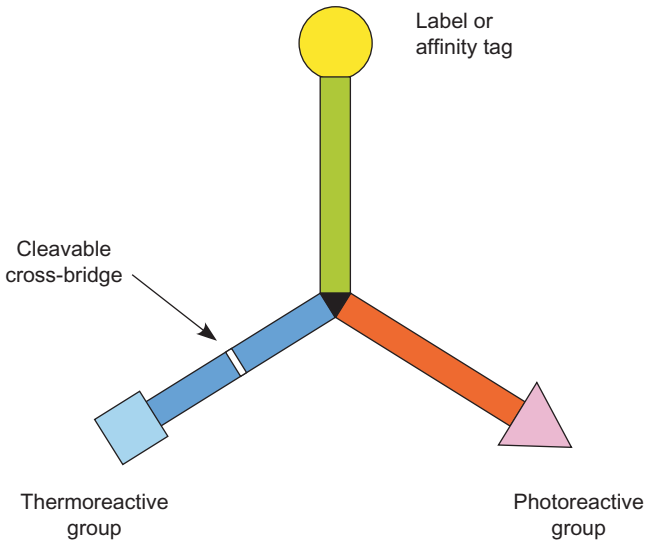

FIGURE 24.10 Trifunctional label transfer agents contain two arms with terminal reactive groups and a third arm with a label or affinity tag, such as a biotin group. One of the reactive groups typically is thermoreactive to couple with bait proteins, while the second reactive group usually is photoreactive. The thermoreactive arm has a cleavable cross-bridge to facilitate release of the captured protein and transfer of the label of affinity tag to it.

components (Puchulu-Campanella *et al.*, 2012), investigation into the interaction of human frataxin with ISU (Watson *et al.*, 2012), and to study the interaction complex between cell adhesion molecule L1 with matrix metalloproteinase 14 and adenine nucleotide translocator at the plasma membrane (Loers *et al.*, 2012).

The following sections describe three types of label transfer reagents, which are all built with a biotin handle. Note: A new version of a trifunctional label transfer agent was recently described for studying receptor–ligand interactions and termed the TRICEPTS reagent (Frei *et al.*, 2012). This crosslinker is described in Chapter 7, Section 5.

3.1. Sulfo-SBED

Sulfo-SBED is sulfosuccinimidyl-2-[6-(biotinamido)-2-(*p*-azidobenzamido) hexanoamido] ethyl-1,3′-dithiopropionate), a trifunctional reagent containing an amine reactive sulfo-NHS ester on one arm, a photoreactive phenyl azide group on the second arm, and a biotin handle on its third arm (Figure 24.11) (see Chapter 7, Section 2, for a general description and use). This compound has found great utility in capturing protein interactions and subsequently isolating them for analysis. A purified bait protein initially is labeled with sulfo-SBED by its sulfo-NHS ester to form amide linkages through reaction with lysine or N-terminal amines. The modified bait is then incubated with a sample and biomolecules are allowed to interact with it. Finally, the sample is exposed to UV light and the photoreactive group is able to couple with nearby amine groups on any interacting proteins. The resultant complex can be purified, identified, or detected through specific binding to the biotin groups (Figure 24.12 and 24.13).

Sulfo-SBED is soluble in organic solvents, such as DMSO (125-m*M*), DMF (170-m*M*), and methanol (12-m*M*), or to a lesser degree in pure water (~5-m*M*). The solubility of sulfo-SBED in buffered aqueous solutions may vary from about 0.1-m*M* to 3-m*M* (e.g., ~1-m*M* in 0.1-*M* PBS). However, to dissolve sulfo-SBED at higher concentrations in a reaction buffer, first dissolve it in a water-miscible organic solvent such as DMSO or DMF and transfer an aliquot to the aqueous buffer solution. Use no more than about 1 to 10% of solvent in the final buffered reaction mixture to prevent buffer precipitation and minimize the denaturation of proteins.

Bait proteins modified with sulfo-SBED may precipitate if the level of modification is too high, primarily due to the hydrophobic nature of the crosslinker and the biotin handle. To prevent precipitation or at least minimize it, adjust the molar excess of sulfo-SBED over the bait protein to a level where the protein remains in solution. Some precipitation may be removed by centrifugation or filtration prior to use.

A derivative of sulfo-SBED containing a thiol-reactive pyridyl disulfide group on its thermoreactive arm has

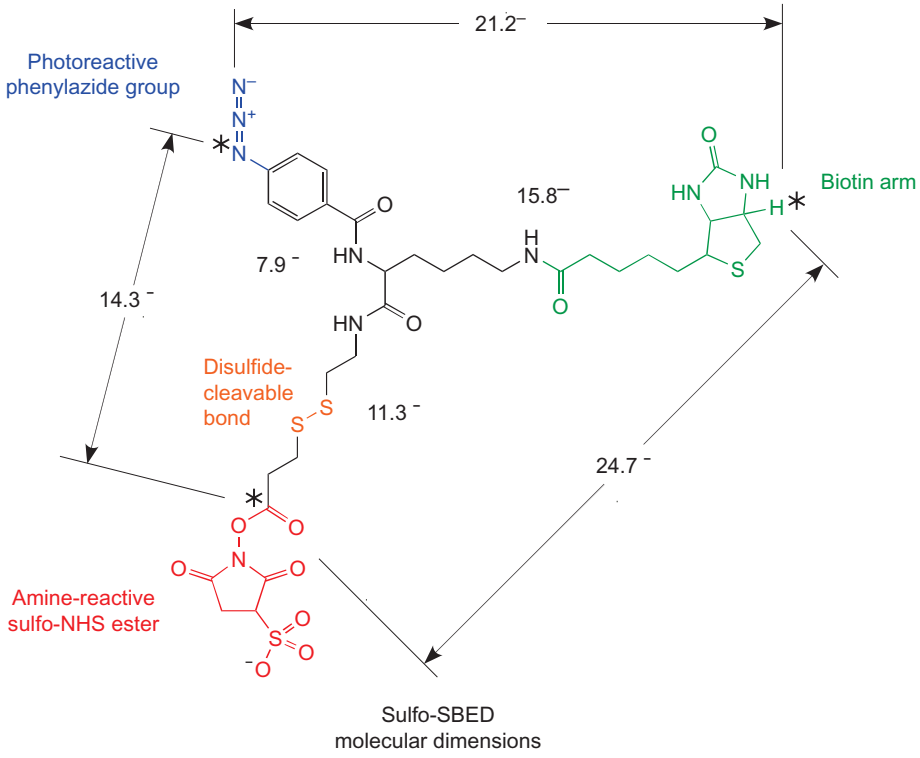

FIGURE 24.11 Sulfo-SBED is a label transfer agent that contains a water soluble sulfo-NHS ester to label bait proteins and a phenyl azide group for photoreactive capture of a prey protein. The biotin label can be used for detection or isolation of protein–protein conjugates using (strept) avidin reagents. The stars indicate the atoms that were used to measure the indicated molecular dimensions.

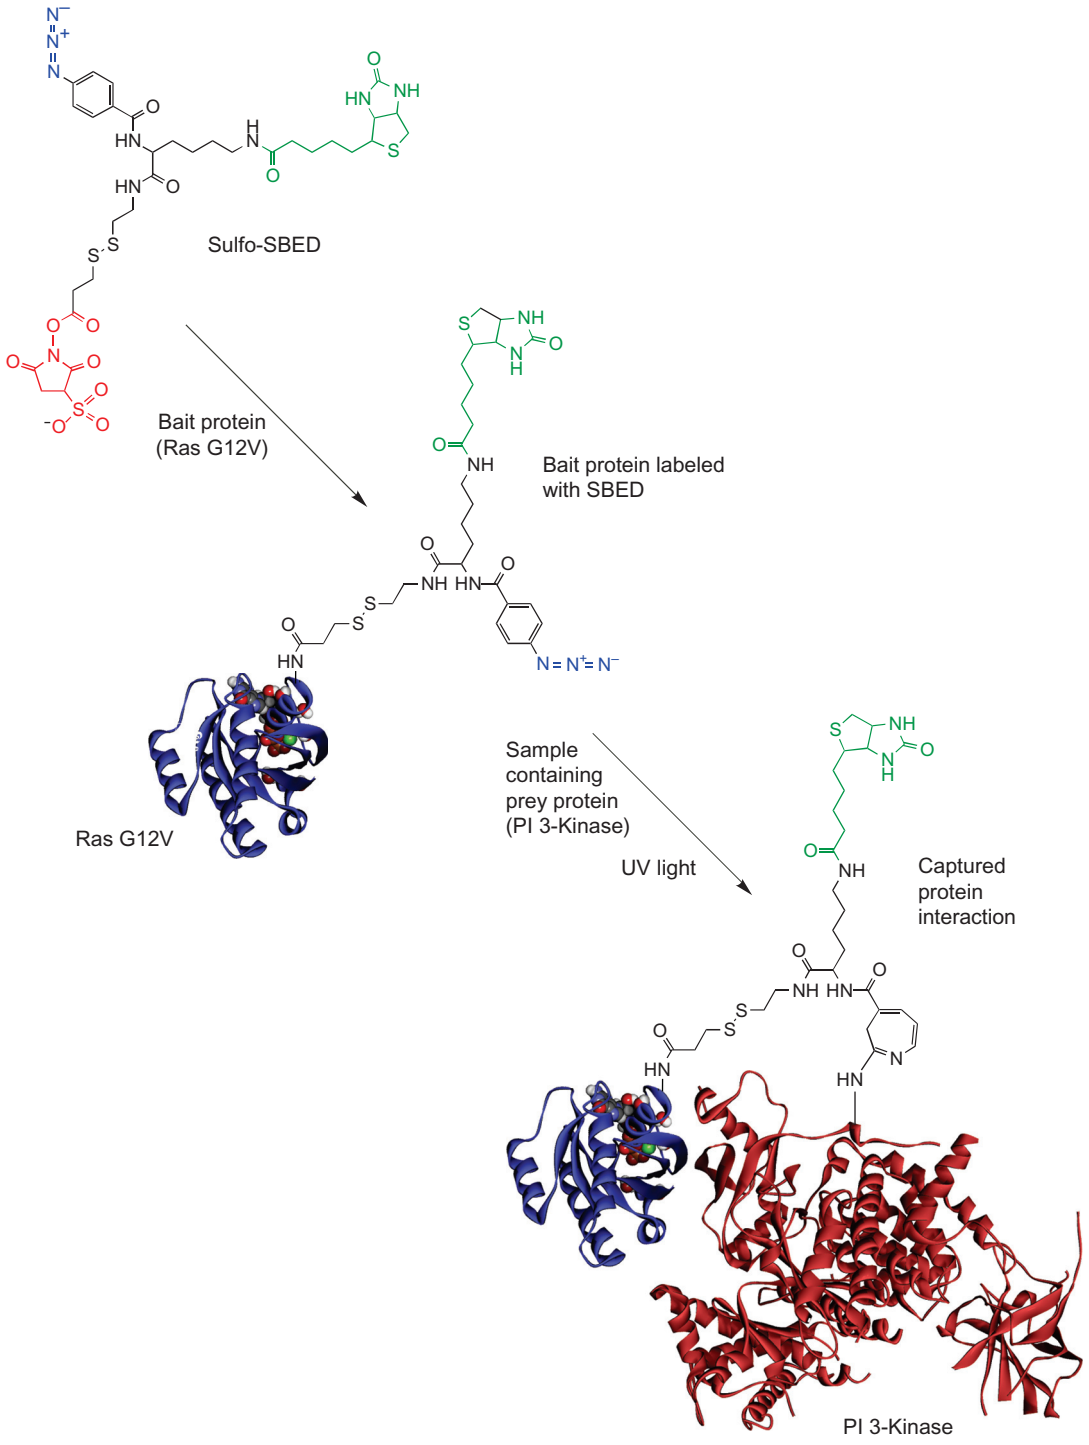

FIGURE 24.12 Sulfo-SBED is first used to label a bait protein through reaction of the sulfo-NHS ester with available amine groups on the protein, yielding an amide bond linkage. This labeled bait protein is then added to a sample containing proteins that potentially could interact with the bait. After an incubation period, the sample is exposed to UV light to photoactivate the phenyl azide group. This reaction causes any interacting prey proteins to be crosslinked with the bait protein, forming a complex containing a biotin affinity tag.

been reported for modification of bait proteins containing a cysteine residue. Reaction of this compound with a thiol results in the formation of a reversible disulfide linkage. After capturing interacting proteins with this reagent, reduction of the disulfide transfers the biotin label to the unknown prey protein(s). This compound was prepared from sulfo-SBED by reduction of the disulfide in its sulfo-NHS ester arm followed by reaction

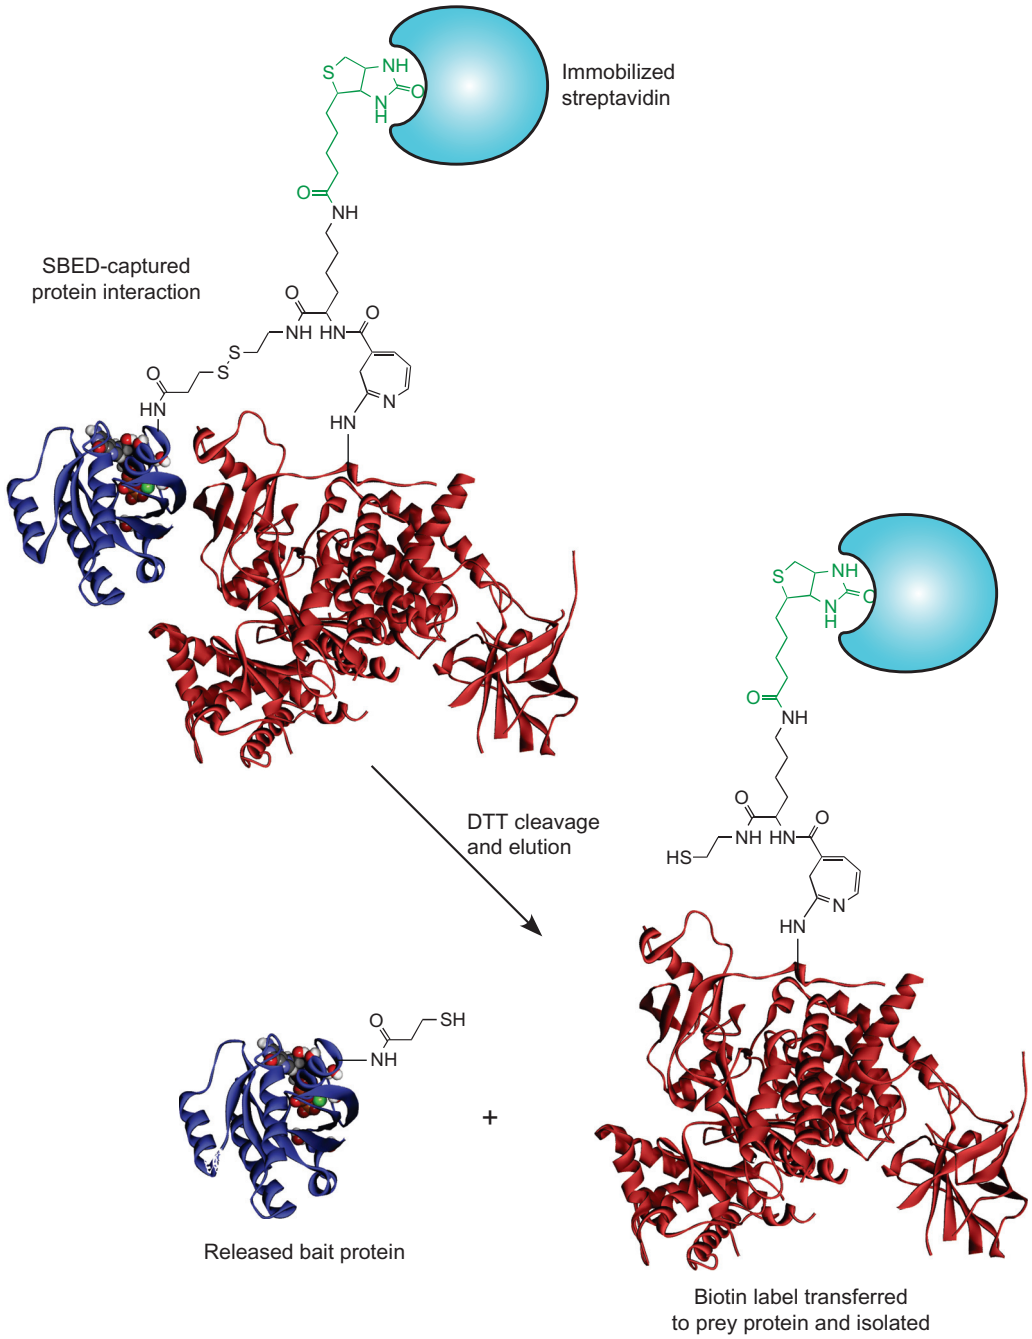

FIGURE 24.13 A sulfo-SBED-captured protein interaction can be released using DTT to cleave the disulfide within the cross-bridge leading to the bait protein. The result transfers the biotin label to the unknown interacting protein. The biotin tag thus allows the interacting protein to be detected or isolated using (strept)avidin reagents.

with 2,2′-dithiodipyridine to give the thiol-reactive compound, 1-[6-(biotinamido)-2-(*p*-azidobenzamido)-hexanoamido]-2-(2′-pyridyldithio)ethane (Figure 24.14) (Alley *et al.*, 2000; Ishmael *et al.*, 2001, 2002; Trakselis, 2005). This derivative has most of the features of sulfo-SBED in terms of being a trifunctional label transfer agent containing biotin, but extends its application to sulfhydryl-containing bait proteins.

