Preface to the Third Edition

In the years since the publication of the second edition, the field of bioconjugation has continued to advance at an incredible pace. Since 2008, over 54,000 additional journal publications have appeared in the biological, medical, polymer, material science, and chemistry journals that at least mention the terms "bioconjugate" or "bioconjugation." In addition, many tens of thousands of new links to Internet sites with bioconjugation information also have appeared in this time frame, including sources from academic, corporate, and personal web pages. These journal articles and links describe many new reagents and reactions for forming bioconjugates of all types, including the formation of unique complexes in solution as well as the coupling of molecules to solid-phase surfaces or particles. In addition, exciting new methods are appearing for the application of bioconjugates in highly sensitive assays and detection schemes, for *in vivo* imaging and diagnosis, for therapeutic drug targeting, in the capture and purification of biomolecules, for catalysis and chemical modification, and for vaccine development and immune modulation. These recent advances in bioconjugate techniques have resulted in two new chapters and many new sections and updates throughout the book, as well as the rearrangement and consolidation of chapters to more logically group topics together having common themes.

The third edition also contains two major chapters that were obvious gaps in the previous editions: Chapter 1 is an extensive introduction to the vast field of bioconjugation, while Chapter 15 describes the reagents and techniques used for the immobilization of ligands onto chromatography supports. The new comprehensive introduction to the book begins by describing the basic principles of bioconjugation along with presenting important strategies for designing optimal conjugates for a wide range of applications. Chapter 1 also reviews the major application areas where bioconjugates are being used today and describes the conjugate designs associated with each of these applications.

In addition, the new Chapter 15 contains one of the most extensive overviews of immobilization chemistry ever presented. It begins by reviewing the basic principles of affinity chromatography along with the resins and other solid-phase options used to couple affinity ligands of every type, including proteins, antibodies, enzymes, peptides, nucleic acids, other biomolecules, metal chelates, and organic mimetics. It also presents numerous options for activating supports and the coupling reactions that can be used for covalently attaching ligands onto them. These methods can also be successfully applied to the immobilization of molecules onto any other particle or surface material desired. The resultant affinity supports can be used for capturing target molecules, in the purification of proteins, for studying protein or oligonucleotide interactions, for proteolysis and enzyme catalysis, for removing contaminants from solution, or for developing biosensors and assays for a host of analytes.

Another major change that is immediately noticeable with this edition is the use of full-color illustrations. Literally hundreds of new and updated figures now use color to better illustrate reactions or to show how bioconjugates are being used in applications. While the design of the book may have been radically changed and updated with this edition, it is my hope that the reader will continue to find it useful in the design of new bioconjugates.

Important Information

HEALTH AND SAFETY

This book describes hundreds of reagents, reactions, and applications for use in bioconjugation. Most of the compounds are highly specialized and we have very little information regarding their toxicological properties. At a minimum, bioconjugation reagents should be considered irritants and handled with care. However, the overwhelming majority are known to be reactive and any individual compound or solvent can be corrosive, hazardous, toxic, volatile, flammable, explosive, or otherwise dangerous to personal health and safety. For this reason, the use of any reagent or protocol described in this book should be carried out by taking the appropriate precautions. Before utilizing any of these methods, the user agrees to take complete responsibility and personal liability for any and all risks associated with the reagents and reactions described in this book or within the references cited. Before starting an experiment, the user agrees to reference the appropriate Material Safety Data Sheets (MSDS) relative to every compound or component used in a reaction and to completely understand the properties of the reactions being contemplated. The use of personal protective equipment (PPE), fume hoods, and proper laboratory techniques can ensure safety for both the user and other people in the immediate vicinity. In addition, the disposal of waste materials should be performed according to the appropriate environmental regulations to prevent toxic elements or compounds from entering the water, air, or soil. The inappropriate disposal of excess reagents or reaction byproducts may be harmful to people and the environment.

INTELLECTUAL PROPERTY

Throughout this book I have provided references related to the reagents, reactions, and techniques used in bioconjugation. There are many additional references that can be found by performing the appropriate key word searches on the Internet. However, such knowledge does not necessarily provide the liberty to legally use these reagents and applications for commercial purposes without consideration for existing intellectual property rights. While in some cases pertinent patent references are provided within the book, this is done only to supply additional technical details about the topic being discussed and not to imply anything about freedom to operate.

Today, nearly every important reagent or method reported in the literature has a patent or patent application associated with it, especially if it has potential commercial value. A search of the patent databases, such as the United States Patent and Trademark Office (http://www.uspto.gov/) or the European Patent Office (http://ep.espacenet.com/) for key words or the names of inventors can provide a list of existing issued patents or patent applications related to a bioconjugate technique or compound.

It is the responsibility of the reader to become familiar with the patents and claims that may cover particular compounds, compositions, reactions, or their methods of use in bioconjugate applications. If patents or patent applications exist, it is important that the appropriate permission or a license be obtained from the owner of such intellectual property before exploiting it for commercial use.

Acknowledgments

I thank the thousands of researchers, many of whose names appear in the reference section, who have developed and optimized hundreds of reagents and applications related to the modification, conjugation, and immobilization of biomolecules and affinity ligands. Their work made this book possible. I also want to thank Barb Tanaglia, Sally Etheridge, Crystal Gomez, Heather Flynn, and Brian Weathers for their expert help in obtaining journal references. I also greatly appreciate Craig Smith for reviewing the new material and being supportive of my writing. In addition, I thank Funmilayo Suleman for literally reading the entire second edition and providing helpful feedback on how to make this edition even better. I also thank Peter Bell, Julie Kremer, and Alan Doernberg for providing corporate approval for this entire endeavor. Although Thermo Fisher Scientific did not sponsor the project, the company provided great motivation for me to undertake the effort and complete the third edition.

Finally, special thanks to the one who made it all possible.

Dedication

For *Amy and Meghan*, who, since the second edition was published, have now graduated from college and are pursuing careers in biology and medicine. Also for baby *Violet*, who hopefully someday will be able to read and appreciate a future edition of this book.

CHAPTER

1

Introduction to Bioconjugation

The field of bioconjugation has had a deceptively quiet, but at the same time enormous, impact on science and technology. The use of bioconjugates may not be the focus of many popular press science articles or noticed as important for news stories; nevertheless, the ability to produce discrete bioconjugate complexes having unique properties suitable for a wide variety of applications has become the underlying success story of many research endeavors. Bioconjugation has made possible the discovery of new biomolecules, the elucidation of complex biological processes, and the spawning of entire industries within the medical, diagnostics, life sciences, microelectronics, and material sciences fields. The use of bioconjugates in an almost unending number of applications has also made possible a multibillion dollar worldwide economy that functions to cure diseases and discover the very secrets of life. The process of securing grant money, venture capital investment, or corporate R&D funding often includes the proposed use of novel bioconjugates as key components in reaching technical goals. Indeed, many of the largest pharmaceutical and biotech companies now depend upon bioconjugation to design their future product pipelines and maintain a vital edge over the competition. The "magic bullet" and "targeted drug" concepts often desired in drug development are heavily contingent on the creation of highly specific bioconjugates with therapeutic efficacy toward certain cells, tissues, or disease states. Without the advance of bioconjugate techniques to enable this process, the world would not have anywhere near the invention and innovation that have taken place over the last few decades in the life science and medical fields.

A search for any particular bioconjugate type using PubMed or other major science and technology search engines typically yields at least hundreds or, more likely, thousands of hits. The actual percentage of all publications that use bioconjugates to perform methods critical to scientific discovery may not be determinable precisely, but it is likely to be an overwhelming majority of all life science research being done and published today. In fact, most activities in biological research could not be done easily, if at all, without the use of one or more bioconjugate reagents to assay, detect, track, image, or capture target molecules, or effectively target and treat diseases.

Throughout this book, the techniques of producing and using bioconjugates are presented with a view toward providing options for designing similar conjugates for new or existing applications. This chapter is meant to provide an introduction to aid in understanding the breadth and depth of this field, while acting as a guide to rationally choosing bioconjugate components and reaction strategies for designing effective reagents.

1. WHAT IS BIOCONJUGATION?

In its most fundamental aspect, bioconjugation simply involves the attachment of one molecule to another, usually through a covalent bond, to create a complex consisting of both molecules linked together (Figure 1.1). In most cases, at least one of the molecules is of biological origin or is a fragment or derivative of a biomolecule. In some situations, the conjugate that is formed is entirely synthetic, but its use is directed toward biological or life science applications. When forming such bioconjugates, the process can yield a composite having approximately equal proportions of each component or create a conjugate purposely designed to have more molecules of one component than the other. The final form that the bioconjugate takes is dependent on the

FIGURE 1.1 Forming a basic conjugate often involves the reaction of two molecules and a crosslinking agent that covalently links the components together. In some conjugation schemes an activation agent is used that results in the linking of two molecules without an intervening cross-bridge between them.

desired application and the components and methods used to couple them together. With an understanding of the basic concepts of bioconjugation, this process can be done without difficulty and even become controllable through the appropriate choice of reagents, reactions, and conditions.