Sulfo-SBED has been used to investigate protein–protein interactions in the following applications: to study the bacteriophage T4 replisome (Ishmael *et al.*, 2003), cell surface antigens of mycoplasma species bovine group 7 in binding and activation of plasminogen (Bower *et al.*, 2003), bacterium–host protein–carbohydrate interactions (Ilver *et al.*, 2003), transcription activator interactions with multiple SWI/SNF subunits (Neely *et al.*, 2002), binding

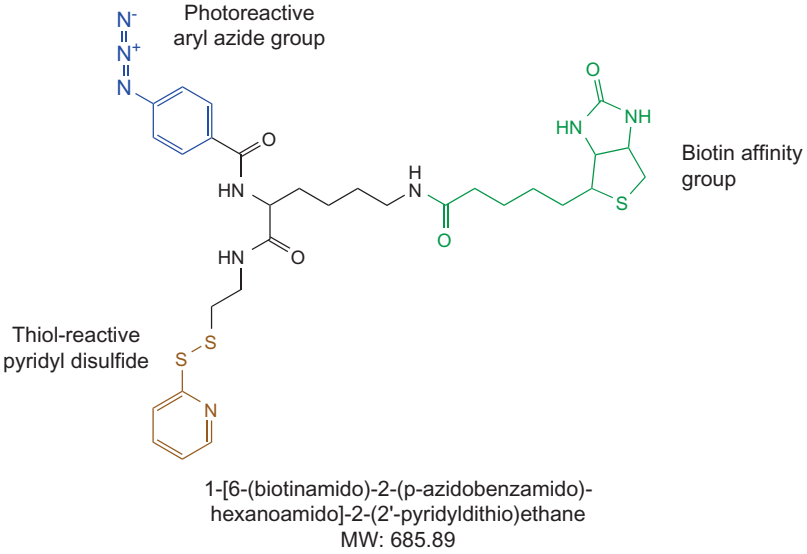

FIGURE 24.14 A trifunctional label-transfer reagent containing a thiol-reactive pyridyl disulfide group, a photoreactive phenyl azide, and a biotin affinity tag. This compound can be used to label bait proteins through available thiol groups and capture interacting prey proteins by photoreactive conjugation.

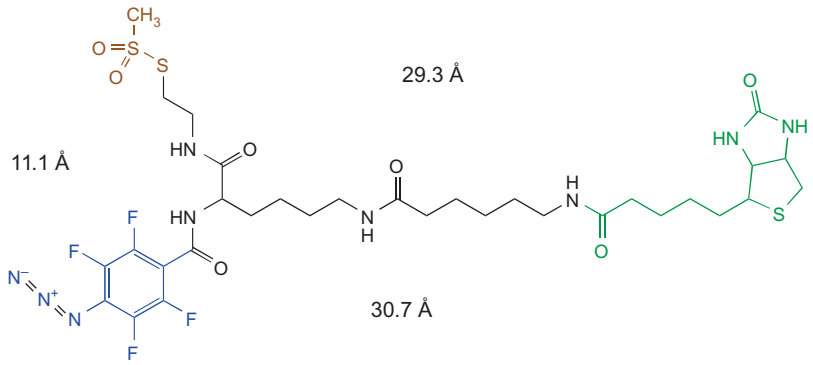
of protein D/E to the surface of rat epidermal sperm (Tubbs et al, 2002), and the gp41–gp59 complex in bacteriophage T4 helicase (Ishmael *et al.*, 2002); to identify a region in alcohol dehydrogenase that binds to α-crystallin during chaperone action (Santhoshkumar and Sharma, 2002), regions of the mouse CD14 molecule required for toll-like receptor 2- and 4-mediated activation of NF-κB (Muroi *et al.*, 2002), and active site residues of cyclophilin A that are important for signaling via CD147 (Yurchenko *et al.*, 2002); to map protein–protein interactions in the bacteriophage T4 DNA polymerase holoenzyme (Alley *et al.*, 2000); to study the import of adenovirus DNA involving the nuclear pore complex receptor CAN/ Nup214 and histone H1 interactions (Trotman *et al.*, 2001), insulin-like growth factor (IGF)-1 interaction with IgG-binding proteins (Horney *et al.*, 2001), 3F3/2 anti-phospho-epitope antibody binding to the mitotically phosphorylated anaphase-promoting complex/cyclosome (Daum *et al.*, 2000), SH3 binding sites of ZG29p in its interaction with amylase (Kleene *et al.*, 2000), and the proteasome activator PA28 in Hsp90-dependent protein refolding (Minami *et al.*, 2000); to investigate functional elements in α-crystallin (Sharma et al., 2000) and *Helicobacter pylori* adhesin binding to fucosylated histo-blood group antigens (Ilver *et al.*, 1998); to identify low abundance proteins by electrophoresis and MALDI-TOF MS (Bergstrom *et al.*, 1998) and molecular probes for muscarinic receptors (Jacobson *et al.*, 1995); to quantitate triple-helix formation (Geselowitz and Neumann, 1995) and to study prion–protein interactions with its receptor (Santuccione *et al.*, 2005); to study the activation of Hsp70 chaperones (Steel et al, 2004), the effect of oxidized βB3-crystallin peptide on lens βL-crystallin and its interaction with βB2- crystallin (Udupa and Sharma, 2005), and the effect of oxidized βB3-crystallin peptide on the thermal aggregation of bovine lens gamma-crystallins (Udupa and Sharma, 2005); for the mass spectrometric detection of affinity-purified crosslinked peptides (Hurst *et al.*, 2004); to map protein interfaces combined with MALDI-TOF and ESI-FTICR mass spectrometry (Sinz *et al.*, 2005); to study the activation of the antioxidant enzyme 1-CYS peroxiredoxin and its requirement for glutathionylation mediated by binding with GST (Manevich *et al.*, 2004); to investigate the recruitment of HAT complexes by direct activator interactions with the ATM-related Tra1 subunit (Brown *et al.*, 2001); to identify annexin A2 heterotetramer as a receptor for the plasmin-induced signaling in human peripheral monocytes (Laumonnier *et al.*, 2005); to investigate the role of proteasome activator PA28 in Hsp90-dependent protein refolding (Minami *et al.*, 2000); to confirm the interaction between human frataxin and the scaffold protein ISU with mass spectometry detection (Watson et al, 2012); to investigate the binding of receptor tyrosine kinase TrkB to the neural cell adhesion molecule (NCAM) (Cassens *et al.*, 2010); and to study an interaction complex at the plasma membrane (Loers *et al.*, 2012).

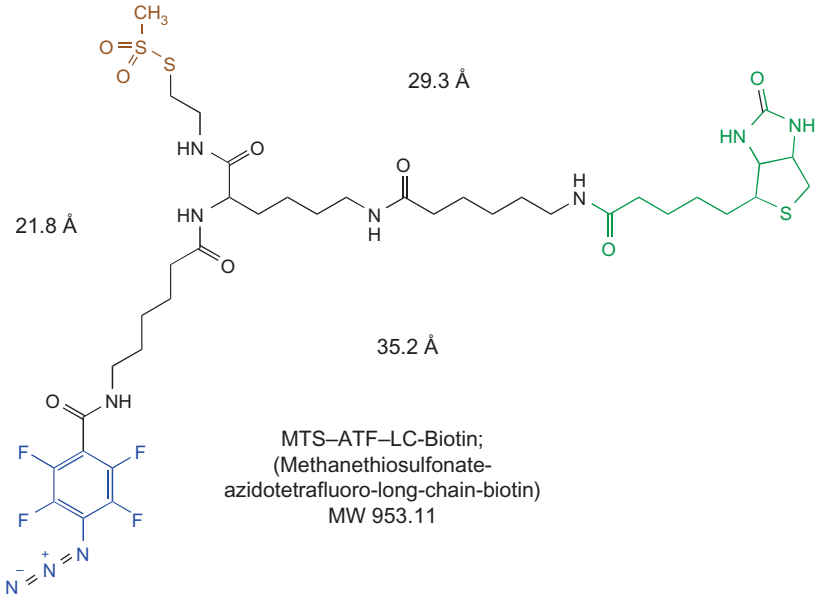
In addition to the use of sulfo-SBED to capture unknown prey proteins interacting with labeled bait proteins, the reagent may also be used to study the interaction interfaces between two known proteins that specifically interact. Sinz *et al.* (2005) used this approach to identify the interaction surfaces between calmodulin and M13, which is a short peptide from skeletal muscle light-chain kinase. In this application, calmodulin was labeled with sulfo-SBED and allowed to interact with purified M13. After an incubation period, the solution was exposed to UV light and the two proteins were crosslinked together. Next, the conjugated proteins were proteolytically digested with trypsin and the resultant biotinylated peptides were enriched on a column of immobilized monomeric avidin (Thermo Fisher). The crosslinked peptides come from one

peptide segment of calmodulin and one peptide segment of M13. Finally, these biotinylated and crosslinked peptides were identified using nano-HPLC separation into a nano-ESI-FTICRMS with software-facilitated deconvolution of the peptide identities. Such analysis provides insight into the interaction surfaces involved with the binding event between the two proteins.



The following protocol represents a suggested method that will work well for many proteins. It is a blend of protocols used in the literature and recommended by Thermo Fisher in the sulfo-SBED instruction manual. Modifications to reaction conditions may be necessary in certain cases to maintain protein stability or solubility, depending on the properties of the particular bait protein being used.

Protocol



1. Dissolve a purified bait protein in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, or a similar buffer at neutral pH, which does not contain any competing amines (i.e., avoid Tris or imidazole). The bait protein may be at a concentration of anywhere from 0.1 mg/ml to 10 mg/ml. Prepare the solution in a dark tinted vial or wrap the vessel in foil to prevent light exposure when the crosslinker is added.
2. Prepare a solution of sulfo-SBED in dry DMF or DMSO at a concentration of 40 µg/ml. Protect from light.
3. Add a quantity of the sulfo-SBED solution to the bait protein solution so that a 1- to 5-fold molar excess of crosslinker over the bait protein results in the reaction mixture. Mix well. Using greater quantities of sulfo-SBED to the bait protein may result in precipitation due to the hydrophobic nature of crosslinker. In addition, over modification of the bait protein with the crosslinker may block sites of protein interaction, thus preventing complex formation. As a practical example, Horney *et al.* (2001) used a 1:1 molar ratio of sulfo-SBED to the bait protein IGF-1 with success.
4. React for 30 min at room temperature or 2 h at 4°C. Continue to protect the solution from light.
5. Remove excess crosslinker and reaction by-products by dialysis or size exclusion chromatography. For small quantities of bait proteins, dialysis may be the better choice, because gel filtration columns often bind enough protein nonspecifically to make recoveries unacceptably low.
6. Add the labeled bait protein to a sample containing the putative interacting prey proteins. The quantity of bait protein to be added to a given sample should be within the same concentration level as the amount of prey proteins present. The optimal level of addition may have to be determined by varying the amount of bait protein concentrations in a number of sample solutions to decide which concentration results in the best interaction complexes being formed.
7. Incubate the sample mixture for at least 1 h at room temperature or under conditions optimal for the interaction to be studied.
8. Expose the sample to UV light to photoactivate the aryl azide and cause the conjugation reaction to occur. For best results, use a UV lamp that irradiates in the range of 300 to 370 nm. Irradiate for 2 to 15 min, using a briefer exposure when using UV lamps of greater wattage.
9. Interaction complexes that were captured by the crosslinking reaction can be recovered or analyzed using the biotin groups. An immobilized streptavidin support, for instance, can be used to purify the conjugates away from other sample proteins. Alternatively, a streptavidin–HRP conjugate can be used to probe a western blot after electrophoresis separation of the sample. Reduction of the conjugate may be performed by cleavage of the disulfide bond with DTT. The typical addition of DTT to the electrophoresis sample buffer will facilitate disruption of the complexes and transfer of the biotin label to the interacting prey proteins. This reduction step can also be performed using 50-m*M* DTT or 50-m*M* TCEP in aqueous solution to permit recovery of the biotinylated prey proteins on immobilized streptavidin. Alternatively, the use of an affinity support having milder elution characteristics for biotinylated proteins, such as immobilized monomeric avidin, would facilitate isolation of the biotinylated complexes or prey proteins under non-denaturing conditions.

3.2. MTS–ATF–Biotin and MTS–ATF–LC-Biotin

MTS-ATF-biotin is 2-[N2-(4-Azido-2,3,5,6-tetrafluorobenzoyl)-N6-(6-biotinamidocaproyl)-L-lysinyl]ethyl methanethiosulfonate and MTS-ATF-LC-biotin is 2-{N2-[N6-(4-Azido-2,3,5,6-tetrafluorobenzoyl)-6-aminocaproyl]-N6-(6-biotinamidocaproyl)-L-lysinylamido}ethyl methanethiosulfonate. Both reagents are trifunctional crosslinkers similar in design to sulfo-SBED discussed previously, but in addition to the biotin handle they contain a thiol-reactive group and an enhanced photoreactive, perfluorinated phenyl azide group. The two reagents differ in the length of the cross-bridge in the photoreactive arm, with the LC version containing an extended aminocaproyl spacer. Relative to the spacing possible between the reactive groups on these compounds, the LC version therefore provides nearly twice the maximal molecular distance over its shorter analog (21.8 Å *versus* 11.1 Å) (Figure 24.15). Thus, interacting proteins may be captured either through use of a long or short crosslink, depending on the optimal distances

MW 953.11

FIGURE 24.15 Two similar label transfer reagents containing a thiol-reactive methanethiolsulfonate group to label bait protein through available sulfhydryls, a tetrafluorophenyl azide group for high-efficiency photoreactive conjugation with interacting prey proteins, and a long biotin affinity tag. The lengths indicated in the figure represent the distances between the reactive linking site on one arm and the reactive group or biotin outer ring hydrogen atom on the adjacent arm. The point of measurement on the reactive groups is the last atom that is retained in any crosslink formed after the coupling reaction takes place.

between the proteins—or at least to the nearest thiol on the bait protein.

Both MTS–ATF–biotin and MTS–ATF–LC-biotin contain a methanethiolsulfonate group (MTS) on their thermoreactive arm which is able to couple with the sulfhydryl on a cysteine residue. This reaction proceeds with loss of the methyl sulfonate leaving group (sulfinic acid) to produce a disulfide linkage (Figure 24.16). Unlike a pyridyl disulfide group, however, which also reacts with thiols to form disulfide linkages, the MTS group is unstable to hydrolysis in aqueous solution, especially if other strong nucleophiles are present. Therefore, most MTS compounds dissolved or brought into PBS buffer at physiological pH will hydrolyze with a half-life on the order of 10 to 15 min. However, they also have very rapid reactivities with thiols (Stauffer and Karlin, 1994; Holmgren *et al.*, 1996; Liu *et al.*, 1996). If the parent MTS reagent is fully water soluble, the reaction with a thiol on a bait protein can take place with high yields in just a matter of minutes. However, both of these trifunctional label transfer compounds are hydrophobic, so their MTS reactivity in the aqueous phase may be somewhat slower than corresponding hydrophilic MTS reagents.

For use in studying protein interactions, these compounds are first reacted with a thiol on a purified bait protein to form a disulfide bond. Since the reagents are water insoluble, they must be dissolved in an organic solvent such as DMF or DMSO and then an aliquot

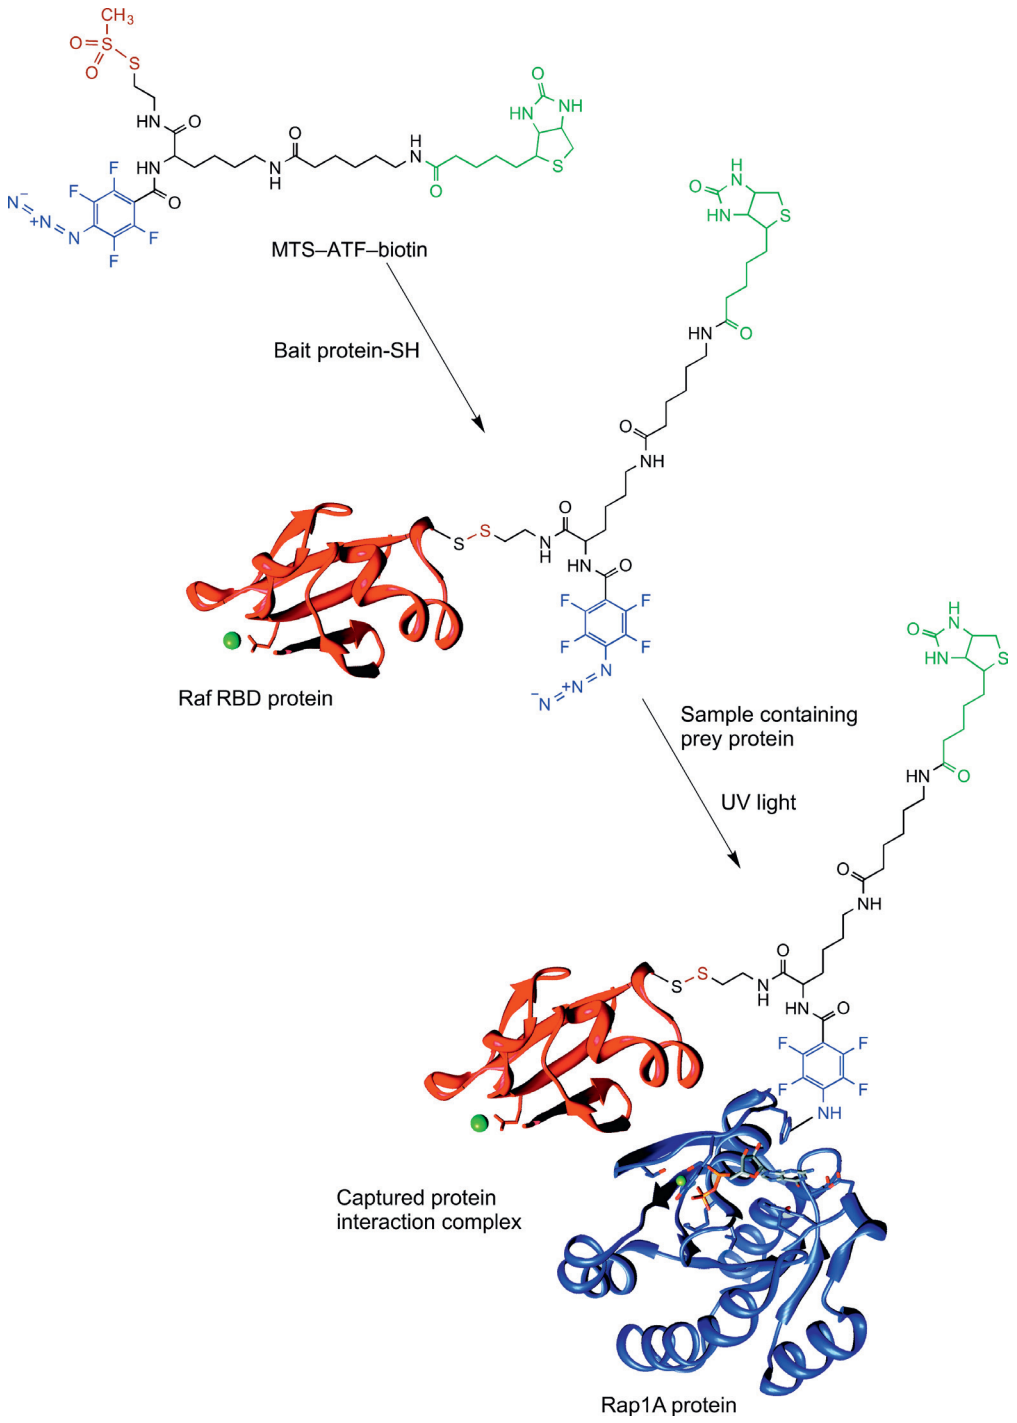

FIGURE 24.16 MTS–ATF–biotin can be used to modify a bait protein using an available thiol group to form a disulfide bond. The labeled bait protein is then allowed to interact with a sample containing proteins that potentially can interact with the bait. After an incubation period, the sample is exposed to UV light to photoactivate the tetrafluorophenyl azide group. This reaction causes any interacting prey proteins to be crosslinked with the bait protein, forming a complex containing a biotin affinity tag. Subsequent cleavage of the disulfide bond to the bait protein using DTT transfers the biotin group to the unknown interacting protein. The labeled prey protein can then be detected or isolated using (strept)avidin reagents.