The process of making bioconjugates from individual molecules thus creates new complexes having the combined properties of each constituent from which it is made. The result forms novel constructs having characteristics not normally found among naturally occurring substances. For instance, attaching a fluorescent label to an antibody creates a targeting complex that can be used to bind specifically to a desired biomolecule through the antigen binding sites on the antibody, and then, due to the fluorescent properties of the label, the targeted biomolecule can be detected—a feature which would not be possible using the unlabeled antibody alone. Thus, the formation of a useful bioconjugate begins by envisioning the features that are desired in the final complex and then choosing the components necessary to create it. Figure 1.2 illustrates some bioconjugate types that can be made by linking two or more molecules together. These designs are by no means exhaustive; the functionality that can be built into a bioconjugate by connecting two or more molecules

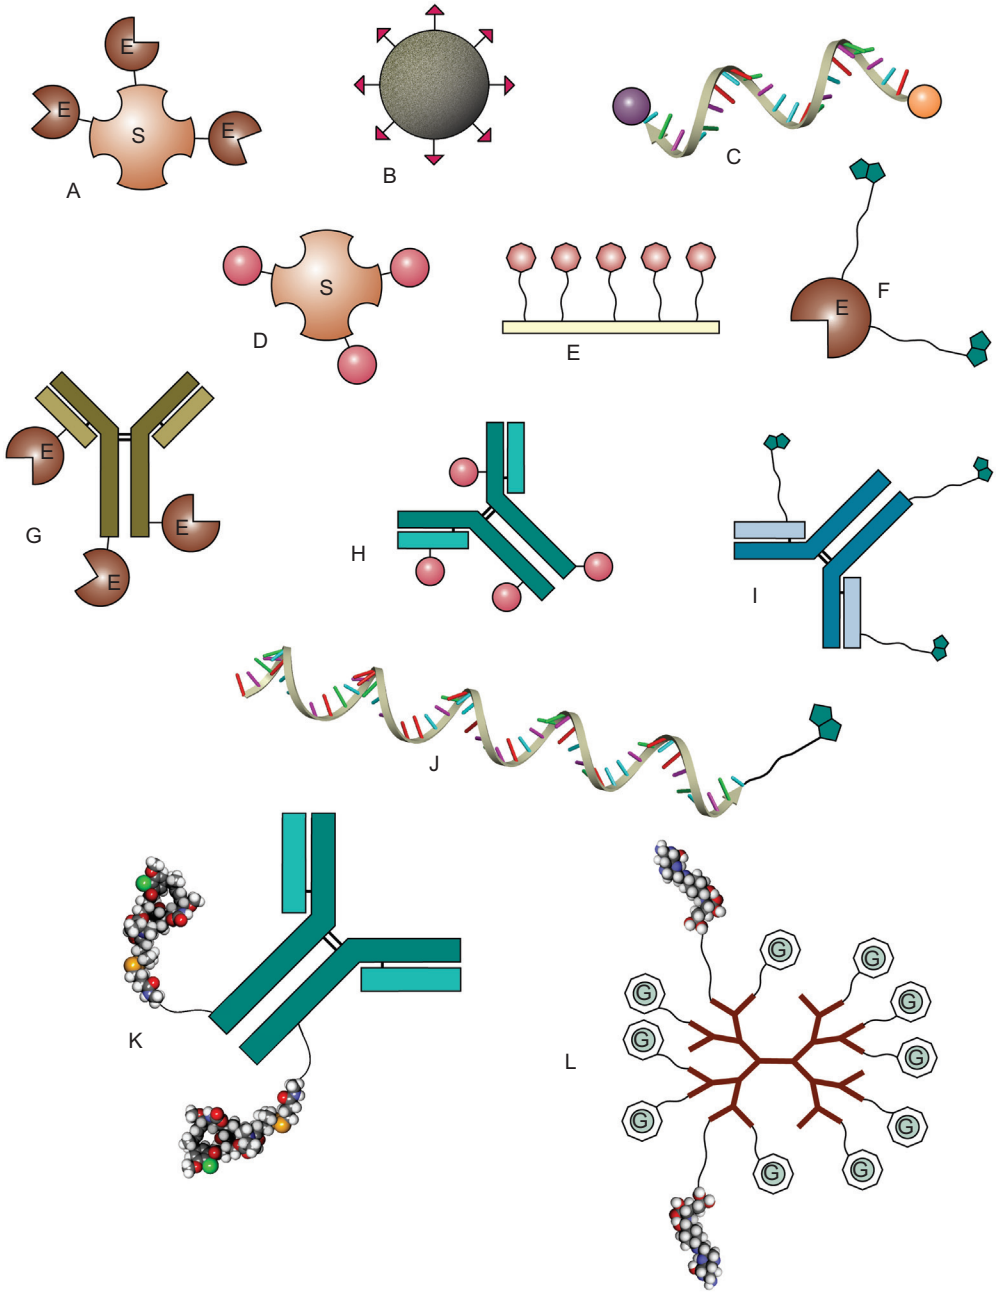

FIGURE 1.2 Some of the common bioconjugate designs often used for life science applications include (A) streptavidin–enzyme conjugate, (B) an immobilized affinity ligand on a particle, (C) an oligo molecular beacon probe containing two fluorescent labels or a fluor and a quencher at each end, (D) fluorescently labeled streptavidin, (E) an affinity ligand attached to a surface, (F) a biotinylated enzyme, (G) an antibody–enzyme conjugate, (H) a fluorescently labeled antibody, (I) a biotinylated antibody, (J) a biotinylated oligo probe, (K) an antibody–drug conjugate, (L) a gadolinium chelate-modified dendrimer containing folate molecules for targeting.

together is limited only by the imagination and the individual components available to assemble it.

The process of creating bioconjugates is typically carried out using reactive crosslinking agents that have been specially designed for this purpose or through the use of an appropriate reactive group on one of the molecules to facilitate the conjugation. The coupling reaction can also be accomplished using secondary activating agents that create an intermediate reactive group on one of the components to be conjugated. Most of the reactive groups used for this process can then be made to couple with specific functional groups on one or more of the molecules to be conjugated, thus linking them together into the final complex. Figure 1.3

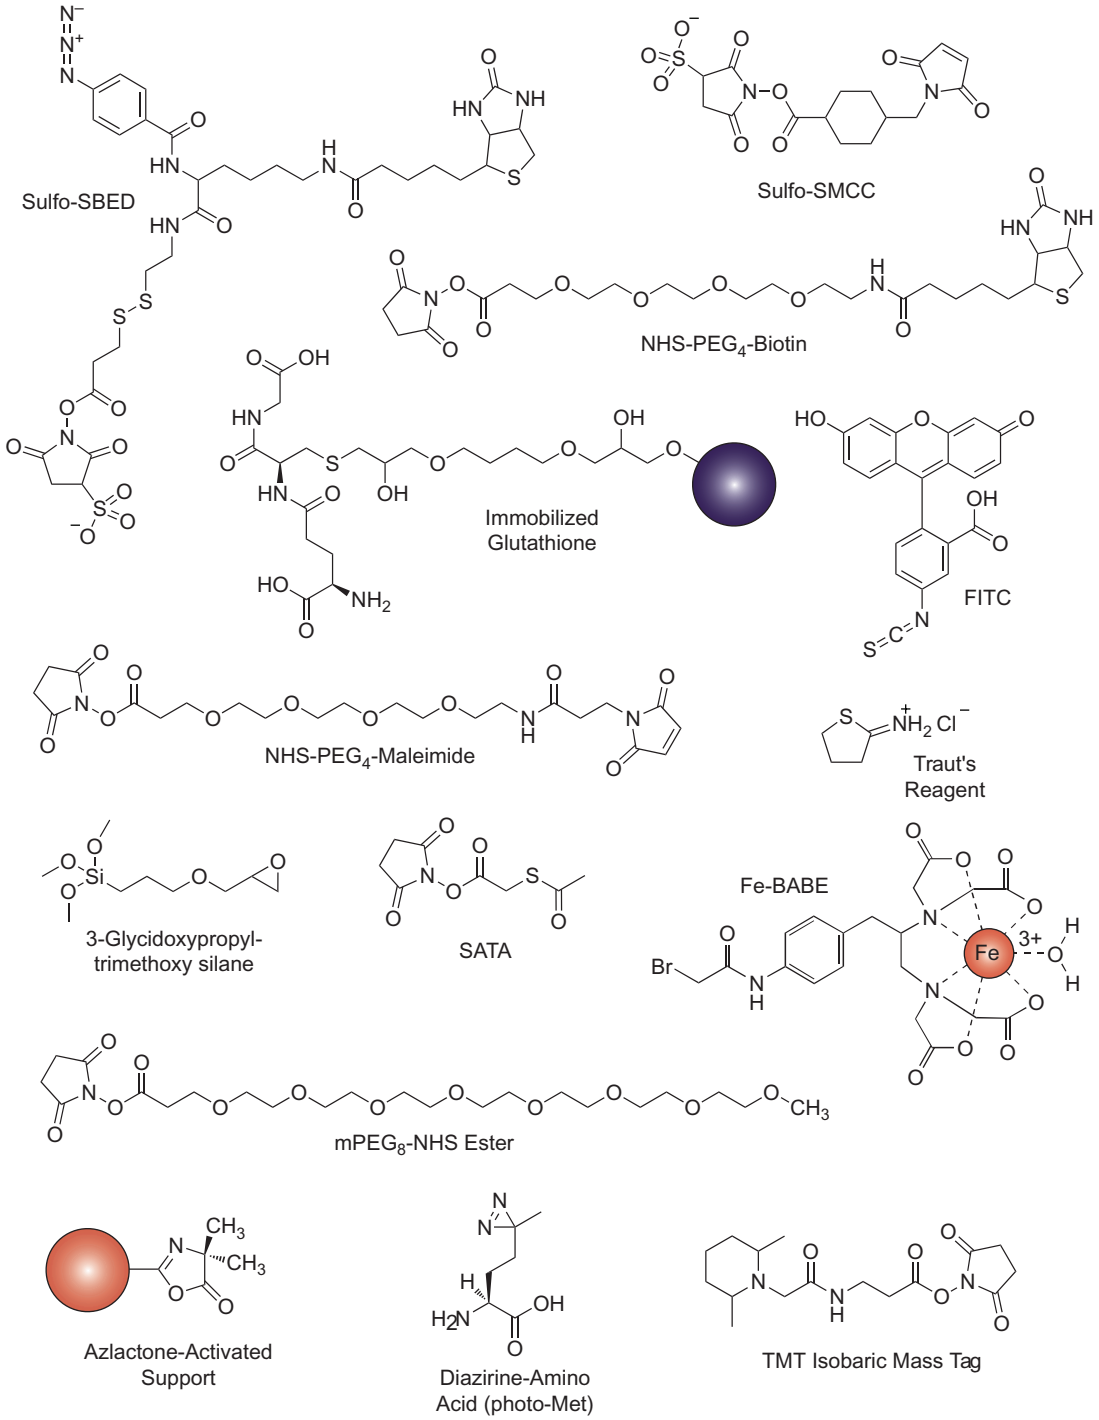

FIGURE 1.3 A selection of common bioconjugate reagents used to modify, label, or crosslink biomolecules.