added to the bait protein in an aqueous buffer to initiate the reaction. Once modified, the biotinylated bait protein is then incubated with a sample containing potential interactive prey proteins. After an incubation period, initiating the photoreaction by exposure to UV irradiation captures the interacting proteins. Any interaction complexes thus formed can be isolated or detected using the biotin handle. In addition, the

disulfide bond formed with the bait protein during the crosslinking reaction can be reduced to cleave the conjugates and transfer the biotin label to the unknown interacting prey proteins. This is a powerful way of labeling unknown interacting proteins for subsequent analysis.

MTS–ATF–biotin and MTS–ATF–LC-biotin have been used to study the piccolo NuA4 acetylation of nucleosomal histones (Huang and Tan, 2012), to investigate protein interactions involving the SufBCD Fe-S scaffold complex binding with SufA for Fe-S cluster transfer (Chahal *et al.*, 2009), in the characterization of carriers and receptors of the Lewis^X glycan (Katagihallimath, 2008), and to study the piccolo NuA4-catalyzed acetylation of nucleosomal histones (Huang and Tan, 2012). The following protocol should be used as a suggested starting point to develop optimized methods for studying specific protein interactions. The bait protein to be modified with MTS–ATF–biotin or MTS–ATF–LC-biotin should be purified and contain at least one accessible thiol for reaction with the MTS group. Ellman's reagent (Chapter 2, Section 4.1) may be used to determine if a sulfhydryl is present and able to react with the crosslinkers. A free thiol may also be created by reduction of internal disulfides or through the use of a thiolation reagent. However, adding thiols by chemical derivatization may not be advantageous, because this will create numerous surface modifications, which may have detrimental effects on protein–protein interactions.

Protocol

1. Dissolve a thiol-containing bait protein in 10-m*M* HEPES, 0.15-*M* NaCl, pH 7.5 or in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Other buffers around physiological pH will work well; however, avoid the presence of reducing agents containing thiols (i.e., DTT or 2-mercaptoethanol). Typical concentrations that will work with the suggested protocol range from 100 µg/ml to 10 mg/ml, but higher concentrations are preferred to give high reaction yields.
2. Dissolve MTS–ATF–biotin or MTS–ATF–LC–biotin in DMF or DMSO at a concentration of at least 10 mg/ml. Protect from light.
3. Add a quantity of the crosslinker solution to the bait protein solution to provide a 1 to 5 molar excess of the crosslinker over the quantity of protein to be modified. The addition of the organic solution containing the crosslinker should be performed so that the final reaction contains no more than 10% organic solvent. Even lower concentrations of solvent may be required for certain sensitive proteins.
4. React for at least 30 min at room temperature or 1 h at 4°C. Continue to protect the solution from light.
5. Remove excess crosslinker and reaction byproducts by dialysis or size exclusion chromatography.
6. Add the labeled bait protein to a sample containing the putative interacting prey proteins. The quantity of bait protein to be added to a given sample should be within the same concentration level as the amount of prey proteins present. The optimal level of addition may have to be determined by varying the amount of bait protein concentrations in a number of sample solutions to decide which concentration results in the best interaction complexes being formed.
7. Incubate the sample mixture for at least 1 h at room temperature or under conditions optimal for the interaction to be studied.
8. Expose the sample to UV light to photoactivate the aryl azide and cause the conjugation reaction to occur. For best results, use a UV lamp that irradiates in the range of 300 to 370 nm. Irradiate for 2 to 15 min, using briefer exposures when using UV lamps of higher wattage.
9. Interaction complexes that are captured by the crosslinking reaction can be recovered or analyzed using the biotin groups. For instance, immobilized streptavidin can be used to purify the conjugates or a streptavidin–HRP conjugate can be used to probe a western blot after electrophoresis separation of the sample. Reduction of conjugates may be performed by cleavage with DTT of the disulfide bond linking the bait protein. This can be performed using 50-m*M* DTT or 50-m*M* TCEP in aqueous solution to permit recovery of the biotinylated prey proteins on immobilized streptavidin. Alternatively, the use of an affinity support having milder elution characteristics for biotinylated proteins, such as immobilized monomeric avidin, would facilitate isolation of the biotinylated complexes or prey proteins under nondenaturing conditions.

4. METAL CHELATES IN THE STUDY OF PROTEIN INTERACTIONS

Certain bifunctional metal chelating agents have been used to investigate protein interactions by virtue of their ability to generate reactive oxygen species that affect protein structure in the immediate vicinity of their modification site. The following sections discuss two applications of such chelate labels, one of which cleaves peptide bonds while the other one causes covalent crosslinks to occur between interacting protein structures.

4.1. FeBABE for Protein Mapping Studies

Transition metals such as iron can catalyze oxidation reactions in aqueous solution, which are known to cause modification of amino acid side chains and

damage to polypeptide backbones (see Chapter 2, Section 1.1) (Halliwell and Gutteridge, 1984; Kim *et al.*, 1985; Tabor and Richardson, 1987). These reactions can oxidize thiols, create aldehydes and other carbonyls on certain amino acids, and even cleave peptide bonds. The purposeful use of metal-catalyzed oxidation in the study of protein interactions has been applied to map interaction surfaces or identify which regions of biomolecules are in contact during specific affinity binding events.

Hydroxyl radical "footprinting," as the technique is called, can produce a picture of where ligand binding sites are located or map the interaction surfaces of protein complexes. An early example of this application was used to map the binding site of protein–DNA interactions (Tullius and Dombroski, 1986; Latham and Cech, 1989). Hydroxyl radicals are generated by an EDTA chelated iron(II) complex using a redox reaction involving hydrogen peroxide and ascorbic acid. In this case, the EDTA chelate is merely added to the solution of the interacting protein and DNA. Nonselective cleavage of the DNA strand (and protein) then occurs everywhere except at the region in which the interaction takes place, thus leaving a "footprint" of the interacting partners.

A second iteration of this reagent involves the attachment of affinity ligands to the EDTA chelator group to direct the hydroxyl radical generator to specific binding pockets on proteins and receptors. Hoyer *et al.* (1990) created a biotin–EDTA derivative that was able to bind to the biotin binding pocket on streptavidin and cause peptide cleavage in the region immediately surrounding the binding site. Similarly, Schepartz and Cuenoud (1990) formed a trifluoroperazine-based affinity reagent containing an EDTA group to map the binding site of the calcium binding protein calmodulin. Once affinity reagents of this sort bind to their receptor protein, hydroxyl radical footprinting can identify exactly where in the protein's three-dimensional structure the interaction took place.

Rana and Meares (1990, 1991) created a more versatile footprinting reagent by synthesizing a bifunctional metal chelating agent with an EDTA group on one end and a bromoacetyl group on the other end. This compound, Fe(III) (S)-1-(*p*-bromoacetamido-benzyl)ethylene diamine tetraacetic acid (or FeBABE, pronounced "iron-babe"), resulted in a universal modification reagent for protein interaction footprinting which could be used to study interacting protein complexes or other biomolecules (Figure 24.17). The bromoacetyl group of FeBABE can react with a thiol to form a thioether bond (Figure 24.18). Thus, proteins or other molecules containing a thiol can be covalently modified with the

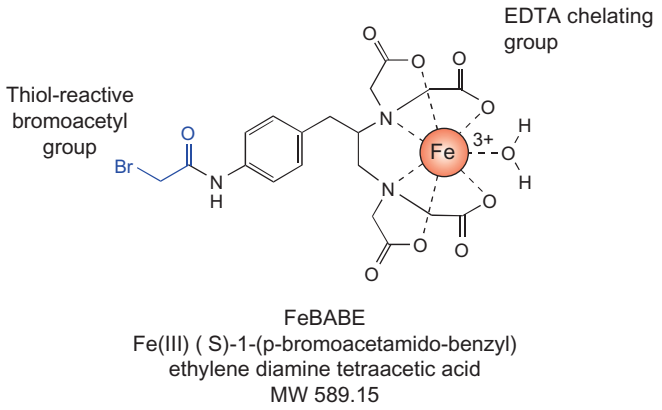

FIGURE 24.17 FeBABE is a bifunctional chelating agent containing an EDTA group on one side and a thiol-reactive bromoacetyl group on the other end. The EDTA group is coordinated with an iron ion.

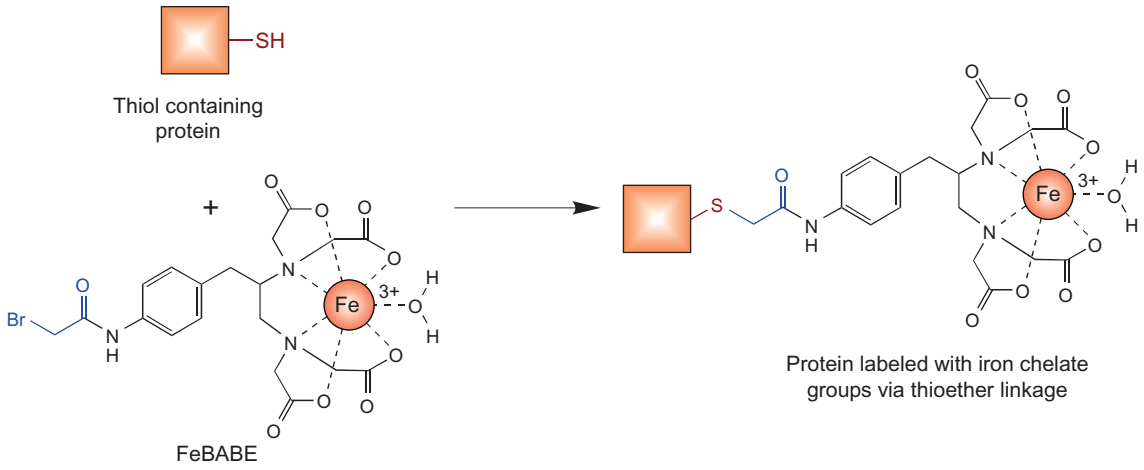

FIGURE 24.18 FeBABE can be coupled to an available thiol group on a bait protein using the bromoacetyl reactive group to form a thioether linkage.

FeBABE reagent forming a hydroxyl radical probe to footprint interacting domains. Such modified bait proteins are termed "artificial proteases" because of their ability to chemically cleave peptide bonds.

The reactions involved in the cleavage of biological molecules by FeBABE and similar iron–EDTA complexes have been theorized to involve two possible processes. Rana and Meares (1991) speculated that the reaction proceeds by the coordination of peroxo oxygen to the iron chelate group. They also found that O_2 might participate in this type of reaction, as evidenced by the successful incorporation of ^{18}O into the carboxyl terminus of cleaved peptide chains of human carbonic anhydrase. This peroxo–metal complex may facilitate subsequent nucleophilic attack of oxygen on the carbonyl carbon of a peptide bond, which then results in cleavage of the peptide bond through oxygen atom transfer to the carbonyl carbon, forming a C-terminal carboxylate. Figure 24.19 schematically shows part of this reaction sequence.

Another proposed mechanism involves the well known Fenton reaction, which is catalyzed effectively

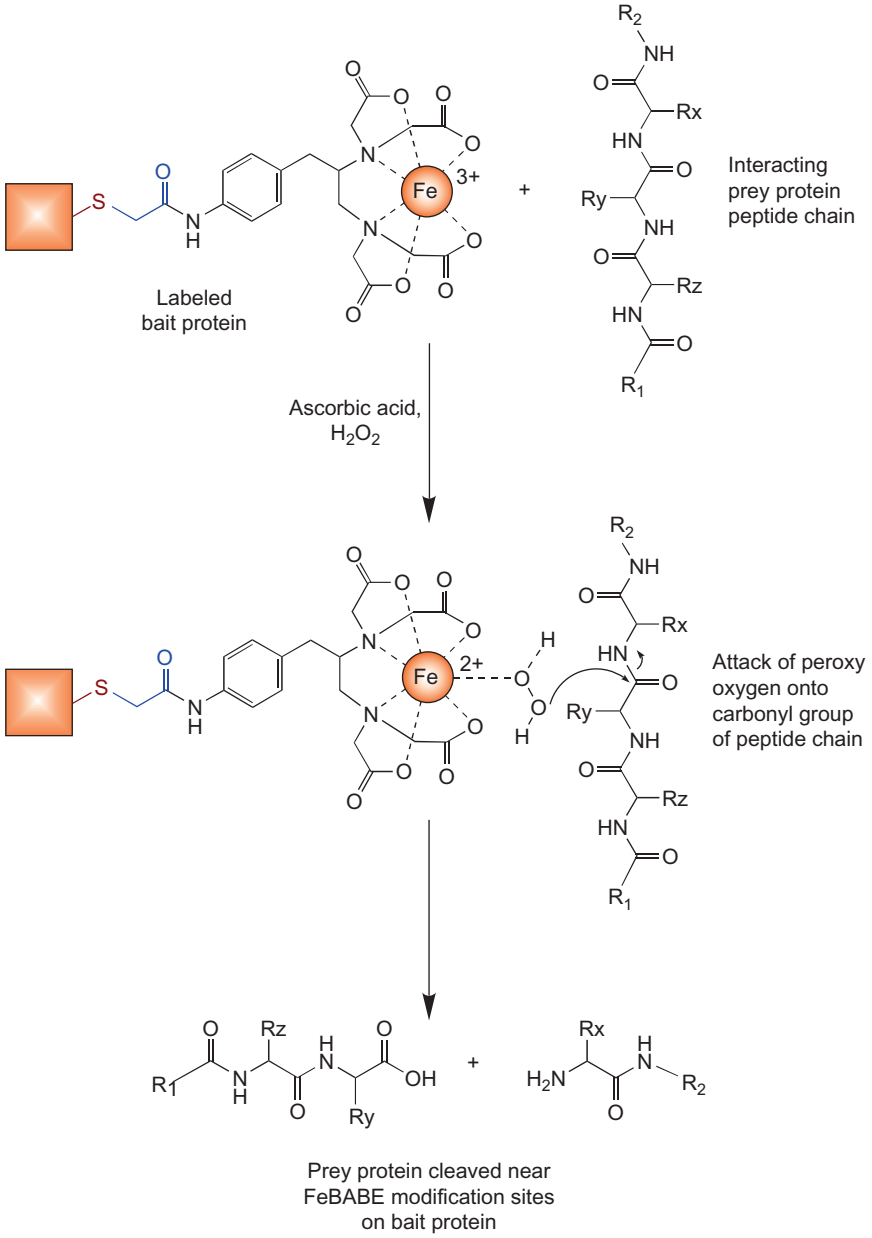

FIGURE 24.19 The cleavage reaction of FeBABE involves a catalytic process using peroxide and ascorbate to form reactive oxygen species. Any protein structure in the immediate vicinity of the FeBABE label on the bait protein will undergo peptide bond cleavage.

by Fe^{2+}–EDTA complexes. In this process, the ascorbate functions by reducing the FeBABE Fe^{3+} complex to Fe^{2+}, producing the ascorbate radical ($Asc^{\cdot -}$). The reduced iron can then form hydroxyl radicals through the Fenton reaction, which re-oxidizes the iron to the Fe^{3+} state. As additional Fe^{3+} is formed, ascorbate then regenerates the active Fe^{2+} chelate by reduction, resulting in the formation of the ascorbate radical. The entire process thus is catalytic and may occur numerous times at the site of one FeBABE modification, potentially resulting in a number of peptide bond fragmentations. Notice also that the FeBABE reagent can be used in an initial EDTA–Fe^{3+} form or in the reduced EDTA–Fe^{2+} form, as addition of the peroxide/ascorbate activators can catalyze the reaction process from either metal oxidation state.

$$\text{EDTA–Fe}^{2+} + \text{H}_2\text{O}_2 \rightarrow \text{EDTA–Fe}^{3+} + {}^{\cdot}\text{OH} + \text{OH}^{-} \quad \text{Fenton reaction}$$

$$\text{EDTA–Fe}^{3} + \text{ascorbate} \rightarrow \text{EDTA–Fe}^{2+} + \text{Asc}^{\cdot -} + \text{H}^{+} \quad \text{Regeneration with ascorbate}$$

The FeBABE modifying group is approximately 12 Å in length. Peptide bond cleavage can occur anywhere on a protein surface that is within molecular distance of the iron chelate modifying group. Cleavage probably does not occur at distant sites, because the peroxo oxygen or hydroxyl radical intermediates are extremely reactive and will quickly react with the neighboring peptide structure or be quenched by ascorbate in solution. An interacting protein that is within the molecular distance of FeBABE's reach therefore is susceptible to peptide bond cleavage.