illustrates some of the major types of reagents used for bioconjugation techniques. These are just a few of the tremendous number of reactive compounds that are available today for modification or conjugation purposes. Many other specific examples of bioconjugation reagents can be found throughout this book.

The reactions commonly utilized to form bioconjugates can be selected from perhaps 1 to 2 dozen principal reactive groups that are commonly used for creating covalent bonds with various functional groups on biomolecules. Of these dozens of choices for reactions, probably less than 10 are used routinely to effect the conjugation of the overwhelming majority of bioconjugates created. The reader will notice that throughout this book time and again the same basic reactions and reagents are used to form diverse conjugates that are useful in a broad range of applications.

The key to forming a successful bioconjugate is to select the proper crosslinking reagents that in turn contain the appropriate reactive groups, which will couple with the chemical functionalities available on the molecules to be linked together. In a sense, it is like choosing the right building blocks needed to construct the final structure of a molecular assembly. Just like a square peg that will not fit into a round hole, improper choice of crosslinkers or reactive groups will not yield the desired bioconjugate or may result in a suboptimal one. Therefore, a basic understanding of the reactions of bioconjugation is essential to understanding how to build a useful conjugate for a particular application. This is not to say one has to become an expert at synthetic organic chemistry to make a successful bioconjugate; rather, one only needs to gain enough knowledge to make the right reagent choices. Matching the correct crosslinking agents or reactive groups with the accessible functional groups on the components to be conjugated is the first step to building a successful and active bioconjugate complex.

Thus, bioconjugates can be constructed by the judicious coupling of two or more individual components to create a multifunctional complex having two or more properties combined into a single macromolecule. The conjugate may contain one or more affinity molecules, which can be used to target, capture, or detect another biomolecule; it may also contain one or more detection molecules or enzymes, toxins, drugs, or other components having some other specific activity or purpose. In addition, some bioconjugates are made using supplementary molecular scaffolds that may not be an active component of the bioconjugate, but are nevertheless important in constructing the final complex. Just like girders in a building, a molecular scaffold can be used to construct the bioconjugate by providing the core structure and attachment points for linking additional molecules into the overall assemblage of parts (Figure 1.4). The scaffold may also allow more copies of a certain molecule to be coupled and therefore become more actively present in the final conjugate than would be possible without its use. Multivalent scaffolds in particular might provide greater numbers of attachment points for coupling detection molecules, thus potentially increasing the detection sensitivity of a bioconjugate in an assay. Therefore, a given bioconjugate might contain components directly linked together to form a complex or it can be made with intermediary molecules which do not have functional activity in the final reagent, but nevertheless contribute to its properties as a whole.

In addition, bioconjugates can be designed to contain small molecule affinity ligands that specifically interact with other proteins, and these proteins in turn can function as scaffolds for increasing conjugate functionality through noncovalent interactions. For instance, biotin can be attached to one molecule and used as an affinity handle to interact with (strept)avidin reagents. The interaction between biotin and (strept)avidin is extremely strong (Chapter 11), and this permits highly specific interactions to occur with the biotinylated conjugate. For instance, forming a bioconjugate by attaching a biotin label to an antibody permits detection of a targeted protein through use of a second bioconjugate, such as a fluorescently labeled (strept)avidin complex. A biotinylated bioconjugate can also be captured and purified from a complex sample solution using an immobilized (strept)avidin particle or resin.

The intermediary use of a biotin–(strept)avidin complex in assays provides another type of bioconjugate scaffold for increasing assay or detection sensitivity. A biotinylated antibody is often used to target an analyte, while a secondary detection conjugate formed using (strept)avidin linked to another detection molecule provides the signaling agent. The docking of the (strept) avidin conjugate onto the biotinylated antibody carries with it more detection molecules than could be coupled to the antibody directly. The use of two conjugates in this assay design therefore provides increased sensitivity beyond that possible using a single antibody-detection conjugate alone.

The differences in function and use between a directly labeled antibody-detection conjugate *versus* a biotinylated antibody plus a secondary labeled (strept)avidin conjugate reflect the fact that the function of a given bioconjugate is usually determined by the individual constituent properties making up the whole. In this sense, a fluorescently labeled antibody can be used and detected directly, while a biotinylated antibody has to be used with another bioconjugate, such as a fluorescently labeled (strept)avidin molecule, to provide the same type of detection capability as the direct bioconjugate (Figure 1.5).

The combined properties of a given bioconjugate—all its various components linked together—thus

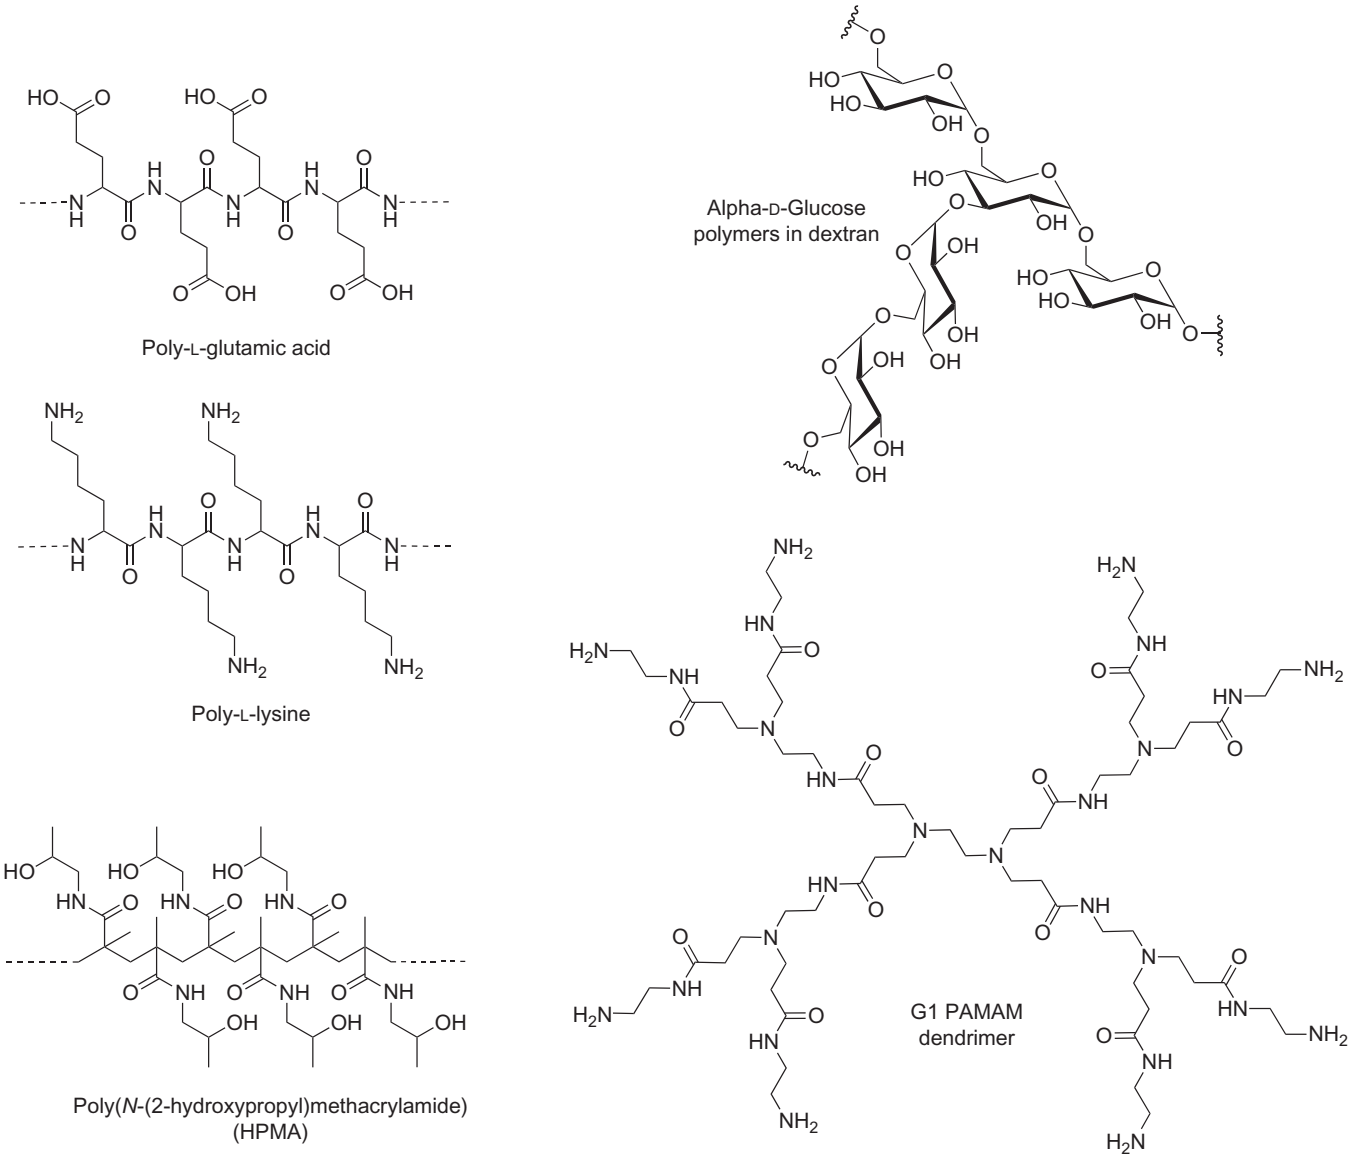

FIGURE 1.4 Polymeric molecular scaffolds often used in bioconjugate design to carry targeting molecules, detection components, or biotherapeutic agents.