In use, a bait protein labeled with FeBABE is bound to an interacting prey protein and the peroxide/ascorbate cleavage reagents added to initiate the protein mapping reaction. After the cleavage process is complete, the peptide fragments on each protein are analyzed to gleam information about the interaction surfaces, which will be left relatively unaffected by the reaction. Obviously, to utilize this technique the two interacting proteins must be highly pure and their amino acid sequences known.

Typically, a bait protein is labeled with FeBABE at any available cysteine thiol group. If no free thiols are available, disulfides may be reduced to create sulfhydryls or a thiolation reagent may be used to add them to the protein surface (see Chapter 2, Section 4.1). Care should be taken when adding thiols through thiolation, however, because too high a substitution level could affect the ability of the bait protein to bind to the prey protein. One to three thiol substitutions on the surface of a bait protein should be sufficient to modify it with FeBABE and study protein interactions. A third option for adding a thiol is to change recombinantly one amino acid in the bait protein's sequence to a cysteine. Site-directed mutagenesis can create a thiol at a known region of the protein's surface, thus permitting the study of protein interactions through rational design of FeBABE modifications.

In order to facilitate analysis of FeBABE-produced fragments, the prey protein or biomolecule is labeled at one end with a tag that can be detected after electrophoresis, usually in a transfer blot. The tag can be a fusion tag, such as 6xHis, or any other group that can be targeted with an antibody and detected. Alternatively, radiolabels and fluorescent labels have been used with prey molecules, including the use of end-labeled DNA to study where DNA binding proteins dock onto the oligonucleotide sequence.

The fragments formed by FeBABE fragmentation are analyzed by comparing them to enzymatic or chemical cleavage patterns observed by treatment on the same prey protein. Since the cleaved prey protein is detected by its end-labeled tag, the only fragments detected are those that extend from the end labeled terminal to the point of cleavage. Comparison with known fragmentation patterns using protease digestion or chemical cleavage provides information as to the approximate size of the FeBABE fragment and its point of cleavage.

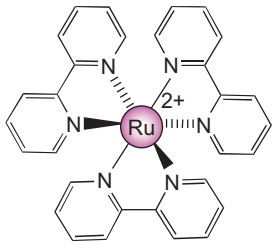
FeBABE has been used to study protein interactions involving the RNA polymerase RbpA (Hu *et al.*, 2012), in mapping protein interactions of the ATP-dependent chromatin remodelers (Hota *et al.*, 2012), to examine the binding of the Swi2/Snf2 remodeler protein Mot1 in complex with its substrate TBP (Wollmann *et al.*, 2011), and to identify the point of interaction between transcriptional factor SoxS and a subunit of RNA polymerase (Zafar *et al.*, 2011).

The following protocol assumes that the user has at least two pure proteins (or biomolecules) of known sequences which are able to interact specifically in solution. One of the two proteins (the prey) is end labeled with a fusion tag or another detectable component and the other protein contains at least one thiol group. All buffers and reagents used in this protocol should be of high purity and contain a very low metal content to prevent nonspecific cleavage reactions.

Protocol

This protocol is based on the procedure of Rana and Meares (1991) and the instruction booklet provided by Thermo Fisher for use with the FeBABE kit.

1. Dissolve the bait protein to be modified with the FeBABE reagent in 50-m*M* MOPS, 100-m*M* NaCl, 1-m*M* EDTA, 5% glycerol, pH 8.2 (coupling buffer).



The protein first may be treated by dialysis with EDTA to remove residual metals (30-m*M* MOPS, 4-m*M* EDTA, pH 8.2), and then dialyzed into the final coupling buffer for the reaction with FeBABE.

2. Dissolve FeBABE in DMSO at a concentration of 5 mg/ml (8.5 nmol/µl) and add an aliquot of this solution to the thiol-containing bait protein solution to obtain a 2- to 20-fold molar excess of the reagent over the protein concentration. Protect the FeBABE solution and the reaction mixture from light, as exposure to light will degrade the bromoacetyl reactive group. The optimal molar excess of FeBABE over the bait protein may have to be determined by experimentation. Since thiols are typically limited in number in most proteins, an excess of FeBABE reagent will not result in more labels than the total number of thiols present, provided the suggested reaction conditions are maintained.
3. Incubate the reaction mixture at room temperature or 37°C for 1 h.
4. Purify the modified bait protein from excess reactants by desalting or dialysis. During this process buffer exchange the labeled bait protein into 50-m*M* MOPS, 120-m*M* NaCl, 0.1-m*M* EDTA, 10-m*M* $MgCl_2$, 10% glycerol, pH 8.0. Components may be added or removed from this buffer to promote the protein interaction being studied as long as they do not interfere with the subsequent FeBABE cleavage reaction (i.e., they do not contain transition metals like iron or copper, oxidants, or reducing agents).
5. Dissolve or buffer exchange the prey protein into 50-m*M* MOPS, 120-m*M* NaCl, 0.1-m*M* EDTA, 10-m*M* $MgCl_2$, 10% glycerol, pH 8.0.
6. Mix the labeled bait protein with the prey protein at equal molar ratios and incubate for 30 min at room temperature to create protein interaction complexes.
7. Initiate the cleavage reaction by the addition of an 8-fold molar excess of ascorbate (over the concentration of protein) followed by an 8-fold molar excess of H_2O_2. Mix well.
8. React for 10 to 30s at room temperature.
9. Quench the cleavage reaction by the addition of an equal volume of SDS electrophoresis sample buffer containing up to 40% glycerol. The SDS will denature and disrupt the protein interaction and glycerol acts as a free radical scavenger, thus effectively quenching the reaction.
10. Analyze the cleaved proteins by SDS gel electrophoresis and western blotting, followed by specific detection of the prey protein label. Comparison of prey protein fragments formed by chemical and enzymatic digestion can yield information as to the site of the resultant FeBABE-mediated cleavage.

4.2. Ru(II)bpy_3^{2+} for Light-Triggered, Zero-Length Crosslinking of Protein Interactions

In many instances within cells or on cell membrane surfaces, large protein complexes are formed containing many different proteins specifically interacting to effect biological processes. Protein machines of this type are difficult to capture and study using traditional crosslinking agents, because the resultant reactions may link some of the proteins, but not all of them in the complex (Friedrichson and Kurzchalia, 1998; Simons *et al.*, 1999). In addition, covalent modification of many nucleophilic groups in a protein by the electrophilic reactive groups of standard crosslinking reagents can decorate the surface of proteins with these compounds and affect nonspecific protein interactions.

Fancy and Kodadek (1999) developed a novel protein crosslinking process using a metal chelating reagent that can be activated by visible light and effect zero-length crosslinks between proteins. Photo-induced crosslinking of unmodified proteins (PICUP) can capture protein interactions without the use of modifying agents such as organic crosslinkers or fusion tags, thus maintaining the interacting proteins in their native structure and conformation. The reaction is mediated by the chelate ruthenium(II) tris(bipyridine) (Ru(II)bpy_3^{2+}; pronounced "rūbippy"; see Figure 24.20) in a two-step reaction involving light absorption by the bipyridine groups followed by energy transfer and excitation of the Ru(II) metal to an excited state intermediate. Subsequent reaction of the excited-state Ru(II)bpy_3^{2+} with persulfate anion results in the formation of a sulfate radical and Ru(III). The Ru(III) group is then postulated to undergo a one-electron transfer to tyrosine side-chain phenolic groups in proteins, resulting in the formation of a tyrosine radical. This highly reactive intermediate can rapidly react with neighboring nucleophilic groups in proteins or with another nearby tyrosine phenolic group, resulting in the formation of tyrosine dimers or a tyrosine heteroatom arene linkage with nearby

Ruthenium(II) tris(bipyridine) chelate

FIGURE 24.20 The structure of Ru(II)pby_3^{2+} a chelated ruthenium ion coordinated with three bipyridine groups.

nucleophilic groups. Either route of reaction can result in the formation of covalent bonds between protein amino acids. If the linkages are formed between interacting proteins, then these complexes are captured for subsequent analysis. The proposed reactions of Ru(II)bpy$_3^{2+}$ in the light-mediated zero-length crosslinking of interacting proteins are shown in Figure 24.21.

The following protocol was successfully used to study the interactions of the 180-amino acid C-terminal domain of yeast TATA box binding protein (TBP), the Gal80 protein, and the Gal4 activation domain of the associated transcription factor complex (Fancy and Kodadek, 1999). It was also used for the study of the amyloid β-protein (αβ) assembly (Bitan *et al.*, 2003), to characterize the tRNA-specific adenosine deaminase (tadA) from *E. coli* (Wolf *et al.*, 2002) and to understand the nature of the interaction between MIP-1a and proteoglycans (Ottersbach and Graham, 2001). The reaction

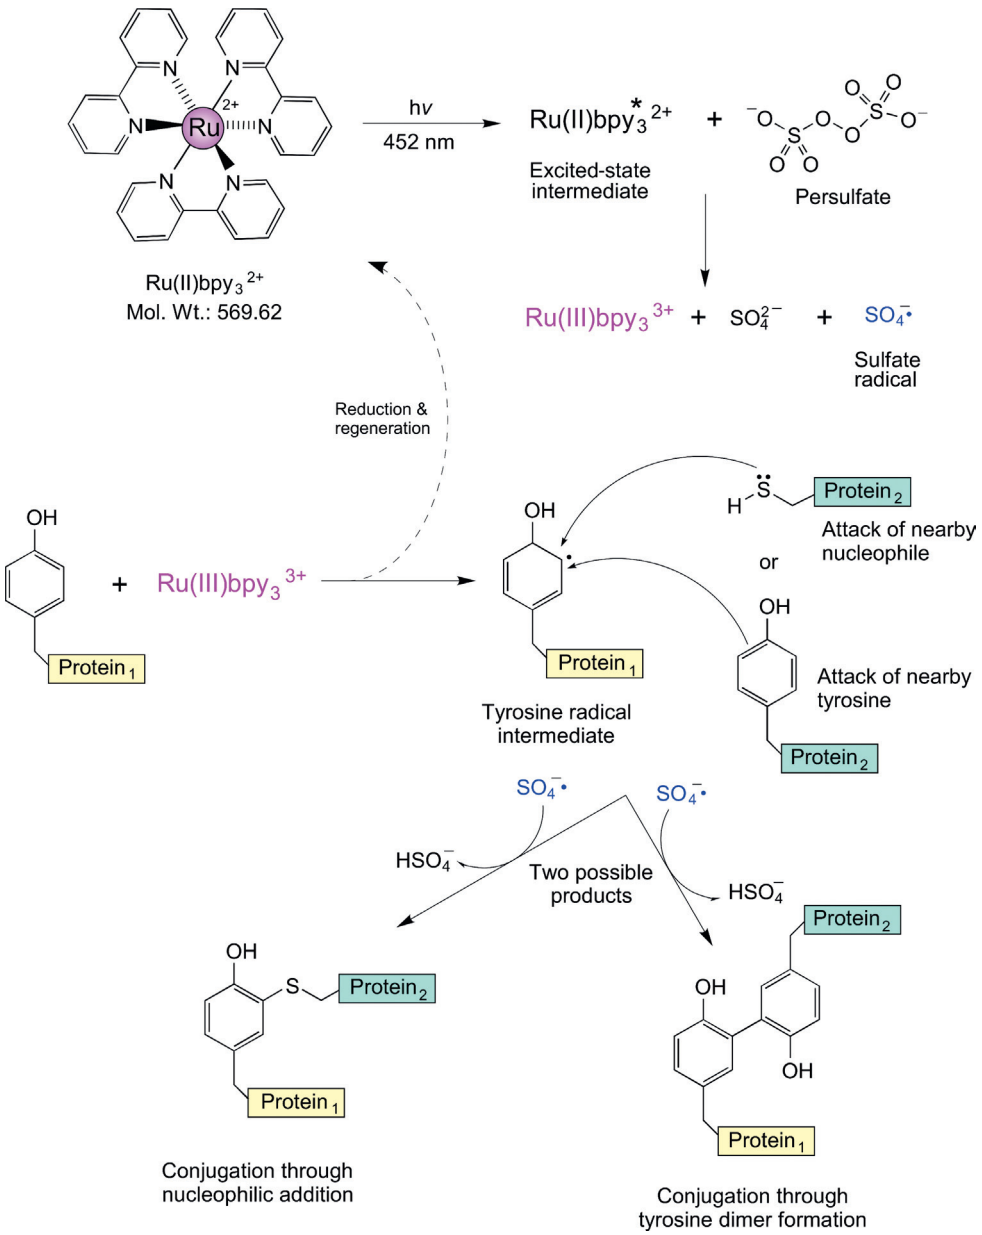

FIGURE 24.21 The reactions of Ru(II)pby$_3^{2+}$ are catalyzed by light at 452 nm that begins by forming an excited state intermediate. In the presence of persulfate, a sulfate radical is formed concomitant with the oxidative product Ru(III)bpy$_3^{3+}$. This form of the chelate is able to catalyze the formation of a radical on a tyrosine phenolic ring that can react along with the sulfate radical either with a nucleophile, such as a cysteine thiol, or with another tyrosine side chain to form a covalent linkage. The result of this reaction cascade is to cause protein crosslinks to form when a sample containing these components is irradiated with light.

is very efficient and typically can result in conjugation yields of 60% or better between interacting proteins. In fact, the conjugation efficiency may yield crosslinks between proteins that are not specifically interacting. To limit the degree of extraneous conjugation, the addition of a nucleophile in the reaction medium (e.g., histidine) can help to restrict crosslinks only to proteins that are in close contact, as in those that are forming interaction complexes at the time.

Protocol

1. Adjust the protein sample concentration to be between 0.01 µ*M* and 20 µ*M* by dilution in 20 µl of reaction buffer: 15-m*M* sodium phosphate, 150-m*M* NaCl, 0.125-m*M* $Ru(bpy)_3Cl_2$ (pH 7.5). The protein sample should not contain any components that are easily oxidized by the reaction, such as thiol reducing agents (e.g., DTT). The addition of histidine to the reaction buffer (7.5-m*M*) can be performed to modulate the crosslinking reaction and limit the degree of protein conjugation between non-interacting proteins. The presence of other nucleophiles will also inhibit the crosslinking reaction, such as Tris buffer or DTT.
2. Add an aliquot of ammonium persulfate (APS) to make a final concentration of 2.5-m*M*. Protect from light until ready to start the reaction.
3. Illuminate the sample in a small open tube or the well of a microplate by placing a white light source approximately 5 to 50 cm from the sample. If a weak light source is used, such as a flashlight, move the light source closer to the sample, but if a strong photoflood lamp is used, then use the greater distance measurement to avoid heating the sample. Illuminate the sample for 0.5 to 30s, depending again on the intensity of the light source.
4. Immediately after irradiation, stop the reaction by the addition of 7 µl of 4× SDS electrophoresis loading buffer or the equivalent (with a high concentration of reducing agent present): 0.2-*M* Tris, 8% SDS, 2.88-*M* β-mercaptoethanol, 40% glycerol, 0.4% xylene cyanol, 0.4% bromophenol blue. Heat the sample at 95°C for 5 min and analyze the complexes formed by electrophoresis.

glutaraldehyde activation using, 631–637
periodate oxidation and reductive amination, 623–628
trichloro-s-triazine (TsT) activation, 666–670
using glycidol to form periodate-oxidizable diols, 628–629
Amine-reactive tetrafluorophenyl (TFP) ester, 803
Amines
acylation with
citraconic anhydride, 190–191
glutaric anhydride, 189
maleic anhydride, 190
succinic anhydride, 188
blocking
of, 221
with
acetic anhydride, 222–223
sulfo-NHS-acetate, 221–222
coupling
by reductive amination, 272
using
CMC, 266
DCC, 268
DIC, 268–269
EDC, 259–260
with
carbodiimides, 237–238
Woodward's reagent K, 269–270
detection
of, 202–203
using OPA, 182
with OPA, 203
for blocking aldehydes, 227
with TNBS, 202–203
introduction of, 194–203
Mannich reaction with formaldehyde, 291–292
modification with
glutaraldehyde, 206–207
SFB, 205–206
SFPA, 205–206
reaction with
acyl azides, 233
aldehydes, 235–236
alkyl halides, 298
ANB-NOS, 322
anhydrides, 238
aryl halides, 236, 242
chloroacetic acid, 194
dehydroazepines, 315–316
diazopyruvates, 330
difluorobenzene derivatives, 289
epoxides, 236, 294
formaldehyde, 291–292
glutaraldehyde, 292–293
GMBS, 310–311
haloacetyl compounds, 241*f*
HSAB, 320
imidoesters, 237, 284–285
isocyanates, 233
isothiocyanates, 229–232
maleimides, 241*f*
MBS, 306
NHS esters, 233–234, 277–278
NHS-ASA, 317–318
p-nitrophenyl diazopyruvate, 330
PNP-DTP, 331
SADP, 323
SAED, 325–326
SAND, 323
SANPAH, 321–322
SIAB, 307
SMCC, 304
SMPB, 309
SMPT, 302–303
SPDP, 300–301
sulfonyl chlorides, 234–235
sulfo-SAMCA, 329–330
sulfo-SAPB, 325
sulfo-SBED, 342–343
tosylate esters, 235
reactions of, 229–240
reversible blocking with maleic anhydride, 223
synthesis from azides, 776