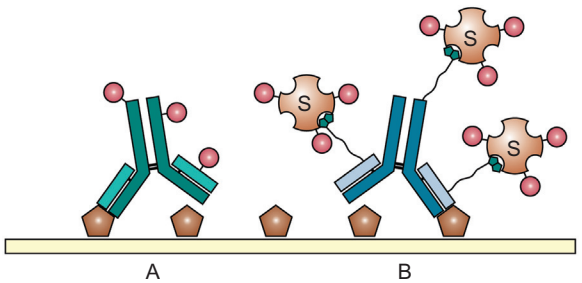

FIGURE 1.5 Comparison of the use of a fluorescently labeled antibody *versus* a biotinylated antibody used with a fluorescently labeled streptavidin conjugate. The multi-layered effect of the streptavidin–biotin interaction provides additional detection molecules able to dock at the site of a target molecule, thus providing potentially higher sensitivity in assays.

govern the properties, applications, and methods for its use. Designing a useful bioconjugate entails envisioning the preferred characteristics and methods of use for the final complex and then choosing the best components and reaction strategies to produce the desired product or products. On the surface, it may seem that the use of a fluorescently labeled antibody produces a simpler and thus a better conjugate than the use of a biotinylated antibody combined with a fluorescently labeled (strept) avidin complex, because a single conjugate is easier to make and use. However, that straightforward conclusion does not tell the whole story. The biotinylated antibody can have multiple biotins on its surface which permit the docking of multiple (strept)avidin molecules on each antibody. If each (strept)avidin molecule also

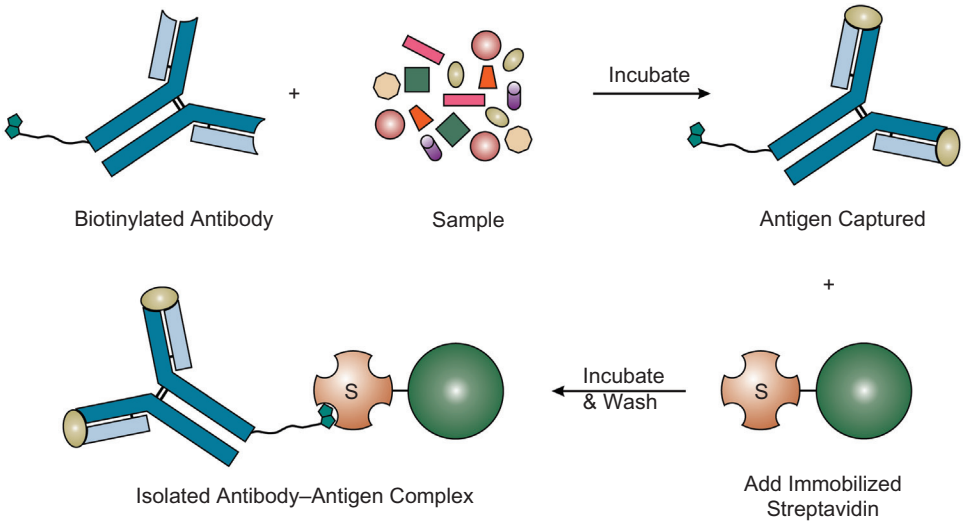

FIGURE 1.6 Immobilized streptavidin used to isolate a biotinylated antibody–target protein complex by immunoprecipitation (IP). A primary labeled antibody is allowed to incubate with a sample containing proteins and the antibody binds to its target. The biotin affinity tag facilitates isolation of this complex by binding to the immobilized streptavidin on an insoluble particle.

contains multiple fluorescent labels, then the resultant complex can possess many more fluorescent molecules than a directly labeled antibody can have attached to it. Therefore, when used in an assay to detect a target molecule, the biotinylated antibody combined with a fluorescently labeled (strept)avidin conjugate can result in much higher fluorescence signals than the fluorescently labeled antibody alone. Multi-layered conjugate complexes often result in greater numbers of molecules being assembled at the site of a targeted analyte, thus recruiting greater conjugate activity at that site as well.

In addition, some bioconjugates like a biotin-modified antibody can have multiple uses. Not only can a biotinylated antibody be used in an assay or detection process but it can also be used to bind to a target protein in a cell lysate and then isolate the target by use of an immobilized (strept)avidin affinity support (Figure 1.6). Thus, the preparation of a single bioconjugate consisting of a biotin-modified antibody can have multiple uses due to the combined properties of its constituent parts. It is clear that envisioning how a bioconjugate ultimately will be used is essential in choosing the optimal bioconjugate to make. The next section will explore this aspect in greater detail.

2. BIOCONJUGATION STRATEGY AND DESIGN

The strategies used to develop bioconjugates for particular applications can be as highly varied as the reactions and components that are used to form such complexes. Bioconjugates can be used in a multitude of applications and in each case the particular bioconjugate that performs best is a result of careful design and is often meticulously optimized for its intended use (see Section 3, this chapter). Each component of the bioconjugate should be considered as being an active part of the entire reagent. Every element has a role to perform that is essential to the functioning of the bioconjugate in its intended application. If any one part performs poorly then the activity or specificity of the entire conjugate is also likely to suffer. For this reason, it is essential to optimize each bioconjugate with its application in mind. This section provides some general guidelines to the design of bioconjugates along with some strategies for choosing the right components and reactions to form the final complex. Reference will also be made to the appropriate chapters within the book for further information regarding functional groups that can be used as well as the conjugation reagents, scaffolds, targeting agents, detection components, polymers, particles, antibodies, and any other molecules that may be incorporated into the final bioconjugation reagent. In addition, it is recommended that the Table of Contents and the Index be consulted to cross-reference the appropriate pages that best relate to the type of bioconjugate being designed and the reactions used to produce it. This section then leads into an extensive review of bioconjugation, especially highlighting how it has been used to create reagents that have become essential to countless fields in science and technology.

2.1. Start with the Application in Mind

The ultimate use of a bioconjugate should be carefully considered in order to properly design its components to be appropriate to the envisioned task they must perform. In addition, the conditions under which the bioconjugates are to be used should be taken into

account, because certain components might not perform well in the anticipated medium or environment. For this reason, it is important that when beginning to design any bioconjugate its ultimate application must first be considered before initiating any experimental procedures to actually make the conjugate. If the bioconjugate is to be used in an assay for example, the most appropriate components might consist of a targeting molecule coupled to a detection element, so that the final complex can bind and interact with its target and then be detected. Alternatively, if the final bioconjugate is to be used in the purification of a target molecule, an appropriate conjugate might consist of an insoluble support or particle to which an affinity ligand is attached. Therefore, each bioconjugate application may have radically different conjugate construction requirements.

The design of a new bioconjugate for a unique application might best be explored by first considering the bioconjugates that others have used in similar applications. Section 3 of this chapter should therefore be carefully reviewed as a guide to the bioconjugate types that have been used successfully for published applications. In addition, the entire history of bioconjugation may be consulted through the literature to determine the scope of bioconjugate designs useful in different types of situations. Table 1.1 lists some of the major applications of bioconjugation along with the conjugate styles that have been applied to work with them. This table is not meant to be exhaustive in its presentation of every conjugate that has ever been reported, but only to provide major examples, which can be used as a starting point for the development of new bioconjugates. Since the component options in designing a bioconjugate are vast and the reactions that can be used in producing it are many, the options available in creating a new conjugate can be almost daunting. For this reason, it is extremely useful to gain knowledge of the bioconjugate types and construction details that others have used successfully in similar situations before embarking on a new design. Even with this knowledge, however, it is likely that for a new application, the bioconjugation construction methods will still have to be optimized to work well in the intended application.

For instance, the design of a fluorescently labeled antibody may appear to be quite trivial on the surface, especially with so many years of history in the literature involving the fluorescent modification of antibodies. To prepare this type of conjugate, it seems to be merely a matter of coupling a reactive fluorescent molecule with the desired purified antibody. Using known reaction protocols, such as those described in Chapter 10, one can obtain a labeled antibody that could be used to detect a target molecule. Upon closer inspection, however, the process for creating this conjugate is much more complex. Unless you have experience with similar conjugations using exactly the same fluorescent label that you want to use again, the first variable in the process is to choose an appropriate reactive dye. The choice may be governed by the wavelength of excitation and emission or it may be determined by the general wavelength region that is required for successful use in the desired application. For *in vivo* imaging applications, for instance, the antibody should be labeled with a fluorescent dye that has spectral properties in the far-red to near-infrared (NIR) region of the spectrum, whereas for general cell staining applications the dye could have emission properties anywhere from the UV to the NIR region, which also covers all of the visible wavelengths. Another set of criteria for dye selection in making this type of conjugate is limitations that may exist related to the instrument used for fluorescence detection. For instance, if there is access to a fluorescent microscope with filter sets already available for dyes in the fluorescein (488), Cy3, and Cy5 wavelength ranges, then it would be appropriate to make the antibody conjugate using dyes that correlate with these wavelengths.

In addition, fluorescent dyes may be chosen for antibody conjugation based on their relative hydrophobicity or hydrophilicity. In certain applications, it is far better to choose a dye that is more hydrophilic to prevent antibody aggregation or to reduce the potential for nonspecific binding of the conjugate in an assay. Most dyes have highly hydrophobic, aromatic core structures that can interact nonspecifically with many hydrophobic regions on biomolecules or interact with surfaces used in assay procedures. The use of hydrophilic dyes containing negatively charged sulfonates or neutral PEG chain modifications can dramatically reduce nonspecific binding and enhance assay signal-to-noise ratios. Conversely, the use of dyes with somewhat less water solubility may be appropriate if the antibody conjugate is to be used for *in vivo* imaging or cell-based imaging where efficient penetration of membrane structures is required to reach a desired target. In this case, the use of dyes containing fewer sulfonates (e.g., perhaps no more than two to three negative charges on a large cyanine-type dye) can perform better in the intended application than dyes containing more hydrophilic groups or a greater number of charges. Thus, the performance of the conjugate in its intended application often dictates the best choice of fluorescent dye derivative to use in the conjugate design. Testing of several potential choices to optimize the performance of a dye–antibody conjugate should be carried out in order to obtain the best possible result.

Another important consideration when making a conjugate is the relative ratio of each component in the final complex. In the dye-labeled antibody example, typically it is important to have more than one dye modification on each antibody molecule. This has the effect of increasing the fluorescence intensity of each antibody as

TABLE 1.1 **Bioconjugate Components and Designs Used for Major Applications**

Application	Bioconjugate Components	Bioconjugate Reagents	Bioconjugate Designs
Enzyme Immunoassays	Antibodies; enzymes; scaffolds; biotin; streptavidin; particles; microwells; planar surfaces; antigens; affinity ligands	Heterobifunctional aliphatic crosslinkers; heterobifunctional PEG-based crosslinkers; multifunctional scaffolds; zero length crosslinkers; homobifunctional crosslinkers; thiolation reagents; biotinylation reagents; activated particles, microwells, or surfaces	Antibody–enzyme; biotinylated antibody plus streptavidin–enzyme; biotinylated antibody, biotinylated enzyme, plus streptavidin; antibody–particle or antibody–surface for capture; antibody–polymer–enzyme; streptavidin—polymer–enzyme plus biotinylated antibody; immobilized antigens or affinity ligands
Fluorescent Immunoassays	Fluorescent dyes; antibodies; scaffolds; biotin; streptavidin; phycobiliproteins or tandem dyes; lanthanide chelates; quantum dots; particles; microwells; planar surfaces	Reactive fluorescent dyes; multifunctional scaffolds; reactive phycobiliproteins or reactive tandem dyes; bifunctional lanthanide chelators; activated particles, microwells, or surfaces; heterobifunctional crosslinkers; PEG-based crosslinkers; zero length crosslinkers	Antibody–dye; biotinylated antibody plus streptavidin–dye; antibody–phycobiliprotein; streptavidin–phycobiliprotein; antibody–lanthanide chelate fluor; antibody–quantum dot; antibody–dye-doped-particle; antibody–tandem dye; streptavidin–quantum dot; streptavidin–tandem dye; quencher–fluor–oligonucleotide molecular beacon; quencher–fluor–peptide molecular beacon; inhibitor–dye; antibody–polymer dye; antibody–particle or antibody–surface for capture
Chemiluminescent Immunoassays	Acridinium esters; antibodies; streptavidin; biotin; particles; microwells; planar surfaces	Reactive acridinium ester compounds; biotinylation reagents; activated particles, microwells, or surfaces	Antibody–acridinium ester; biotinylated antibody plus streptavidin–acridinium ester; antibody–particle or antibody–surface for capture
Hybridization Assays, including FISH	Fluorescent dyes; synthetic or genomic oligonucleotide probes; enzymes; biotin; streptavidin; particles; microwells; planar surfaces; digoxigenin (DIG); haptens	Reactive fluorescent dyes; modified or activated oligo probes; activated particles, microwells, or surfaces; biotinylation reagents; DIG-11-dUTP	Oligonucleotide–dye; hapten–labeled oligo; biotinylated oligo; quencher-dye–labeled oligo for molecular beacon; oligo–particle or oligo–surface for capture; reactive oligo probe
ChIP Assays	Oligonucleotide probes; particles; microwells; planar surfaces; zero length crosslinkers; antibodies	Functionalized oligo probes; activated particles, microwells, or surfaces; crosslinking agents	Oligonucleotide–biotin; oligo–particle or oligo–surface for capture; Antibody–enzyme; antibody–dye; streptavidin–enzyme; streptavidin–dye; biotinylated antibody; oligo–particle or oligo–surface for capture
IP and Co-IP Assays	Antibodies; interacting prey protein; particles; microwells; planar surfaces	Activated particles, microwells, or surfaces; crosslinking agents; biotinylation agents	Antibody–particle or antibody–surface for capture; biotinylated antibody; streptavidin–particle or streptavidin–surface for capture
Cellular Imaging and *in vivo* Imaging	Antibodies; enzymes; fluorescent dyes; biotin modifications; streptavidin; nanoparticles; oligonucleotides; peptides; fluorescent proteins; bioluminescent enzymes; split enzymes or fluorescent proteins	Heterobifunctional aliphatic crosslinkers; heterobifunctional PEG-based crosslinkers; multifunctional scaffolds; zero length crosslinkers; homobifunctional crosslinkers; thiolation reagents; biotinylation reagents; activated particles; reactive fluorescent dyes	Antibody–enzyme; biotinylated antibody; antibody–dye; streptavidin–dye; fluorescent active site warhead probes; molecular beacon fluor–peptide–quencher or fluor–oligo–quencher probes
Flow Cytometry	Antibodies; fluorescent dyes; phycobiliproteins; tandem dyes; streptavidin; biotin; quantum dots; nanoparticles; magnetic particles	Heterobifunctional aliphatic crosslinkers; heterobifunctional PEG-based crosslinkers; multifunctional scaffolds; zero length crosslinkers; homobifunctional crosslinkers; thiolation reagents; biotinylation reagents; activated particles; reactive fluorescent dyes	Antibody–dye; biotin–antibody; antibody–phycobiliprotein; streptavidin–dye; streptavidin –phycobiliprotein; antibody–tandem dye; streptavidin–tandem dye; antibody–quantum dot; antibody–magnetic particle; antibody–nanoparticle

Immunohistochemical Staining	Antibodies; enzymes; scaffolds; biotin modifications; streptavidin; fluorescent dyes; nanoparticles; colloidal gold; quantum dots	Heterobifunctional aliphatic crosslinkers; heterobifunctional PEG-based crosslinkers; multifunctional scaffolds; zero length crosslinkers; homobifunctional crosslinkers; thiolation reagents; biotinylation reagents; activated particles; reactive fluorescent dyes	Antibody–enzyme; biotinylated antibody; antibody–dye; streptavidin–dye; streptavidin–enzyme; antibody–gold; antibody–quantum dot
Homogeneous Protein Assays	Antibodies; fluorescent dyes; fluorescent proteins; quenchers; bioluminescent enzymes; split reporter enzymes; split fluorescent proteins; lanthanide chelates; phycobiliproteins; oligonucleotide probes	Reactive fluorescent dyes; reactive lanthanide chelates; reactive phycobiliproteins; reactive oligo probes	Antibody–dye; antibody–lanthanide chelate; fluor–peptide–quencher; fluor–peptide–fluor; antibody–phycobiliprotein; antibody–oligo
Homogeneous DNA Assays	Oligonucleotide probes; fluorescent dyes; quenchers; polymerase and other enzymes; minor groove binding dyes	Modified oligos; reactive fluorescent dyes; reactive quenchers	Dye–oligo–quencher; dye–oligo–dye; dye–primers
Vaccines and Immunogens	Carrier proteins; haptens; antigens; peptides; carbohydrates; protein fragments; synthetic scaffolds	Heterobifunctional aliphatic crosslinkers; heterobifunctional PEG-based crosslinkers; multifunctional scaffolds; zero length crosslinkers; homobifunctional crosslinkers; thiolation reagents	Crosslinked proteins; carrier–peptide; carrier–carbohydrate; carrier–hapten; crosslinked viral particles; carrier-–protein fragments or domains; polymerized antigens
Tumor Targeting	Antibody or antibody fragment; alternative targeting scaffolds; polymers; dendrimers; chemotherapeutic drugs; toxins; enzymes; prodrugs; haptens or ligands	Heterobifunctional aliphatic crosslinkers; heterobifunctional PEG-based crosslinkers; PEGylation agents; multifunctional scaffolds; zero length crosslinkers; homobifunctional crosslinkers; thiolation reagents; spacer arms	Antibody–drug; antibody–enzyme; antibody–polymer–drugs; antibody–polymer–dye–drug; hapten–drug; ligand–drug
Catalytic Transformations	Enzymes; particles; resins; biotin; streptavidin; chemical reactants	Reactive particles; reactive resins; activation agents; crosslinkers	Enzyme–particle; enzyme–resin; biotin–enzyme; streptavidin–resin; reactant–particle
Affinity purification	Beaded porous supports (resins); nonporous particles (microparticles or nanoparticles); membranes; monoliths; surfaces; antibodies; proteins; peptides; small molecule affinity ligands; metal chelates; carbohydrates; organic mimetic ligands	Activation agents; spacer arms; crosslinkers	Primary affinity ligand coupled to a bead, particle, surface, membrane, or monolith; immobilized streptavidin to immobilize biotinylated affinity ligands; protein A or protein G coupled to a support to immobilize antibodies