Amino acids, 128–131
aliphatic, 128, 128*f*
analogs, 757, 768, 770, 777
analysis, 402
aromatic, 128*f*
aromatic, hydrophobic, 128–129
azide analogs, 504–505
detection with OPA, 203
ionizable, 129, 129*f*
nonpolar, 144
oxidation of, 139–142
polar, hydrophilic, 129
solvent accessibility of in proteins, 143
2-Amino Benzamide, 218–220
α-Amino group, 128
of biocytin, 495
N-[6-(7-Amino-4-methylcoumarin-3-acetamido)hexyl]-3′-(2′-pyridyldithio)-propionamide, *see* AMCA-HPDP
2-Amino-(6-amidobiotinyl)-pyridine, *see* BAP
Aminoalkylation, 195
4-Aminobenzoic acid
in *p*-aminobenzoyl biocytin, 498–499
p-Aminobenzoyl biocytin, 978
diazotization of, 498–501
general description and use, 498–501
modification of DNA with diazo derivative, 978
4-Aminobenzyl phosphonic acid, 55*f*
p-Aminobenzylcarbamate group, 12
N-(4-Aminobutyl)-*N*-ethylisoluminol, 985–986
6-Aminocaproic acid
in
biotin-LC-hydrazide, 494
NHS-LC-biotin, 485–486
of NHS-LC-fluorescein, 400–401
Amino-carboxylate spacers, 725, 732–734
bis-carboxylate spacer compounds, 736–737
coupling with 6-aminocaproic acid, 733–734
PEG-based, 734–736
coupling to DSC-activated support, 734–736
coupling to periodate-oxidized agarose, 736
examples, 735*f*
2-Aminoethanesulfonate, *see* Taurine
2-Aminoethanol
reaction with periodate, 249–250
Aminoethyl-8, 197
general description and use, 197
2-Aminoethyl-2′-aminoethanethiolsulfonate, *see* AEAETS
Aminoethylation, 197
of cBSA, 842–843
Aminoethylthioacetyl spacer, 931
5-aminolevulinic acid (ALA), 103
7-Amino-4-methylcoumarin
derivatives of, 418
7-Amino-4-methylcoumarin-3-acetic acid, *see* AMCA
7-Amino-4-methylcoumarin-3-acetyl hydrazide, *see* AMCA-hydrazide
7-Amino-4-methyl-2(1H)-quinolinone, 453
2-Amino-2-methyl-1propanol, 953
Aminooxy derivatives, 252
Aminooxy group, formation on a chromatography support, 702–708
ligand coupling, 706–708
of carbohydrates to aminooxy supports, 707–708
of oxidized glycoprotein, 706–707
of sialic acid groups on glycoproteins, 706
protocol, 704–706
Aminooxy–aldehyde chemoselective ligation reaction, 765
Aminooxy–aldehyde reagent pairs, 763–766
Aminooxy-modified antibody, conjugation of, 805–806
Aminooxy-PEG_3-SS-PEG_4-biotin, 815*f*
Aminooxy-PEG_4-biotin, 815*f*
biotinylation of carbohydrate, 816
biotinylation of glycoprotein, 816
Aminooxy-PEG_{11}-biotin, 815*f*
Amino–PEG_n–carboxylate compounds, 820*f*
6-Aminopenicillanic acid (6-APA), 84
2-(3-Aminophenol)-6-(4-amino-1-naphthol)-4-chloro-s-triazine, 53
p-Aminophenyl-β-D-lactoside, 371
β-(*p*-Aminophenyl)ethylamine, 859
Aminophenyl boronic acid
cycloaddition reaction of, 258
β-(*p*-Aminophenyl)ethylamine, 151, *see also* APTS
3-Aminopropyltrimethoxysilane, 577–578
3-Aminopropyltriethoxysilane (APTS), 792
1-Aminopyrene, 753
2-Aminopyridine, 218–220, *see also* APTS
Aminosilanes, 538
Amino-thiol spacers, 725
Aminoxy amine, 252
Aminoxy group, 142, 389, 760
of O-ECAT reagent, 529
Aminoxy–aldehyde reactions, 41
Aminoxy-containing isotopic tags, 33
Ammonia, 151–152, 241, 291–292, 862
coupling to aldehydes, 201
Ammonium chloride, 400, 410
Ammonium ion
reaction with an epoxide, 236
Amorphous cellulose supports, 593–594
AMP, immobilized, 969–970
Amphipathic, 925, 927–928, 935
Amphiphilic, 921
Ampicillin, 86*f*
Amyloid β-protein precursor inhibitor, 93
An, 749
ANB-NOS
general description and use, 322
Anderson, 226, 248, 270, 865
Andersson, 741–743
Ando, 402
Angiotensin II, 280
Anhydrides, 187–191, 223
as blocking agents, 222–223
formation using DCC, 268
glutaric anhydride, 189–190
maleic anhydride, 190
modification of
amines, 187–191
of
DTPA, 507–508, 893
SAMSA, 174
reactions of, 238
succinic, 188–189
3, 6-Anhydro-L-galactopyranose, 591–592, 591*f*
Anikeeva, 456–457, 460
Aniline, 151–152
Aniline derivatives, 513
Anin, 246
Anjaneyulu, 263, 265, 277, 852
Annan, 524
Annunziato, 233, 250
Anterograde tracing studies, 483
Anthopoulos, 746
Anthranilic acid, 218–220
Anthraquinones
reactions of, 254–255
Antibodies, 138–139, 178, 196, 221, 304–305, 308, 315, 318–319, 508
activation with
PDTP, 910
SMCC, 916
SPDP, 903, 907
sulfo-SMCC, 872, 915
adsorption density onto particles, 556
biotinylated, 438, 468, 475, 479–480, 883–884
biotinylation at sulfhydryl sites, 490
biotinylation of, 891–892
carbohydrate specific, 215
carrier-specific, 844
class, 868
conjugates with
enzymes
removal of unconjugated enzyme, 887–891
lymphokines, 896
conjugation
through carbohydrate regions, 870
to
liposomes, 938–939
toxin using SIAB, 913
toxins using cystamine, 910–911
toxins using SMPT, 908
toxins via disulfide exchange, 903
using
aldehyde/hydrazine reaction, 762
glutaraldehyde, 878–880
with
enzymes, 870–891
glutaraldehyde, 879
intact toxins, 900
periodate-oxidized HRP, 204
phycobiliproteins, 438–439
reduced antibodies, 872–874
ricin A chain using SMPT, 908
SMCC-activated enzymes, 871
toxins using oxidized dextran, 919–920
coupling to
carboxylate particles, 580
dendrimers, 364–365
hydrazide particles, 572
liposomes using NHS-palmitate, 942–943

coupling toxins to, 896
coupling with deglycosylated ricin A chains, 900–901
cross-linking with DSP, 279
cytotoxic complexes, 896
detection using
biotinylated immunoglobulin binding proteins, 468
protein A–gold, 584
dextran conjugate with toxins, 896–897
digestion with pepsin, 885
directed against cross-bridge, 300
drug conjugates of, 896
EDC conjugation to liposomes, 944
effect of sodium cyanoborohydride, 272
enzymatic digestion of, 869
enzyme conjugates of, 955
enzyme conjugation
controlling size of conjugates, 881
with DPDPB, 288
fluorescein labeled, 399–400, 478
fluorescently-labeled, 399, 892–893
fragments
conjugation using, 884–887
functioning as B chain in immunotoxins, 900
β-galactosidase conjugate, 954–955
glucose oxidase conjugate, 955
glycosylation sites, 868
gold labeled, 583
gold labeling of, 585–586
humanized mouse monoclonals, 897
immobilization, protein A/DMP method, 286
immunotoxin conjugate design, 900
labeling with
AMCA-hydrazide, 423
NHS-fluorescein, 401
NHS-rhodamine, 412
radionuclides, 507, 893
TRITC, 410
liposome conjugates, 896–897, 921
modification, with
and conjugation of, 867
fluorescein-5-thiosemicarbazide, 406
with
bifunctional chelating agents, 507
biotin-HPDP, 491–492
chelating polymer, 508
chelation agents, 893
DFA, 509–510
DTPA, 507–508
DTTA, 509
NHS-iminobiotin, 487–489
NHS-LC-biotin, 486
sulfo-NHS-SS-biotin, 489
^{99m}Tc through sulfhydryls, 510
monoclonal, 507, 896
optimal fluorophore incorporation, 893
papain digestion of, 886*f*
partial reduction using DTT, 917–918
partially reduced, 917
periodate oxidation of, 882
periodate oxidized, 883–884
conjugation with amine or hydrazide derivatives, 883–884
pI of, 582
preserving antigen binding sites, 299
primary, 893
production, 839
protection of antigen binding site, 138
radioimmunoconjugates, 507
radiolabeled, 870
radiolabeling of, 893
reactions with sodium cyanoborohydride, 235–236
recombinant, 870, 897
reduction
of disulfides, 178–179
with 2-mercaptoethylamine, 182, 421
reductive amination with enzymes, 882
role of, in immunotoxins, 900
SATA modified, 877–878
secondary, 893
single-chain, 898
site-directed conjugation of, 869–870
SMCC activated, 901–902
structure of, 867–868, 868*f*
as targeting component, 951
thiolation
at carbohydrate residues, 510–511
of, 871
using
PDPH, 510–511
SPDP, 913–914
with
2-iminothiolane, 875
SATA, 168–169, 877
SPDP, 904–908
Antibody immunoconjugates for cancer, 896
Antibody recognition
against a cross-linker, 846
Antibody response
to liposome immunogens, 937
toward
cross-linker, 855–856
polymerized haptens, 846
Antibody targeting for biotherapeutics, 89–95
Antibody titer, 840
Antibody–alkaline phosphatase ADEPT conjugate, 98–99
Antibody–alkaline phosphatase conjugate, 35*f*
Antibody–antigen binding regions, 93
Antibody–antigen complex, 712–713
Antibody-based therapeutic bioconjugate, 98
Antibody–deglycosylated ricin A chain
large-scale preparation of, 908
Antibody-detection conjugate *vs* a biotinylated antibody, 4
Antibody-directed enzyme prodrug therapy (ADEPT), 98, 897
Antibody–drug conjugates (ADCs), 89–90, 897–898
cytotoxic drug component of, 90
examples, 92*f*
research, 93
use of, 90–93
Antibody–dye conjugates, 7–10
Antibody–enzyme conjugates, 10, 35–36, 206, 277, 304–305, 308
conjugates with antibodies
removal of unconjugated enzyme, 887–891
purification by immunoaffinity chromatography, 889
purification using metal chelate affinity chromatography, 890
removal of unconjugated enzyme, 887–891
staining using, 43
Antibody–enzyme conjugation, 206, 294, 307
using NHS ester–maleimide cross-linkers, 871–872
Antibody–liposome conjugates, 939
Antibody–QD conjugate, 37
Antibody–toxin conjugates
formation via pyridyl disulfide cross-linkers, 903
Anti-CD25 monoclonal antibody conjugate, 101–102
Anti-CD33-immunotoxin conjugate, 89–90
Antigen binding sites, 178, 182, 312, 510–511, 868, 874–875, 883–884, 886–887, 889–890, 893, 897, 902, 956
blocking of, 867, 869
Antigen presenting cells (APCs), 124, 843
Antigen specificity, 507
Antigenic determinants, 900, 938–939
Antigenic specificity, 867
Antigenicity, of liposomal vesicles, 937
Antigen–MHC complex, 839
Antigens, 411, 491–492, 845, 891, 938–939
attachment to liposomes, 921
definition of, 839
detection of using fluorescently-labeled antibodies, 892–893
detection using
biotinylated antibodies, 475
gold particles, 580–581
encapsulation in liposomes, 937
immobilized, 867, 889
localized using avidin–biotin interactions, 468
Antimisiaris, 937
Antioxidants, 518
Antiparallel, 164
Anti-p22^{phox} antibody, 432–433
Aoi, 366–368
Aorta, 280
AP, 870
APDP
general description and use, 332–333
iodination of, 522
Apelin, 349
APG, 339–340
Aplysia gonad lectin, 586
Apple, 196, 843, 937
APTS, 578
fluorescent dye linked, 578
general description and use, 539
glass slide modification using, 382
reaction conditions, 539
silica particle modification using, 575–576
Arabidopsis PP2-A1 phloem lectin, 53
Arabinose, 149
Archakov, 991
Arg-Gly-Asp (RGD), 109–110

Arginine, 129
  oxidation of, 141–142
  pKa, 129–130
  reaction
    of guanidinyl group with glyoxals, 339
    with
      APG, 339
      glyoxal, 251
  solvent exposed area, 144
Arginine vasopressin
  conjugation with cBSA, 843
Argon laser, 414, 417–418
Argon–krypton mixed laser, 414, 417–418
Argos, 143
Arima, 359
Armstrong, 483, 549
Arnaud, 447
Aromatic amine, 764–765
Aromatic amino acids, 128*f*
Arriagada, 576
Arroyo, 424
Arsenate, 953
Arshady, 557–558
Artificial proteases, 1011–1012
Aryl aldehyde PEG reagents, 802–806
Aryl aldehydes, 802
Aryl amine, 236
Aryl azides, 331–332, 484
  effect of
    hydroxyl groups on ring, 316–317
    nitro groups on ring, 316
  general properties, 290
  in biotinylation reagents, 496–497
  iodinatable, 522
  of
    ABH, 336–337
    ABNP, 341
    ANB-NOS, 322
    APDP, 332–333
    APG, 339–340
    ASBA, 338
    ASIB, 331–332
    NHS-ASA, 317–318
    photobiotin, 497
    SADP, 323
    SAED (AMCA derivative), 325–326
    SAND, 322–323
    SANPAH, 321–322
    SASD, 318
    sulfo-SAMCA (AMCA derivative), 329–330
    sulfo-SAPB, 325
    sulfo-SBED, 342–343
  perfluorinated, 315–317
  reaction with sulfhydryls, 317
  reactions of, 254
  ring expansion of, 315–316
Aryl carbamate bond, 392–394
Aryl halides, 289
  chemistry of, 236
  reactions of, 242
Aryl ketones, 40
Aryl phosphonates, 67
Aryl thioester, 781
Arylamines, 151, 201
  formation by reaction with diflurobenzene derivatives, 289
Arylating agents
  reactions of, 242
ASBA
  general description and use, 338–339
  iodination of, 521
Ascorbate, 511, 770, 951–952
Ascorbate radical, 1012–1013
Ascorbic acid, 136–137, 149–150, 235–236, 1011
  for reductive amination, 272
Ashcroft, 745–746
Ashwell, 154, 200, 203
Asialofetuin, immobilized, 901, 916
ASIB
  general description and use, 331–332
Asparagine, 129, 154
  solvent exposed area, 143–144
Asparagine–glycine bonds, 227–228
Aspartic acid, 129
  oxidation of, 141–142
  pKa, 129
  solvent exposed area, 144
Aspergillus niger, 955
Aspergillus Restrictus, 898
Astatine, 514
Atassi, 190–191, 223
Atha, 406
Atkinson, 281
Atomic mass units (amu), 993–994
ATP, 136–137, 163
ATP analogs, 66–67
ATPase, 286–287, 404, 406, 413
Atrial natriuretic factor, 280
Auristatins, 90
Autofluorescence, 418–419
Auxillary chromatographic methods, 51
Avastin, 89
Avian sarcoma virus, 287
Avidin, 315, 341, 372, 381, 479–480, 485–486, 488–494, 500, 979–980
  activation with *bis*-hydrazides, 295
  affinity constant with biotin, 465
  binding to
    ABNP cross-links, 341
    biotinylated PE in liposomes, 939–942
    biotinylated phospholipids, 940
    sulfo-SBED cross-links, 342–343
  biotin binding site, 479–480
  charge interaction with quantum dots, 457
  comparison to streptavidin, 466
  conjugates of, 465
  conjugation
    to
      HRP using reductive amination, 472
      liposomes, 940–941
    using
      glutaraldehyde, 474–475
      reductive amination, 472–474
    with
      enzymes using SMCC, 469
      ferritin using reductive amination, 472
      HRP using reductive amination, 473–474
      phycobiliproteins, 438–439
      phycoerythrin, 478
  denaturation of, 465
  dendrimer derivative, 376
  double labeling systems using, 475
  effect of periodate, 388–389
  as egg-white protein, 482
  enzyme conjugate of, 483, 497
  enzyme labeled, 469
  fluorescently labeled, 468, 475–479
  general description and use, 465–467
  gold labeled, 468, 583
  gold labeling of, 587
  HABA binding characteristics, 481
  hydrazide-activated, 295, 468, 957
  iminobiotin binding of, 487
  immobilized, 343, 489, 491–492, 496
  interaction with
    biotin, 465–467, 483, 891–892
    biotinylated antibodies, 891–892
    biotinylated liposomes, 943
    iminobiotin, 481
  maleimide-activated, 471
  modification with adipic dihydrazide, 210
  nonspecific binding properties, 465–466
  optimal fluorescein labeling level, 476
  optimal molar ratio to enzyme in conjugates, 474
  phycoerythrin conjugation of, 475
  preparation of conjugates, 469–475
  purification using immobilized iminobiotin, 488
  radiolabeled, 468
  structure and properties, 465
  thiolation
    using SATA, 472
    with
      2-iminothiolane, 478
      SATA, 169
  toxin conjugate, 897
  toxin labeled, 468
Avidin–biotin assay, 496
Avidin–biotin complex, 479–480
Avidin–biotin systems, 465
Avigad, 151, 200, 205
Avouris, 748