it is docked upon its intended target. Each fluorophore adds another potential photon emission to each conjugate molecule. However, having more dyes modifying an antibody is not always better than fewer dyes. At a certain substitution level the fluorescent dyes may cause aggregation of the antibody or start to quench the potential fluorescence output due to dye–dye interactions and energy transfer instead of emission. For a given antibody–dye complex there is a certain level of dye substitution that will provide maximal signal in an assay without the potential for precipitation or quenching. That optimal conjugate can only be determined through experimentation by making a number of trial dye–antibody conjugates in small amounts so that each preparation has a slightly different dye substitution level. Testing each of the conjugates for their fluorescence intensity, solution stability, and assay performance will determine which one is best for the intended application.

2.2. Designing the Optimal Bioconjugate

One of the most important aspects in the successful formation of a bioconjugate involves having sufficient knowledge of the structural, chemical, and activity characteristics of the components to be bound together. To design a linking strategy that will form the final complex while still maintaining all the functions of its individual parts is not a trivial matter. A successful process not only involves knowledge of the reactive groups, reagent types, and functional groups present on the biomolecules but also includes an understanding of how modification of a biomolecule can potentially affect its activity. Using current knowledge of protein three-dimensional structure and function, including active site constituents and stability considerations, the reaction strategies for bioconjugation can be designed to maximize the potential activity and function of the final conjugate. With this information, functional groups near binding sites or active centers can often be avoided through careful selection of the proper crosslinking agents or reaction conditions. In some cases, unique functional groups (e.g., bioorthoganol; see Chapter 17) or a functional group with a limited frequency of appearance on a biomolecule (e.g., cysteine thiol groups) can be chosen for conjugations that position the modifications or crosslinks away from the active centers or binding sites, thus helping to preserve activity in the final bioconjugate.

As the technology of bioconjugation advances, certain types of conjugates that have been used for years may be redesigned with newer techniques to provide better functionality. For instance, one of the earliest bioconjugate types consisted of radiolabeled complexes formed by attaching a radioactive atom to a biomolecule. Radioiodination involves the covalent modification of certain organic groups within a molecule with a radioactive iodine-125 atom (or another radiolabel) to form a detectable complex, such as in the modification of tyrosine or histidine residues within proteins or activated aromatic rings within small molecules (Chapter 12). Many antibodies were initially labeled in this way to provide the combination of specific antigen binding with radioactive detection. These early bioconjugates were used in many research and diagnostic assays to detect and quantify target molecules. Beginning in the mid-1970s, however, with the advent of antibody–enzyme conjugates, these new detection complexes started to replace radiolabeled conjugates due to the stability and safety concerns of radioactive compounds and due to the increased performance and sensitivity of enzymatic detection. Radioactive bioconjugates are still used in many important applications, but the main focus for radiolabels now is not for *in vitro* research assays or diagnostic testing but rather for advanced *in vivo* therapeutic targeting and imaging of tumor cells.

The methods and reactions used to make bioconjugates have evolved over the years in more ways than one. Early methods of forming conjugates often involved the use of homobifunctional reactants that almost uncontrollably polymerized the components of the bioconjugate. An example of this type of reaction is the use of glutaraldehyde to form antibody–enzyme conjugates. Glutaraldehyde is an effective crosslinker, but the conjugate that is formed too frequently contains high-molecular-weight components and even partially precipitates due to the oligomerization of antibody and enzyme during the reaction (Figure 1.7). More advanced crosslinkers are now available to remedy this situation and provide more control in the reaction process. For this reason most antibody–enzyme conjugates are no longer made using glutaraldehyde. As the science of bioconjugate techniques progresses, new reagents and reactions continually provide additional options for producing better bioconjugates. Even familiar bioconjugates that have been prepared and applied in research for decades might be improved by redesigning the bioconjugation strategy originally used to make them.

The process of bioconjugation, under the most controlled and optimal conditions, can still result in a number of different structural species making up the final composition. When two components are reacted together and at least one of them has multiple sites for covalent attachment, such as on proteins which contain multiple amines, the resultant bioconjugate will likely have a distribution of molecular weights around an average mass. For instance, the process of modifying a protein using an amine-reactive biotinylation compound can yield an almost Gaussian distribution of the number of biotins coupled per protein, the mean of which is dependent on the molar excess of biotin reagent used over the quantity of protein added at

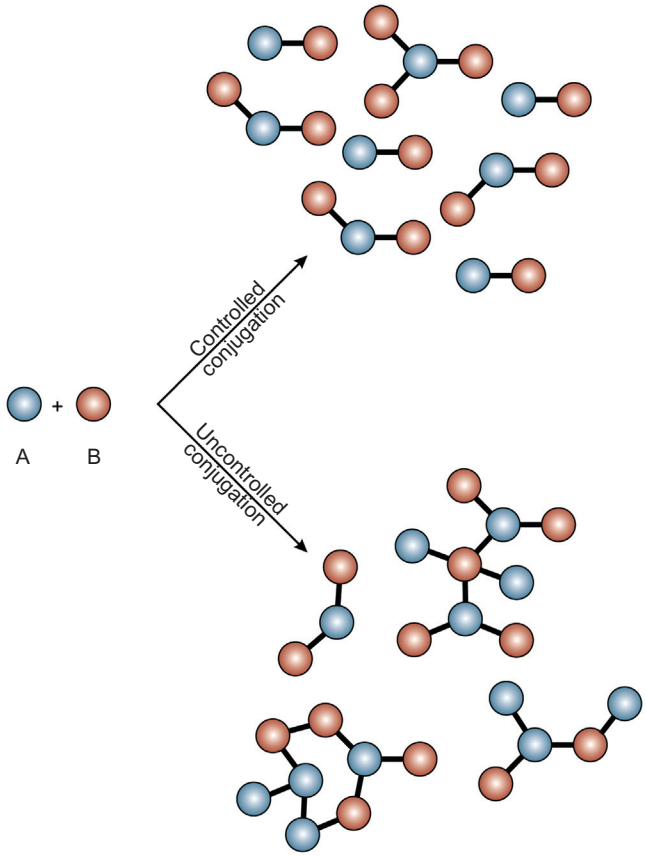

FIGURE 1.7 Oligomerized bioconjugation *versus* controlled bioconjugation. Uncontrolled conjugation can result in high-molecular-weight complexes being formed, which may aggregate or precipitate out of solution over time. Using methods of conjugate formation that limit the size of the resulting complex can enhance stability in solution and increase assay performance in certain applications.

the start of the reaction. For instance, if a 10-fold mole excess of NHS-PEG_4-biotin (Chapter 18) is added to an antibody, the final bioconjugate might have an average of perhaps seven biotins per antibody molecule, but there will also be species present in the population having a range of substitutions from perhaps three biotins to even 12 or more biotins per antibody, which on the high end even exceeds the amount of biotinylation reagent initially added (Adamczyk *et al*., 1996). There are at least two reasons for this phenomenon: (1) reaction yields are never 100% efficient (especially in this example with competing hydrolysis of the reactive NHS ester group on the biotinylation compound) and therefore some molecules will be more effectively modified than others; and (2) local concentration differences caused when the reaction components are first mixed together may result in some antibody molecules experiencing a higher molar excess of the biotinylation reagent than other antibody molecules experience once the solution is completely homogeneous. Even with such a large distribution of different degrees of biotinylation, if reaction conditions are used that carefully control the amount of modification, it will help to maximize the activity of the conjugate and make production of the final complex more reproducible.

Bioconjugates can also take on many different shapes or structures. The simplest form is a bifunctional conjugate created by reacting two different components together. However, occasionally bioconjugates are made from more than two components, forming trifunctional or even multi-functional complexes that have the combination of three or more distinct properties merged together. One molecule may provide targeting capability to bind to a particular biomolecule or cell constituent, while a second component may be a biopharmaceutical agent useful to treat a certain disease, and a third group might provide detection capability (Figure 1.8). Bioconjugates of this type have been formed using molecular scaffolds that have multiple functional groups, which can be used to link together the components of the final complex. For instance, a bioconjugate of this type could be constructed using a dendrimer polymer (Chapter 8) to link together an antibody, a chemotherapeutic drug, and a fluorescent molecule, which together provide tumor targeting, treatment, and fluorescence detection capability all built into the same complex. In addition, Zaman *et al*. (2006) used a dextran polymer to link the chemotherapeutic drug doxorubicin and the hepatocyte-targeting molecule galactosamine to create a multifunctional bioconjugate for the treatment of cancer.