Bioconjugates
applications
assay and quantification, 15–35
chemiluminescent acridinium ester conjugates, 19–20
fluorescent oligonucleotide probes, 20–23
for enzyme-linked immunoassays, 18–19
for FRET assays, 26–27
for limiting nonspecificity in bioconjugate designs, 33–35
in bioluminescence resonance energy transfer (BRET), 29–31
in heterogeneous immunoassays, 16
in molecular beacon-type assays, 27–29
in PCR amplification process, 28
in TaqMan probes, 27–29, 29*f*
molecular scaffolds for assay sensitivity, 23–24
protein fragment complementation assays, 32
split reporter system, 32
used in homogeneous assays, 24–26
composites from, 1–2
conditions for use, 6–7
covalent bond, 1–2
definition, 1–6
designs, 2*f*
detection, tracking, and imaging of biomolecules, role in, 35–49
as interacting protein/or peptide domains, 39–40
as proximity ligation assays, 41–43
detection of sensitivity, 4
for super resolution microscopy, 46–49
for western blot detection, 45
in dual-labeled conjugates of STORM imaging, 49
in fluorescently labeled antibodies, 38–39
in FRET based protease probes, 39
of cell undergoing apoptosis, 39
probing by chemoselective ligation, 40–41
staining with antibody–enzyme conjugates, 43
enrichment, purification, or scavenging of biomolecules, role in, 49–78
affinity capture of post-translational modifications, 56–65
affinity capture of recombinant fusion proteins, 71–75
affinity capture using active site binding probes, 66–71
by antibody-mediated immunoprecipitation, 54–56
covalent fusion tag technology, 75
immunospecific technique, 54–56
scavenging of contaminants or unwanted components, 75–78
using biospecific affinity ligands, 49–54
final form, 1–2
fluorescent label, 2–3
formation of a useful, 2–3
from coupling reactions, 3–4
from individual molecules, 1–2
from reactive crosslinking agents, 3–4
high content analysis (HCA), 35–36
in catalysis and chemical modification, 78–87
immobilized proteases for proteomic analysis, 80–81
immobilized reactors, 81–87
in cell based imaging, 7
in dye-labeled antibody, 7–10
in *in vivo* imaging, 7, 35–36
in therapeutics and *in vivo* diagnostics, 87–119
antibody targeting for biotherapeutics, 89–95
antibody-directed enzyme prodrug therapy, 98–100
boron neutron capture therapy (BNCT), 102–103
for cancer therapy, 88–89
for high contrast imaging, 110–112
for radio imaging, 108–110
in vivo imaging, 103–107, 112–119
photodynamic therapy (PDT), 103–107
polymeric scaffolds and nanoparticles for biotherapeutic conjugates, 95–98
radiolabeled antibody conjugates for cancer, 100–102
molecule affinity ligands in, 4
PEG modification of, 13–15
pharmaceutical and biotech companies, application in, 1
preparation of a single, 6
process of creating, 3–4
radioactive, 10
reagents used to modify, label, or crosslink biomolecules, 3*f*
shapes and strucures, 11
strategies and design, 6–15
application-based, 6–10
components and designs, 8*t*–9*t*
hydrophobic *vs* hydrophilic crosslinker designs, 11
optimal bioconjugates, 10–15
use of molecular scaffold, 11
use of, 1
using PEG-based crosslinkers and thiolation reagents, 35
using supplementary molecular scaffolds, 4
Bioconjugation
reactions of, 229, 230*t*–232*t*
Biocytin, 495
as fundamental unit of sulfo-SBED, 484
general description and use, 482–484
hydrazide derivative, 957
in
p-aminobenzoyl biocytin, 498–499
constructing trifunctional cross-linkers, 341
of sulfo-SBED, 342–343
reaction with biotinidase, 483
use in trifunctional cross-linking reagents, 484
Biocytin hydrazide, 501
general description and use, 495
glycoprotein labeling protocol, 495
Bioluminescence resonance energy transfer (BRET), 29–31
advantages of, 29–31
Bioluminescent enzyme, 29–31
Biomolecules
FITC for labeling, 400
Bioorthogonal, 258
Bioorthogonal chemical labeling techniques, 75
Bioorthogonal reactions, 40–41
Bioorthogonal reagents, 757
BioSepra, 597
Biospecific affinity ligands, immobilization of, 49–50
Biotage, 87
Biotherapeutic conjugates, 95–98
Biotin, 176–177, 315, 479–481, 867, 978
analog of, 481
azido derivative, 771
conjugation with phycobiliproteins, 438–439
diaminopyridine derivative, 218
general description and use, 465, 482–484
importance of valeric acid side chain, 482
in protein interaction reporter design, 996–997
interaction with
avidin, 465–467
streptavidin, 466
lysine derivative of, 483
modification of biomolecules with, 479–480
NHS ester derivative of, 484
of
ABNP, 341
sulfo-SBED, 1003
PEG-phosphine derivative, 504–505
phosphine derivative, 501
protein cofactor, 136–137
reactive derivatives of, 479–480
thioester derivative, 246, 784
Biotin affinity group
TRICEPTS reagent, 348–349
Biotin compounds, 789
Biotin-acylhydrazone-active site probe, cleavage of, 392*f*
1-Biotinamido-4-[4′-(maleimidomethyl) cyclohexane-carboxamido]butane, *see* Biotin-BMCC

for coupling hydrazides to carboxylates, 211
in
coupling ASBA to carboxylates, 338
formation of NHS esters, 233
liposome conjugation, 929
modification of phosphates with *bis*-hydrazides, 214
modification of proteins with *bis*-hydrazide compounds using, 479
quenching with 2-mercaptoethanol, 852
reaction with
AMCA, 419
biocytin, 483
biotin-hydrazide, 494
cystamine, 910–911
lipid derivatives, 929
phosphate groups of nucleotides, 163
reactions of, 237–238, 248
reagents, 259
use in hapten–carrier conjugation, 846–852
Carbohydrate antigens
coupling to carriers using a diazonium reaction, 859
Carbohydrate polymers, 831–838
Carbohydrates, 201, 203, 296, 405, 407, 422
activation of hydroxyls, 152
basic sugar components, 148
biotinylation of, 501
BNAH modification of, 503
conjugation using
carbonyl and sulfhydryl reactive cross-linkers, 312
M_2C_2H, 313
PDPH, 313–314
coupling to
carriers by reductive amination, 865
dendrimers, 370
hydrazide particles, 571
crosslinking methods, 155–156
detection
using
hydrazide compounds, 209–210
hydrazide-avidin, 479
with
hydrazide compounds, 151
lectin–gold probes, 586
functional groups, 149
glycoprotein attachment points, 154
gold labeled, 583
hydrogen bonding, 153
hydroxyl group nucleophilicity, 152
immune response against, 215
labeling with
biotin-hydrazide, 493–494
Cascade Blue hydrazide, 434
Lucifer Yellow CH, 437
Texas Red hydrazide, 417
modification
of, 215
with
AMBH, 175
β-(*p*-aminophenyl) ethylamine, 151
anhydrides, 187
chloroacetic acid, 152
diamines, 199–200
epoxides, 152
of
antibody molecules, 870
avidin, 465–466
on proteins, 137
oxidation
by sodium periodate, 151
with
oxidases, 205
periodate, 249–250, 882
sodium periodate, 204
reaction with
ABH, 336–337
anhydrides, 238
reducing ends, 151
structure, 153
and functionality, 148–155
thiolation of, 510–511
thiolation using PDPH, 510–511
within antibody molecules, 868
Carbohydrazide, 210–211, 214, 571
general description and use, 296
modification of
avidin or streptavidin with, 479
phosphates, 214
of Lucifer Yellow CH, 437
reaction with aldehydes, 210
5-(((2-(Carbohydrazino)methyl)-thio) acetyl)-aminofluorescein
general properties and use, 407–408
Carbon
allotropes of, 741
Carbon dioxide, 270
Carbon nanotubes, 549, 741, 747–755
cycloaddition reactions of, 754–755
detergent or lipid modification of, 750–752
DNA aptamer labeled, 753
fluorescent labeling of, 418
manufacture of, 748
modification
of, 750–752
with
CDI-activated Tween, 751
phospholipid derivatives, 752
properties, 747–749
pyrene modification of, 752–753
Carbonates, 271
chemistry of, 236
Carbonic acid
diester derivative of, 236
Carbonic dihydrazide, *see* Carbohydrazide
Carbonyl
reaction with
M_2C_2H, 313
MPBH, 312
PDPH, 313–314
Carbonyl addition mechanism, 130
Carbonyl diimidazole (CDI), 567, 601–602
activation, 647–652
aqueous coupling protocol, 651–652
ligand coupling to, 651–652
nonaqueous coupling protocol, 652
protocols, 650–651
N,N′ Carbonyl diimidazole (CDI)
carboxylate reactions, 248
hydroxyl reactions, 249

diol cleavable, 388
disulfide containing, 387–388
immunogenicity of, 855–856
of
ABH, 337
ANB-NOS, 322
APDP, 333
APG, 339–340
ASBA, 338
ASIB, 331–332
biotinylation reagents, 480
GMBS, 310
HSAB, 320
MBS, 307, 916–917
SADP, 323–324
SAED, 326
SAND, 322–323
SANPAH, 321–322
SIAB, 307
SMPB, 309
SMPT, 302
sulfo-LC-SMPT, 302*f*
sulfo-NHS-LC-ASA, 318
sulfo-SAMCA, 329–330
sulfo-SBED, 343
SIA, 311
used in immunotoxin conjugates, 900
Crosslinked enzyme aggregates (CLEA), 84
Crosslinked enzyme crystals (CLEC), 84
Crosslinkers
arginine reactive and photoreactive, 339–340
base cleavable, 391
carbonyl reactive and photoreactive, 336–337
carboxylate reactive and photoreactive, 337–339
cleavable, 387
APDP, 332–333
in immunotoxin conjugate design, 900
SADP, 323
SAED, 326
SAND, 322–323
sulfo-SBED, 343
disulfide cleavable, 388
dithionite cleavable, 389
hydroxylamine cleavable, 389
immunogenicity of, 855–856
iodinatable, 519–523
periodate cleavable, 388
sulfhydryl reactive
and photoreactive, 331
determination of activity with SAMSA-fluorescein, 404–405
trifunctional, 341
zero-length, 259
Crosslinking
multi-step protocols, 299
reagents, 259
site-directed, 299
strategies with proteins, 144–148
using
homobifunctional reagents, 144–145
single-step protocols, 275
two-step protocols, 275

Crosslinking agents
disulfide containing
cleavage using DTT, 180
sulfhydryl reactive, 287–288
Crosslinking chemistry, 229
Crosslinking reagents
carbonyl and sulfhydryl reactive, 312
cell permeant and impermeant, 277
disulfide containing
cleavage using DTT, 179–180
heterobifunctional, 299
homobifunctional, 275
iodinatable, 519–523
Cruz, 193
Cryoprotectants, 925
α-Crystalline, 285
CSF-1, 280
C-terminal
pKa, 129
C-terminal thioester
in expressed protein ligation, 782
Cu^{1+}, 140
^{64}Cu, 508
^{67}Cu, 380
Cu-64 labeled antibodies, 100–101
Cuatrecasas, 189, 234, 262, 277–278, 287–288, 465, 859
Cubie, 468
Cuenoud, 1011
Cu(I), 381
as catalyst for click chemistry reaction, 258, 769–776
Cumber, 171, 898–899, 901, 903, 913, 916
Curl, 741
Cusan, 741–743
$CuSO_4$, 770–771
CVF, 898
Cy3, 440
Cy5, 361, 440, 451
as acceptor in LRET, 451
dendrimer labeling, 379
dendrimer modification, 361
tandem dye, 439
Cy5.5, 440–441
Cy7, 440
Cy3 dye, 7, 48
Cy5 dye, 7, 48–49
Cy5.5 dye, 28–29
Cyanide, 953
Cyanine dyes
amine-reactive, 442–444
carbonyl-reactive, 446–447
general description and use, 440
hydrazide-containing, 446
thiol-reactive, 444–446
Cyanobacteria, 438
Cyanoborohydride, 87
activation of hydroxyl particles, 570–571
Cyanuric chloride, 152, *see also* Trichloro-s-triazine
Cyanogen bromide (CNBr), 601–602
activation, 664–670
ligand coupling, 666
protocol, 666
protocol, 665–666
using carbonate buffer, 666
using NAOH titration, 665–666
Cyclic AMP, 163
Cyclic chelating compounds, 508
Cycloaddition, 353–354, 766–767, 769–770
Diels–Alder, 758
of psoralen to thymine, 256
to carbon nanotubes, 754
Cycloaddition reactions, 257–258, 769–776
Cyclodextrin, 95
fullerene interactions, 741–743
Cyclohexane, 469, 948–949
1-Cyclohexyl-3-(2-morpholinoethyl) carbodiimide, *see* CMC; CDI
Cyclooctyne ring
in click chemistry reactions, 775
Cyclopentadiene, 775
Cyclopropanation, 745
Cystamine, 973, 981
coupling to lactose, 901–902
in preparation of immunotoxins, 910–911
modification of
DNA with, 973
oligonucleotides, 178
reaction with proteins, 178
reduction of, 901–902
use for thiolation, 175–176
Cysteic acid, 141
Cysteine, 129, 184, 187, 190–192, 197–198, 307–308, 415, 518, 782, 856, 886
added during peptide synthesis, 856
aminoethylated, 198
biotinylation of, 490
blocking
of, 223
using Ellman's reagent, 186
with iodoacetamide, 224
modification with 2-bromoethylamine, 198
oxidation of, 141
peptide haptens containing, 854
pKa, 131
reaction with
anhydrides, 238
cisplatin, 246
haloacetyl compounds, 240
maleimide-activated BSA, 857
sodium tetrathionate, 224
reactions, 131
site-directed coupling through, 138
solvent exposed area, 144
Cysteine nitrosylation, 61
Cysteine proteases, 67–68
Cystine, 131, 165, 173–174, 184, 198
reduction
of, 178
using DTT, 178
Cytochemical staining, 435–436, 887–888
using avidin–biotin interactions, 468
Cytochrome b559, 280
Cytochrome b562, 781
Cytochrome C, 951–952
Cytochrome C reductase, 281
Cytochrome oxidase, 289–290
Cytochrome P-450, 279, 282–283, 287
Cytochrome P-450 reductase, 287
Cytokeratin, 280
Cytosine, 157, 405, 427
activation with bromine compounds, 969–971
biotin derivative of, 976
hydrazide derivative of, 405
hydrogen bonding, 163–164
labeling with
Cascade Blue hydrazide, 434
fluorescein probes, 407–408
Lissamine rhodamine B sulfonyl hydrazine, 416
Lucifer Yellow CH, 437
mercuration of, 161
modification with
AMCA-hydrazide, 423
biotin-hydrazide, 494, 979–980
reaction with
bisulfite, 159, 160*f*, 968
structure and reactivity, 159–161
thiolation of, 161
transamination of, 968
transamination reactions, 159
Cytosine deaminase, 98
Cytotoxic, 486, 896
Cytotoxic agent
conjugation to dextran, 896–897
Cytotoxic T cell response, 840
Cytotoxicity, 303, 901, 939
mechanism of, for plant toxins, 898
of
dgA–antibody conjugates, 900–901
radioimmunoconjugates, 507–508
single-chain protein toxins, 899
SMCC conjugated immunotoxins, 915
SMPB conjugated immunotoxins, 918
optimal ratio of antibody–dgA conjugates, 907
relationship to use of cleavable cross-linkers, 913
Cy5-type carbocyanine dye, 50*f*

Disuccinimidyl tartarate, *see* DST
Disulfide
between protein subunits, 136
cleavable cross-linkers containing, 387–388
cyclic, 179
exchange reactions of, 242–244
formation with
pyridyl disulfides, 288
sodium tetrathionate, 224
thiosulfonates, 287–288
TNB, 287–288

from pyridyl disulfide reactions, 331
in
antibody molecules, 867–868
cleavable reagents, 388
DSP, 278–279
immunotoxin conjugates, 900
inhibiting formation of, 165–166
of
AMCA-HPDP reactions, 420–421
DTBP, 287
proteins, 131
SAED, 326
SAND, 322–323
SASD, 318
sulfo-SBED, 343
using 2-mercaptoethanol, 180–181
using DTT, 178
using immobilized reagents, 184
using sodium borohydride, 185–186
with 2-mercaptoethylamine, 182
with TCEP, 183
reduction
in antibodies, 870, 872
in immunotoxin action, 900
reversibility of, 223
Disulfide exchange, 179, 226
in preparation of immunotoxins, 903
using
cystamine, 175–176
Ellman's reagent, 911
pyridyl disulfides, 243
Disulfide interchange, 227, 240
prevention by blocking agents, 221
using cystamine, 910–911
Disulfide reducing agents, 85–86
Disulfide reductants, 198, 221, 300, 322–323
effect on iodo-beads, 515
general description and use, 178
immobilized, 184
3, 6-Disulfonate 4-aminonaphthalimide, 435–436
Disulfosuccinimidyl tartarate, *see* Sulfo-DST
5, 5′-dithio-*bis*-(2-nitrobenzoic acid), 243, *see also* DTNB
2, 2′-Dithiobis(ethylamine), *see* Cystamine