The use of the proper molecular scaffold can also amplify the activity of one of the components of a bioconjugate. In this regard, a multivalent polymer or dendrimer can be used to couple numerous copies of a detection molecule or enzyme, while in addition attaching a small number of targeting molecules. This can result in a specific targeting complex with extremely sensitive detection capability. An example of this type of conjugate is a gadolinium-chelate dendrimer that can be used as a contrast agent *in vivo* using magnetic resonance imaging (MRI) (Bourne *et al*., 1996; Bryant *et al*., 1999). The ability to couple multiple copies of the gadolinium chelate to the dendrimer surface significantly enhances the signal beyond that typical of a directly labeled targeting molecule without the use of a scaffold. Attaching a targeting molecule to this modified dendrimer, such as folic acid which is taken up by tumor cells (Swanson *et al*., 2008), then provides specificity for imaging cancerous cells. Kojima *et al*. (2000) also used a similar dendrimer scaffold to attach poly(ethylene glycol) (PEG) grafts and noncovalently encapsulate the anti-cancer drug methotrexate for *in vivo* delivery.

Another important aspect of bioconjugate design is the type of linkage used to attach together the components of the conjugate. The linker strategy can

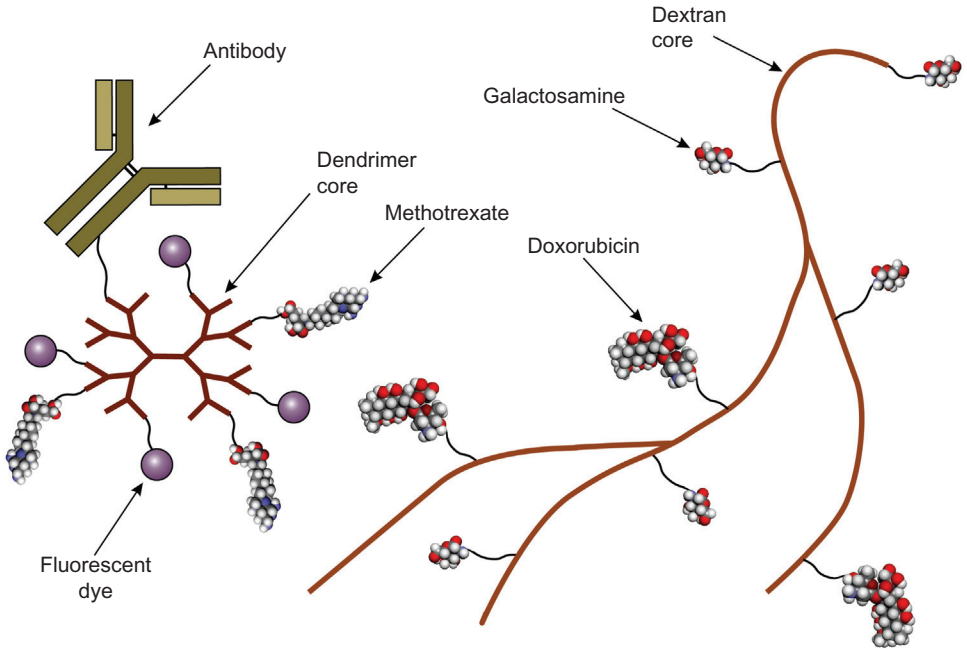

FIGURE 1.8 Examples of multifunctional bioconjugates including the use of molecular scaffolds, such as polymers and dendrimers. Left: A dendritic conjugate containing an antibody for targeting specific epitopes, a chemotherapeutic agent (methotrexate), and a fluorescent dye for imaging. Right: An illustration of a dextran conjugate containing galactosamine residues for targeting hepatocytes and the drug doxorubicin for antitumor activity. The polymeric scaffolds provide multiple sites for conjugation and thus allow more molecules to be attached per conjugate than direct crosslinking could provide.

incorporate multiple reactive groups as well as organic spacer molecules that separate the components and form bridges between the linked molecules in the bioconjugate. The properties of these linker arms can have significant effects on the properties of the final reagent. For instance, some crosslinkers contain hydrophobic spacers consisting of aliphatic or aromatic groups that may work well in forming a bioconjugate, but also might have detrimental effects on conjugate stability or nonspecificity in a given application. Conversely, some linking molecules are hydrophilic, such as PEG-based reagents, and actually increase the solubility of the final bioconjugate in aqueous solution. These property differences between hydrophobic and hydrophilic cross-bridges also apply to modification reagents, such as biotinylation compounds or thiolation reagents, which can affect the properties of intermediates as well as the final bioconjugates. Figure 1.9 illustrates some of the bioconjugation reagents that have similar purposes but differ in spacer arm hydrophilicity. For some applications, however, an extremely hydrophilic conjugate might not be appropriate if the bioconjugate is being designed to pass through cell membrane structures—in which case a more hydrophobic linker may actually perform better. Clearly, the design of every part of a bioconjugate can potentially affect its use and performance in specific applications. This is why there is an emphasis on optimization and testing of more than one bioconjugate design to determine the best possible construction for the desired application.

Even the length and construction of the cross-bridge between two components of a bioconjugate may significantly affect its overall properties. Especially when designing a biotherapeutic agent, the chemical construction of the linkage can have dramatic effects on its *in vivo* efficacy, sometimes in unexpected ways. For instance, Doronina *et al*. (2006, 2008) found that different two-amino acid linkers in the linking arm between an anti-tumor monoclonal antibody and the cytotoxic drug monomethylauristatin F had divergent effects on the toxicity and effectiveness of the bioconjugate. In this case, the construction of the cross-bridge also included a *p*-aminobenzylcarbamate group that was designed to be cleaved by intracellular proteases such as cathepsin B. The presence of this group in the linkage allowed the payload to be released inside the tumor cell, which enhanced its ability to cause cell death. Finally, the authors found that modification of a C-terminal amino acid residue on the drug either improved or impaired potency. Thus, depending on the application, the choice of linker construction should be carefully considered when designing a bioconjugate, including the reactive groups, hydrophilic *versus* hydrophobic cross-bridges, the possibility of incorporating cleavage sites, or the use of complex molecular scaffolds to link the components together. Chapters 9 and 15 discuss various cross-bridge options in greater detail, including the use of many different cleavage groups to release the components of the bioconjugate for specific purposes.

The construction of a bioconjugate using hydrophobic or hydrophilic crosslinkers can also have dramatic effects on reagent stability and nonspecificity, depending on the choice of reagent. Many conjugation schemes involve the modification of one protein with a crosslinker to provide secondary reactive groups and the modification of another protein to create the corresponding functional groups able to link with the

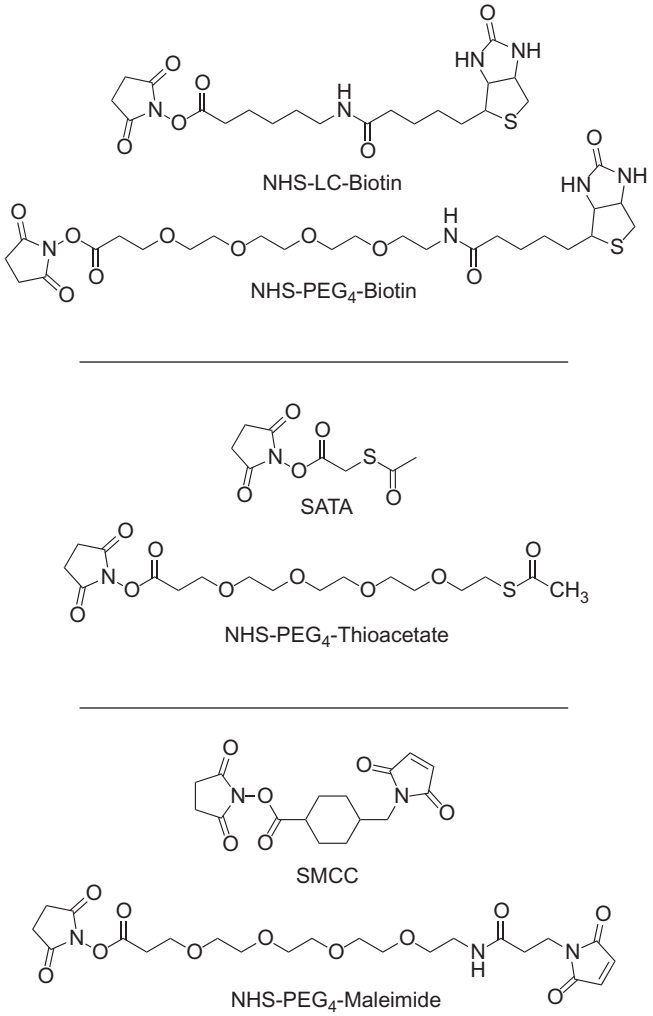

FIGURE 1.9 Hydrophobic *versus* hydrophilic crosslinker designs. Each reagent set provides similar reactivity on both ends, but the pairs of reagents differ by their water solubility and biocompatibility characteristics. Highly hydrophilic reagents such as those made from PEG spacers can offer benefits over aliphatic compounds in their ability to increase conjugate solubility and decrease nonspecific binding with biomolecules.

reactive groups on the first protein. If the initial reactions on the proteins use hydrophobic compounds with aliphatic or aromatic cross-bridges, then both proteins become decorated with these modifications. Such intermediates can contribute considerable hydrophobicity to the individual proteins even before the conjugate is created. Once the two modified proteins are mixed together and the conjugate is formed, the reactive groups or functional groups may be blocked at their ends, but the hydrophobic linker arms still protrude from the proteins. Since these initial modifications typically are done with reagents added in excess to form a multitude of linker arms spread across the protein surfaces, these modifications will still be present in the final bioconjugate. In addition, if every modification site does not result in a protein–protein conjugation event, then in the final complex both proteins will have "dead-end" modifications sticking off their surfaces. Every one of these remaining modification sites potentially can interact noncovalently with hydrophobic pockets on biomolecules (or with each other), thus creating tethers for possible nonspecific binding of the final complex.