Dityrosine, 141, 436
Divinyl sulfone (DVS), 152, 592, 601–602
activation, 677–681, 695
amine-containing proteins/ligands, coupling of, 680
carbohydrates or hydroxylcontaining ligands, coupling of, 680–681
2-mercaptoethanol, coupling of, 681
supports, 677–678
ligand coupling, 679–681
preparation, 678–679
thiol-containing ligand solution, coupling of, 679–680
yield of protein coupling, 677–678
Dixon, 190–191, 223
DLVO theory, 550–551, 581
DMA
general description and use, 285
DMAC, 789, 796, 802–803, 810, 812, 816
DMAP, 234
DMF, 789, 802–803, 810, 812
DMP
general description and use, 285–286
for immobilization of antibodies, 286
DMPA, 927
DMPC, 941
DMPE, 932
DMS
activation of PE, 945–946
general description and use, 286
in conjugation of proteins to liposomes, 945
DMSO, 789, 802–803, 810, 812
and SPAB, 311
SIA and, 311
to solubilize hapten–carrier conjugates, 842–843
DNA, 149–150, 214, 427
activation with
bromine compounds, 969–970
sodium bisulfite, 968
alkaline phosphatase conjugation using DSS, 982–984
base constituents, 157
base pairing, 164, 490
biotinylated, 468
biotinylation of, 975
bis-hydrazide modification of, 968–972
bisulfite catalyzed transamination, 969
carbodiimide coupling through 5′ phosphate, 971–972
chemical modification methods, 966–987
coupling adipic acid dihydrazide at the 5′-phosphate end, 971
CpG nanoparticles, 411
crosslinking methods, 165
cystamine modification of, 973
cystamine modified, 981–982
detection using avidin-biotin interactions, 486
diamine modification of, 968
diamine modified
fluorescent labeling of, 987
labeling with FITC, 987
DSS activated, 983
enzymatic labeling methods, 959–966
nick translation, 960–962
PCR, 959–960
random primed labeling, 959–960
terminal transferase, 959, 964–965
enzyme conjugation techniques, 980–985
fluorescence detection, 442
fluorescent labeling of, 985–987
functional groups, 158
hydrazide modified
conjugation to SFB modified alkaline phosphatase, 985
5′-hydrazide modified, 205–206
labeled with NHS-rhodamine, 411
labeling at 5′-end, 175–176
labeling with
AMCA-hydrazide, 422–423
p-aminobenzoyl biocytin, diazotized, 498–499
BODIPY fluorophores, 425
Cascade Blue hydrazide, 434
fluorescein, 407–408
Lissamine rhodamine B sulfonyl hydrazine, 416
Lucifer Yellow CH, 437
photobiotin, 497
mapping, 497
methylation, 424
modification
and conjugation of, 959
by hydrazide-reactive probes, 405
of, 157
with
biotin-BMCC, 979
biotin-diazonium, 978–979
biotin-hydrazide, 979–980
biotinylation reagents containing hydrazides, 493
bis-hydrazides, 214
cystamine, 175–176
diamines, 200
fluorescein-5-thiosemicarbazide, 406
NHS-LC-biotin, 977–978
PDITC activated, 984
PEG polymers, 359
5′-phosphate group, 929
phosphodiester bonds of, 158*f*
photobiotin modification of, 977
probe design, 165
psoralen coupling, 256–257
purine residues of, 161
reaction with
EDC, 163
N-bromosuccinimide, 969–970
structure, 163
sugar constituents, 162
sulfhydryl modified
coupling of sulfhydryl-reactive fluorescent probes, 987
synthesis, 163
thiolation of, 490, 974
Watson–Crick model, 164
DNA binding proteins, 489
DNA microarrays, 382
DNA polymerase I, 959
DNA probes, 300–301, 410
DNase I, 960–961
DNP, 56
DNPH, 529–530
dNTP, 959–960

Doxorubicin–dendrimer conjugate, 359
DPDPB
  general description and use, 288
DPPC, 937–938
DPPE, 932
  activation with
    MBS, 934–935
    SMPB, 932, 937–938
DPPG, 937–938
Drafler, 336
Draper, 405, 416, 422–423, 427, 434–435, 437, 968–969
Dried milk
  stabilization of colloidal gold suspensions using, 582
Drugs
  conjugation to toxins, 913
  encapsulated in liposomes, 939
  liposome encapsulation, 921
DSC, 236
  activation of
    APTS surfaces using, 542
    hydroxyl particles, 567
  general description and use, 283–284
  reaction with hydroxyls, 249
  Tween 20 activation using, 750–751
DSG, 283
DSP, 278
  dative binding to metallic surfaces, 279
  general description and use, 278
  surface modification, 245
DSPE, 932
DSS, 216, 983
  DNA-alkaline phosphatase conjugation using, 982–984
  for capturing protein interactions, 992–993
  general description and use, 279–280
DST, 388
  general description and use, 281
DTBP
  general description and use, 286–287
DTE, 179, 184, *see also* Ellman's reagent
DTNB, 243
DTPA, 451, 893
  dendrimer derivative, 376, 380
  general description and use, 507–508
  In-111 labeled carbon nanotubes, 754
  isothiocyanate derivative, 380
  isothiocyanatophenyl, 451
DTPA–gadolinium chelates, 359
DTSSP
  general description and use, 279
DTT, 178–180, 184–185, 197, 223–226, 242, 278–279, 289, 300–301, 307–308, 315, 389, 402–403, 518, 807, 903
  affect on aryl azides, 317
  cleaving disulfide crosslinkers, 179–180
  for
    cleavage of APDP, 332–333
    cleavage of pyridyl disulfides, 331
    cleavage of SADP, 323–324
    cleavage of SAED, 327
    cleavage of SASD, 318
    cleaving AMCA-HPDP derivatives, 420–421
    partial reduction of antibodies, 917–918
    reduction of pyridyl disulfides, 510–511, 906–907, 914
    SPDP reduction, 903
  general description and use, 179
  in
    cleavage of aryl-thiol bond, 242
    cleavage of biotin-HPDP modified proteins, 492
    cleavage of sulfo-NHS-SS-biotin modified proteins, 489
    cleaving sulfo-SBED cross-links, 345
    reduction of cystamine, 901–902
  reaction with
    SMPT, 172
    SPDP, 170
  reduction of cystamine-DNA, 974
DTTA
  general description and use, 509
  in time-resolved fluoroimmunoassays, 509
Du Vigneaud, 482

Excitation, 395, 397
Excited-state, 397
Exciton Bohr radius, 455
Expressed protein ligation, 771, 782–785, 783*f*
Exteins, 782
Extinction coefficient, 395
Extrusion (of lipids), 924

F

F-18 affinity probe, 109–110
F-18 labeled antibody mimic (Affibody), 110
^{19}F NMR, 1001
Fab fragments, 869, 891, 898, 900–901
  formation of, 885
  preparation of, 886–887
Fab′ fragments, 304–305, 310, 364–365, 869, 886, 900–901
  conjugation to toxins using Ellman's reagent, 911
  conjugation with toxins using S-sulfonates, 911–912
F(ab′)$_2$ fragments, 304–305, 869, 874, 891, 900–901
  formation of, 885, 885*f*
  preparation of, 885–886
  reduction of, 886
  reduction with 2-mercaptoethylamine, 182, 872
F-actin, 287
Factor V, 318–319
Factor Va, 415
Factor VII, 105–106
Factor XIII, 496
Factor XIIIa
  assay of using 5-(biotinamido) pentylamine, 496
FAD, 136–137, 955
$FADH_2$, 955
Fahien, 287
Fairbanks, 233–234, 277–278

  using fluorescently-labeled antibodies, 892–893
Fluoraldehyde, 182
5′-*p*-Fluorosulfonylbenzoyl adenosine, 67
9-Fluorenylmethyloxycarbonyl (FMOC), 725–726
Fluorescein, 398–408, 429, 892
  aldehyde/ketone and cytosine reactive derivatives, 405
  amine reactive derivatives of, 398–399
  azido derivative, 771
  comparison to
    AMCA, 418–419
    Cascade Blue, 432
    Lucifer Yellow iodoacetamide, 436
  energy transfer from coumarin derivatives, 418
  general description and use, 398–408
  hydrazide derivative of, 407–408
  iodoacetamido derivatives, 401–402
  pH dependence on fluorescence, 398
  quenching of, 476
  silica particle embedded, 577
  similarity to phenolphthalein, 397
  sulfhydryl reactive derivatives, 401
  use with
    terbium chelates, 453–454
    Texas Red, 414
5-fluorescein, *see* SAMSA-fluorescein
Fluorescein (488), 7
Fluorescein Isothiocyanate, *see* FITC

Fluorescein–maleimide, 758
Fluorescein-5-maleimide, 404
  general properties and use, 403–404
Fluorescein-5-thiosemicarbazide, 406*f*, 407–408, 417–418
  general description and use, 406–407
Fluorescence
  effect of
    electron donating groups, 396
    electron withdrawing groups, 396
    halogen atoms, 396–397
    heavy atoms, 396–397
  general description, 395
  indigenous biological, 438

Fluorescence resonance energy transfer (FRET), 439
Fluorescent
  aminopyridine derivatives, 501–502
Fluorescent bead-based affinity assay, 40*f*
Fluorescent *in situ* hybridization (FISH), 985
Fluorescent labeled antibody, 2–4, 2*f*
  vs biotinylated antibody, 5*f*
Fluorescent labeling
  F/P ratio, 400
Fluorescent labels
  effect of iodination of, 396–397
  general description and use, 395
Fluorescent lanthanide chelates, 451
Fluorescent lifetime
  of lanthanide chelates, 447
Fluorescent oligonucleotide probes, 20–23
Fluorescent probes
  antibody labeling with, 892
  coplanar ring structure of, 397
  DNA labeling with, 985
  effect of environmental constituents on fluorescence, 397
  hydrazide derivatives, 957
  photon absorbing additives, 400
  quenching effects, 397
  SAED, 325–326
  similarity to non-fluorescent dyes, 397
  sulfo-SAMCA, 329–330
Fluorescent quenching, 431, 893, 985
  of
    Cascade Blue derivatives, 432
    TRITC, 409–410
Fluorescent rhodamine-alkyne probe, 41
Fluorescent spectroscopy, 398
Fluorescent staining procedures, 398
Fluorescent transfer
  using SAED, 327
Fluorescently label azido amino acids, 41
Fluorescently labeled antibodies, 38–39
Fluorescently labeled pharmacophore, 36–37
Fluorinated aryl azides, 315, 331
Fluorine, 192
N-2-(4-[^{18}F] Fluorobenzamido)ethyl] maleimide, 110
Fluorobenzene derivatives, 236, 242
Fluoromethyl ketone (FMK) group, 39, 119
2-fluoromethylpyridinium (FMP), activation using
  ligand coupling to, 654–655
    aqueous coupling protocol, 654
    nonaqueous coupling protocol, 654–655
  of crosslinked agarose support, 654
  of Toyopearl resin, 653–654
  protocol, 653–654
Fluorophenyl esters, 238
Fluorophores
  encapsulation into liposomes, 938–940, 939*f*
  general characteristics of, 395
  general structure of, 395
Fluorophosphonate, 67
Fluorophosphonate-PEG$_4$-biotin probe, 69*f*
5-Fluorouracil, 741
FMN, 136–137
Fok, 845
Folate binding protein, 372
Folate-containing bioconjugate, 94–95
Folic acid, 11
  coupling to
    carbon nanotube, 752
    dendrimers, 371–372
Folk, 336

Glutaraldehyde, 10, 206, 275, 291, 437, 865, 871, 886–888, 952, 954–955
  1-step conjugation protocol, 880
  2-step conjugation procedure, 880
  2-step conjugation protocol, 880
  activation of
    enzymes with, 475, 956
    PE, 944–945
  avidin conjugation using, 474–475
  concentration used in cross-linking, 864
  coupling to amine particles, 562–564
  cyclized, 206
  general description and use, 292–293
  in conjugation of proteins to liposomes, 944
  modification of amines, 206–207
  reaction with adenine, 162
  two-step cross-linking, 294
  use
    for antibody–enzyme conjugation, 880
    in fixing Lucifer Yellow derivatives, 435–436
    in hapten–carrier conjugation, 863–864
Glutaraldehyde activation using activated amines, 631–637
  formation of aldol condensation unsaturated constructs, 632
  in acidic or neutral pH conditions, 632–633
  intramolecular cyclization reaction, 632–633
  to form dimeric reactive species, 637
  to form monomeric reactive species, 637
Glutaric acid, 189
Glutaric anhydride
  general description and use, 189
  modification of
    APTS surfaces using, 540–542
Glutathione (GSH), 74–75, 179, 184, 402, 415, 422
  immobilized, 1002
Glutathione S-transferase (GST) tags, 74
Glycan, 366–367
  BAP conjugate, 503
  BAP modification of, 501–502
  BNAH modification of, 503
  containing ketone analogs, 760
  containing sugar analogs, 760
  coupling to dendrimers, 370
  coupling to hydrazide particles, 571
  enzymatic release of, 219
  fluorescent labeling of, 219
  labeled with azido-sialic acid groups, 778
  modification
    of, 215, 217–218

with cyanine dye, 446
Glycan biotinylation reagents, 501–505
O-Glycanase, 219
Glycans, 53
Glycated, 235
Glycated hemoglobin, 155–156
Glycated protein, 54*f*
Glycation, 155, 215
non-enzymatic, 138
Glyceraldehyde, 149
Glycerol, 400, 407, 518
for
quenching sodium periodate reactions, 407, 423
in phosphodiglycerides, 925–926
Glycerylphosphate, 845
Glycerylphosphate derivatives, 921
Glycidol, 366, 371–372
for high density modifications, 628
for medium-density modifications, 628–629
for modification of dendrimers, 366
reaction in dioxane, 629
to form periodate-oxidizable diols, 628–629
Glycidol derivatization process, 609–610
3-Glycidoxypropyl trimethoxysilane, 597, *see also* GOPTS
3-Glycidoxypropyltriethoxysilane, 545
3-Glycidoxypropyltrimethoxysilane, 3*f*
Glycidyl methacrylate, 296, 608, 616
Glycidyloxypropyltrimethoxysilane, *see* GOPTS
Glycine
blocking excess glutaraldehyde with, 474–475
for quenching glutaraldehyde reactions, 880–881
in NHS ester reactions, 278
solvent exposed area, 144
Glycobiology, 366–367
Glycoconjugates, 201, 204, 209–210
detection
using hydrazide-avidin, 479
with lectin–gold probes, 586
labeling with
biocytin-hydrazide, 495
biotin-hydrazide, 493–494
Lucifer Yellow hydrazide, 435–436
Texas Red hydrazide, 417
lectin binding, 935–936
Glycoconjugation, 215
Glycogen phosphorylase b, 286
Glycolipids, 154, 204, 930–931
conjugation using lectins, 935–936
detection with lectin–gold probes, 586
labeling with Lucifer Yellow CH, 437
oxidation with sodium periodate, 929
periodate oxidized, 939
reductive amination conjugation, 946
Glycols
as cleavable groups in cross-linkers, 387–388
oxidation with periodate, 203
Glycolysis, 149–150
Glycomics, 60
Glycopeptides, 324

    NHS esters, 233–234, 277
  reactions of, 539
Hydroxyl radical footprinting, 140, 1011
Hydroxyl radicals ($^{\cdot}OH$), 139, 511
  produced from psoralen, 256
Hydroxylamine, 152, 391, 878, 943, 975
  and cleavage of peptide bonds in proteins, 227–228
  as a blocking agent, 227–228
  deprotection of
    SATA with, 168
    SATP, 169–170
  for
    cleavage of *O*-acetyltyrosine, 222
    cleaving ester bonds, 282
    deprotection of SATA-modified molecules, 877
  in
    cleavage of ester containing cross-linkers, 389
    in cleavage of esters, 188
  oxime formation with, 227–228
  reaction with
    pyrimidines, 159
    SAMSA, 174
  reaction with aldehyde, 227*f*
  use in deblocking citraconylated amines, 191
Hydroxylic-containing supports, 598–599
Hydroxyl-reactive immobilization methods, 690–696
  divinyl sulfone (DVS) activation, 695
  epoxide activation, 690–695
  trichloro-s-triazine (TsT) activation, 695–696
Hydroxylysine, 154
Hydroxymethyl Phosphine Derivatives, 239–240, 347–348
p-Hydroxyphenylacetic acid
  use as an iodination scavenger, 319–320
N-Hydroxysuccinimide, *see* NHS
N-Hydroxysuccinimide esters, 195
N-Hydroxysuccinimido-2-iminobiotin, *see* NHS-iminobiotin
N-Hydroxysuccinimidyl chloroformate, 249
N-Hydroxysuccinimidyl-4-azidobenzoate, *see* HSAB
N-Hydroxysuccinimidyl-4-azidosalicylic acid, *see* NHS-ASA
N-Hydroxysulfosuccinimide, *see* Sulfo-NHS
N-Hydroxysulfosuccinimidyl-4-azidobenzoate, *see* Sulfo-HSAB
Hynes, 154
HyperD supports, 597
Hypervariable region, 182, 868–869
Hypobromous acid (HOBr), 139
Hypochlorous acid (HOCl), 139

Imidazole, 129–130, 191–192, 200, 214, 270–272, 512, 878, 971, 973
in NHS ester reactions, 278
reaction with
reaction with NHS esters, 233–234
ring of purines, 161
Imidazole carbamate, 236, 567
hydrolysis of, 272
Imidazolyl carbamate, 249, 270–271
Imide
as product of a hydrazide reaction with a carboxylate, 211
Imidoamide, 237, *see also* Amidine
Imidoesters, 166, 277, 945
chemistry of, 237
homobifunctional, 284–285
of
DMA, 285
DMP, 285–286
DMS, 286
DTBP, 286
Imine, 201
Iminobiotin, 481
immobilized, 488
NHS ester of, 487–488
3, 3′-Iminobispropylamine, 195, 201, 968
Iminodiacetic acid, immobilized, 891
2-Imino-imidazole, 487
Iminophosphorane, 776
2-Iminothiolane, 243, 510, 856, 874–877, 886–887, 913
antibody modification of, 874–877
for thiolation of toxins, 907
general description and use, 166
in
modification of gelonin, 900
thiolation of
antibodies, 871
phycobiliproteins, 439
toxins, 900
modification of
avidin or streptavidin with, 478
gelonin, 907
gelonin or PAPs, 900
side reactions of, 167
toxin thiolation using, 916
use with 4, 4′-dipyridyl disulfide, 227
use with 4, 4′-dipyridyl disulfide, 168
Immobilization, 224, 272, 286, 292
of biotinylated antibodies, 713
using CDI, 270–271
Immobilization of ligands, 629–631
coupling at pH 7.2, 629–630
coupling at pH 10, 630–631
on glutaraldehyde activated supports, 637–638
protocol, 638
Immobilized affinity ligands, 49–50
for purification of IgG antibodies, 52
in immunoprecipitation, 54–56
purification of antibodies, 52–53
purification using, 51–54
proteins targeted, 51
separations using, 53
small molecule substrate analogs or inhibitors as, 53–54
strategies for support, 54
direct antibody coupling method, 54–55
indirect antibody coupling method, 54
of F(ab′)$_2$ fragments to insoluble supports, 54–55
on solid supports, 55
uses, 589
using synthetic organic binding molecule, 52–53
Immobilized 4-aminobenzylphosphic acid, 55*f*
Immobilized antigen with precise binding specificity, 51
Immobilized beta-D-glucose, 53*f*
Immobilized beta-D-mannose, 53*f*
Immobilized chemical reactant, 87*f*
Immobilized conjugate reagents, 87
Immobilized delorazepam derivative, 69–70
Immobilized diazo derivative, 59
Immobilized disulfide reductants, 184–185
Immobilized glutathione, 3*f*
Immobilized 8-hydroxyquinoline, 721
Immobilized immunoaffinity, 71–72
Immobilized immunoglobulin binding protein, 51
Immobilized laccase, 84*f*
Immobilized lectins, 53, 60
Immobilized *m*-aminophenyl boronic acid, 53, 54*f*
Immobilized metal affinity chromatography (IMAC), 543–544
Immobilized metal affinity chromatography (IMAC), 57, 59–60, 63*f*, 78
Immobilized organic pseudo-affinity ligand, 51
Immobilized *p*-amino benzamidine, 55*f*
Immobilized proteases
for cleavage of fusion tags, 81
for proteomic analysis, 80–81
Immobilized protein A, 52, 885
Immobilized protein A/G, 52
Immobilized protein G, 52
Immobilized reactors, 81–87, 951
covalent bond formation, 81
HPLC-based microreactors, 84–85
in the form of enzyme catalysts, 87
noncovalent bond formation, 81
using laccases or tyrosinases, 83
Immobilized saccharide bioconjugates, 53
Immobilized streptavidin, 524, 712
in retrieving a biotinylated antibody, 712–713
preparation of, 713
Immobilized streptavidin, 55–57
Immobilized streptavidin resin, 61
Immobilized sugars, 53*f*
Immonium cation intermediate
in formaldehyde reactions, 292

Poly-L-glutamic acid, 5*f*, 841
  conjugation methods, 845
  use as a carrier, 845
Poly-L-lysine, 5*f*, 327–328, 384, 821, 841
  conjugation methods, 845
  DPA chelate, 453
  in MAP, 846
  modification with DTPA, 508
  succinylated, 510
  used as a carrier, 841, 845
Polymer bound reagents, 86–87
Polymer grafting onto existing substrates, 617
Polymer modification reagents, 821–838
  synthetic and natural polymers, 821
Polymerase chain reaction, *see* PCR
Polymer-based biotherapeutic conjugates, 96*f*, 97*f*
Polymeric lipid nanoparticles (PLNs), 96–98
Polymeric molecular scaffolds, 5*f*
Polymeric nanoparticle based scaffolds, 96–98
Polymeric PEG reagents, 822–831
  carbodiimide coupling of carboxylate–PEG derivatives, 827–828
  CDI activation and coupling, 828–829
  coupling chemistries, 829–830
  in bioconjugate applications, 822
  NHS ester and NHS carbonate activation and coupling, 824–827
  properties in solution, 822
  repeating units of ethylene oxide, 822
  trichloro-s-triazine (TsT; cyanuric chloride), 823–824
Polymeric scaffolds, 95–98
Polymeric supports, 598–620
Polymerization, 145, 553–554
  in
    EDC-mediated peptide–carrier conjugation, 846
    glutaraldehyde cross-linking, 956
    glutaraldehyde reactions, 879
    hapten–carrier conjugation using EDC, 846
    immunotoxin conjugation, 903
  limited with heterobifunctional reagents, 299
  of
    ethylenimine, 197
    maleic anhydride, 190
  prevention by blocking agents, 221
  with EDC, 262
Polymers
  gold labeled, 583
  use as a carrier, 841, 845
Poly(methacrylic acid), 554
Polymethine bridge, 440
Polymethylmethacrylate (PMMA), 550, 553–554
Polymyxin B, 77
Poly(*N*-(2-hydroxypropyl)methacrylamide) (HPMA), 5*f*
Polyoxyethylene sorbitan monolaurate, 750–751
Polyphosphazenes, 821
Polypropylene, 615

Polysaccharide, 407
activation of hydroxyls, 152
as
carriers for antibody conjugates, 896–897
spacer in preparation of immunotoxins, 918
asparatine-linked, 154–155
attachment to proteins, 137
binding of by plant toxins, 898
conjugation using
carbonyl and sulfhydryl reactive cross-linkers, 312
M_2C_2H, 313
MPBH, 312
PDPH, 313–314
detection using hydrazide compounds, 209–210
labeling with
AMCA-hydrazide, 423
biotin-hydrazide, 493–494
Texas Red hydrazide, 417
modification with anhydrides, 187
of antibody molecules, 870
oxidation with
oxidases, 205
periodate, 882
sodium periodate, 204, 880
reaction with
ABH, 336–337
hydrazide compounds, 152
sodium periodate oxidation, 137–138
structure, 152–153
and functionality, 148
thiolation using PDPH, 510–511
Polysaccharide immunogen conjugates, 122
Polysaccharides, 406, 821
Polystyrene, 550, 553–554
adsorption density for proteins, 556
beads, 515
modified with chlorosulfonamide groups, 515
protein denaturation on, 556
Poly(styrene/acrylate), 550
Poly(styrene/butadiene), 550
Poly(styrene/divinylbenzene), 550
Polystyrene/divinylbenzene copolymer particle, 76
Poly(styrene/vinyltoluene), 550
Polysulfone, 615
Polyurethanes, 821
Poly(vinyl alcohol), crosslinked, 613–614
Poly(vinyl alcohol) (PVA), 554, 821
Poly(vinyl alcohol) (PVA) copolymers, 613–614
Poly(vinyl pyrrolidone), 554
Polyvinylamine, 449
Polyvinylidene difluoride (PVDF), 615
Polyvinylpyrrolidinones, 821
Poly(vinyltoluene), 550, 556
Porath, 152, 244, 295, 543–544, 573, 890
Porous membrane supports, 614–618
commercial, 615
construction, 614
convective flow through, 614
internal pore structure of, 614
porosities, 615
process of diffusion in, 614
Porous polymeric chromatography supports, 598–599
Porphyridium cruentum, 438
Porphyrin, 139–140
adsorption onto carbon nanotubes, 753
dendrimer derivative, 380
Porphyrin photosensitizer derivatives, 104
Porstmann, 474
Porter, 246
Posewitz, 543–544
Positrons, 512
Posnett, 846
Post-translational modification, 215, 523, 527–528, 778
Potassium cacodylate, 965
Pow, 583, 846
Powsner, 512
Pozsgay, 215, 759
PPV23, 122
Prato, 743–744
Precipitation
from glutaraldehyde cross-linking, 864
of hapten–carrier conjugates, 842
Pre-column derivatization
using Ellman's reagent, 186
Preformed complex, 507
Preis, 153
Prenylation, 772–774
Preprolactin, 322
Prescher, 505, 757, 771, 775, 777–778
Pressman, 512
Prestayko, 298
Prestwich, 392
Prevnar, 122
Prevnar 13, 122
Prey, 991
Prey protein, 1000, 1002, 1010, 1013
Price, 864
Prime, 244, 554–555
Primers, 959–960, 962–963
Progesterone receptor, 167
Proline, 128
oxidation of, 141–142
solvent exposed area, 144
Pronase, 481
Propargylamido-cysteine, 771
Propargylamine, 770, 800
Propargylamine
Propargyl–PEG_1–NHS ester, 774, 800, 801*f*
Properdin, 281
Propionic acid, 425–428
Propionic anhydride
as mass tag, 524
Prossnitz, 994–995
Prostate-specific membrane antigen (PSMA), 104–105
Prosthetic group
in phycobiliproteins, 438
of HRP, 952
Protease
activity
measurement of, 221
assay using succinylated casein, 188
Protein A, 53, 286, 867
biotinylated, 468–469
gold labeled, 583–584
immobilized, 59*f*, 885–886, 889, 908
Z-domain of, 93–94
Protein A, Protein G, and Protein A/G-mediated immobilization methods, 713–716
protocol, 715–716
Protein complementation assay (PCA), 32*f*
Protein fragment complementation assays, 32
Protein G
biotinylated, 468–469
Protein interaction mapping, 991
Protein interaction reporter (PIR), 996
Protein interactions, 256, 1014–1016
bioconjugate techniques for study of, 989
captured using
DSS or BS^3, 992–993
formaldehyde, 994
homobifunctional crosslinkers, 991–999
MTS-ATF-biotin, 1008–1010
MTS-ATF-LC-biotin, 1008–1010
photoreactive crosslinkers, 999–1002
PIR reagents, 996
sulfo-SBED, 1003
cell surface, 1000
study using
metal chelating groups, 1010–1016
sulfo-SFAD, 1001
trifunctional label transfer reagents, 1002
techniques to study, 991
Protein Mapping, 1010–1014
Protein synthesis
blocking of, 896
Protein–carbohydrate immunogens, 122–123
Protein–palmitate derivative
insertion into liposomal membranes, 943
Protein–protein interactions, 511
Proteins
3-dimensional structure, 134
activation with sulfo-NHS and EDC, 263
active center, 138
biotinylation with sulfo-NHS-biotin, 485
blocking functional groups on, 221
as carriers, 261–262
cationized, 196
cellular internalization of, 418
chelated metals, 137
cleavage of peptide bonds in, 227–228
cofactors, 136–137
conjugation to liposomes, 930–931, 942
creation of pyridyl disulfide groups on, 243
crosslinking methods, 144–148
crosslinking using imidoesters, 285
detection with OPA, 203
diamine modification of, 196
disulfide crosslinks, 131
FITC labeling of, 399
full complement of reactivity, 131
glycoprotein structure, 137
glycosylation, 137
gold labeling, 582
hydrazide derivatives of, 957
hydrazide-activated, 884
hydrophobic core, 129
IgG for conjugation with thiolated, 311–312
indirect iodination of, 519–520

iodination
of, 512
with
chloramine-T, 515
Iodogen, 517
ionizable groups, 131–132
labeled with AMCA, 419
labeling
with
gold particles, 580–581
NHS-fluorescein, 400
p-aminobenzoyl biocytin, diazotized, 498–499
photobiotin, 497
lipoproteins, 137
maleimide activated, 304, 306, 916
measurement of sulfhydryls of, 226
microsequencing, 399
modification, 127
with
biotin-BMCC, 491
biotin-HPDP, 492
bis-hydrazides, 211–212, 479
DTPA, 507–508
iodoacetyl-LC-biotin, 493
NHS-LC-biotin, 486
modifications with SPAB, 311
net positive charge contribution, 129–130
nitration of, 201
nucleophilic groups, 131–132, 134
nucleoproteins, 137
oxidation of, 139–142
passive adsorption of, 556
post-translational modification, 137, 155
prosthetic groups, 136–137
reaction with
SMPT, 302–303
SPDP, 300–301
reduction
of disulfides, 178–179
using DTT, 179
using immobilized reductants, 184
structure and reactivity, 128–144
succinylated, 188
toxoids, 844–845
used as carriers, 841–845
Proteoglycans, 154
Prothrombin, 279
Proximity ligation assay (PLA), 41–43
bioconjugates used in, 41–43
for antibody-based reagents, 41–43
procedure, 43
using two oligo-labeled antibodies, 44*f*
PS, 926
functional derivatives, 929
Pseudomonas toxin A
thiolation with 2-iminothiolane, 904
Psoralen, 498
reactions of, 256–257
Psoralen-PEG$_3$-biotin, 256–257
general description and use, 498
Puchulu-Campanella, 1002–1003
Pulliam, 286
Purine, 157
bromination of, 161
electrophilic reactions, 161
structure and reactivity, 161
Purine-scaffold fluorescent probes, 414
Pushpanathan, 400
pY20, 57
Pyrene
modification of carbon nanotubes using, 752–753
trisulfonated, 432
Pyrene derivatives
Pyrene trisulfonate, 433–434
1-Pyreneacetic acid, 753
1-Pyrenebutyric acid, 753
1-Pyrenebutyric acid *N*-hydroxysuccinimide ester, 753
1-Pyrenecarboxaldehyde, 753
Pyrene-1-isothiocyanate, 753
(1-Pyrenyl)butyic acid hydrazide, 753
2-(1-Pyrenyl)ethyl chloroformate, 753
N-(1-Pyrenyl)maleimide, 753
Pyridine, 592–593
Pyridine-2-thione, 170, 226, 243, 288, 300–301, 421, 491, 903, 975
absorptivity of, 171
extinction coefficient of, 243
Pyridine-4-thione, 226
Pyridoxal-polyphosphate derivatives, 291
Pyridyl disulfide, 226, 302, 331, 387–388, 404–405, 420, 837, 904, 931, 957, 974–975, 981
immobilized, 903
in
biotinylation reagents, 490
carbonyl and sulfhydryl reactive cross-linkers, 312
of
AMCA-HPDP, 420–421
APDP, 332–333
biotin-HPDP, 491
DPDPB, 288
PDPH, 313–314, 510–511
PDTP, 910
SMPT, 302–303, 908
SPDP, 301*f*
on dedrimers, 360
reactions of, 243
use in forming immunotoxins, 903
Pyridyl disulfide activation, 681–687
2, 2′-dipyridyl disulfide, 684
ligand coupling to supports, 685–687
of IgG antibody, 685–686
thiol-containing small ligands, 686–687
preparation of, 684–685
using NHS-PEGN -pyridyl disulfide crosslinkers, 684–685
using PDEA, 685
2-Pyridyldithiol, 300–301
3-(2-Pyridyldithio)propionate, *see* PDTP
3-(2-Pyridyldithio)propionyl hydrazide, *see* PDPH
Pyrimidine, 157
acylation of, 159
electrophilic reactions, 159
halogenation of, 160–161
Pyropheophorbide-a (Ppa), 104–105
Pyrrolidine, 769
Pyruvate dehydrogenase, 286
Pyruvate kinase, 286

Stearylamine
activation with SPDP, 947
functional derivatives, 929
Steel, 1005–1006
Steer, 154
Steptavidin
comparison to avidin, 466
thiolation with SATA, 169
Steric hindrance, 400–401
Sternberger, 475
Stewart, 267–268, 435–436
Stickel, 415
Stilbenedisulfonate receptor, 404
Stirpe, 900
Stöber, 575, 578
Stochastic optical reconstruction microscopy (STORM), 47–48
dual-labeled conjugates of, 49
Stoke's Law, 395
Stokes shift, 424, 427, 431, 451, 477
definition of, 395
of
AMCA derivatives, 423
BODIPY 493/503 C_3 hydrazide, 429
BODIPY FL C_3 hydrazide, 429
BODIPY FL C_3-SE, 425
BODIPY fluorophores, 424
lanthanide chelates, 447
Lucifer Yellow fluorophores, 436
phycobiliproteins, 438
tandem phycobiliprotein conjugates, 439
Stolowitz, 208–209, 447, 766
Straubinger, 938–939
Streefkerk, 880–881
Streptavidin, 315, 341, 374–375, 449, 479–480, 485–486, 488–494, 500–501, 745, 759, 778, 975, 1011
activation with
bis-hydrazides, 295
sulfo-SMCC, 469–470
alkaline phosphatase conjugate, 496
as immunogen carrier for glycans, 501
binding to
ABNP cross-links, 341
sulfo-SBED cross-links, 342–343
biotin binding site, 479–480
conjugates, 895
conjugation
to
ferritin using glutaraldehyde, 474–475
HRP using reductive amination, 473
liposomes, 939–942
using
glutaraldehyde, 474
reductive amination, 472–474
with
enzymes using SMCC, 469
HRP using reductive amination, 473–474
phycoerythrin, 438, 478
effect of periodate, 388–389
enzyme labeled, 469
fluorescent labeling of, 475–479
fluorescently labeled, 349
gold labeled, 468, 583
gold labeling of, 587
hydrazide-activated, 295
iminobiotin binding of, 487
immobilized, 343, 348–349, 391, 486, 489, 491–492, 501, 524, 526, 996–997, 1007, 1010
interaction with
biotin, 483
biotinylated antibodies, 891–892
iminobiotin, 481
modification with
AMCA-NHS, 477–478
FITC, 476
Lissamine rhodamine sulfonyl chloride, 476–477
modified with *bis*-hydrazide compounds, 479
optimal fluorescein labeling level, 476
phycoerythrin conjugate, 374
purification using immobilized iminobiotin, 488
quantum dot conjugate, 460
rate of biotin interaction with, 480
structure and properties, 466
thiolation
using SATA, 472
with 2-iminothiolane, 478
Streptavidin conjugates
as universal detection reagents, 712
Streptavidin–biotin interaction, 49–50
Streptavidin–dye conjugates, 67–68
Streptavidin–enzyme conjugate, 2*f*, 45
Streptavidin-HRP, 1010
Streptavidin-mediated immobilization methods, 712–713
for immobilization of biotinylated antibodies, 713
Streptomyces avidinii, 466
Streptomyces pilosus, 509–510
Strept-tag II, 72
Strickland, 952
Striebel, 374–375

On the cover: Molecular model of R-phycoerythrin, a light-harvesting protein from red algae having bright fluorescent properties. The crystal structure was published in Contreras-Martel, C., Martinez-Oyanedel, J., Bunster, M., Legrand, P. Piras, C., Vernede, X., and Fontecilla-Camps, J.C. (2001) Crystallization and 2.2 A resolution structure of R-phycoerythrin from *Gracilaria chilensis*: a case of perfect hemihedral twinning. Acta Crystallogr. Sect.D 57, 52–60. The coordinates are available on the RCSB Protein Data Bank as structure 1eyx. Molecular graphics and analyses were performed with the UCSF Chimera software package. Chimera is developed by the Resource for Biocomputing, Visualization, and Informatics at the University of California, San Francisco (Sanner, M.F., Olson, A.J., Spehner, J.C. (1996) Reduced surface: an efficient way to compute molecular surfaces. Biopolymers 38(3), 305–320).