These dead-end hydrophobic modification arms can also cause conjugate-to-conjugate interactions, which may result in larger noncovalent complex formation with significant potential for precipitation (Figure 1.10). Antibodies in particular are often succeptible to aggregation in solution even without additional hydrophobic linkers present on their surface. If hydrophobic modification or crosslinking agents are used to form an antibody conjugate, then the result may be to enhance antibody aggregation to the point of significantly lowered stability. Even a single modification reagent used to modify an antibody, such as performing a biotinylation reaction (Chapter 11), can cause immediate or long-term stability issues in aqueous solution. For example, a very popular choice in biotinylation reactions is the use of NHS-LC-biotin (Chapter 11, Section 6.2). This reagent has an extended aliphatic spacer arm between the amine-reactive NHS ester and the biotin group at the other end of the compound. In principle, a long spacer may seem advantageous for increasing the accessibility of a biotinylated antibody to bind with a streptavidin detection conjugate; however, the long aliphatic spacer arms actually cause more problems than advantages. If the biotinylation reagent is reacted in too high a molar excess, the antibody may suffer precipitation almost immediately due to hydrophobic interactions. Even if the biotinylation level is controlled to be at a lower level, the biotinylated antibody will usually slowly aggregate in solution over time through interactions between the biotin tethers on separate biotinylated antibody molecules as well as interactions of the tethers with hydrophobic pockets on the antibodies, thus causing continued activity loss.

By contrast, the use of a hydrophilic biotinylation compound, such as a NHS-PEG$_n$-biotin reagent (Chapter 18, Section 1.3), actually increases the hydrophilicity of a modified antibody after the reaction. Instead of promoting hydrophobic interactions and aggregation, an antibody having PEG-based biotin modifications on its surface becomes more stable in solution and has dramatically lowered nonspecific binding character. Therefore, if water solubility and low nonspecific binding to biomolecules are important criteria in a bioconjugate, it is better to explore the use of hydrophilic crosslinkers and modification reagents in the design strategy.

Another aspect of bioconjugate design to consider is the incorporation of modification agents that can

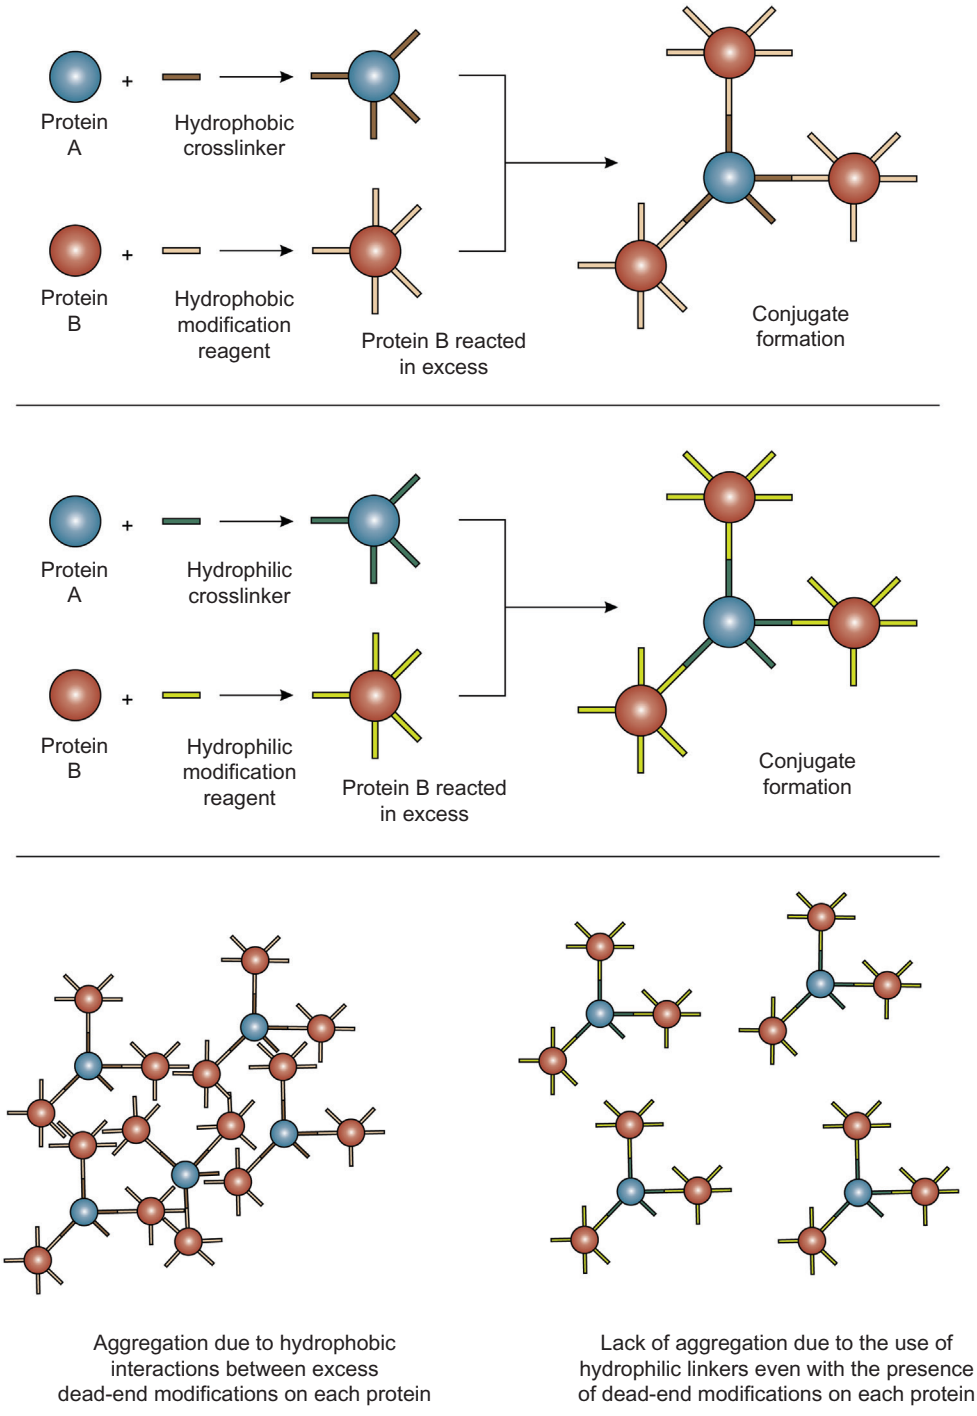

FIGURE 1.10 Conjugates made with hydrophobic reagents *versus* hydrophilic reagents and their propensity to aggregate or remain in solution. Each step in a conjugation process can add hydrophobicity or hydrophilicity to a conjugate. If two proteins are linked together by using crosslinking and modification agents, then their resultant water solubility and biocompatibility are greatly affected by the choice of reagent chosen. If hydrophobic, aliphatic linkers are used, both proteins in the conjugate will display these components on their surfaces, potentially affecting how they behave in solution. If hydrophilic reagents are chosen, such as PEG-based compounds, the molecules are linked by hydrophilic components and both proteins display these reagents on their surfaces. The presence of hydrophobic modifications on protein surfaces may cause aggregation or precipitation of the conjugates over time. It may also cause nonspecific binding characteristics toward molecules in biological samples.

positively affect reagent stability and half-life *in vivo*. One of the most important choices in this area is the use of polyethylene glycol (PEG) modifiers or crosslinkers (Chapter 18). Modification or "PEGylation" of an existing bioconjugate with linear or branched PEG molecules has been shown to enhance water solubility, increase the hydrodynamic volume of a bioconjugate, extend stability and half-life, and reduce immunogenicity and toxicity of drugs *in vivo* (Webster *et al*., 2007; Jevevar *et al*., 2010). PEG modification of bioconjugates can also dramatically improve water solubility and stability of reagents *in vitro*. The presence of PEG groups on a bioconjugate surface reduces nonspecific binding to other biomolecules, thus improving signal-to-noise ratios in assays and potentially enhancing detection sensitivity.

One of the most significant developments in PEG-based reagents in recent years is the new discrete molecules of defined polymer length. The early PEG compounds available for protein modification were all based on polydisperse polymer chain lengths in which a distribution of molecular weights was always present in a given reagent preparation. The discrete PEG compounds, by contrast, are based on pure molecular chain lengths, which provide defined reagents of known mass and properties. Discrete PEG-based crosslinkers and modification reagents are now available for creating bioconjugates of every type, and in most cases are better choices in forming conjugates than the corresponding aliphatic linkers. See Chapter 18 for a complete discussion of PEG reagents for modification and crosslinking, both of the polydisperse and discrete variety.

It should be apparent from this brief introduction that the choices involved in preparing bioconjugates are many, and particularly when designing new reagents, it often involves significant optimization to determine the ideal conjugation strategy from an initial concept that will give the best possible performance in an application. Even with experience, sometimes it is not clear from the outset what will be the ultimate bioconjugate design that will yield the best activity or efficacy. For this reason, it is important that a number of bioconjugate reagents and reactions be investigated—at least by initially putting together several options in theory—before deciding on a design strategy and route of synthesis. Especially when preparing bioconjugates for potential therapeutic or *in vivo* use, it is essential to thoroughly investigate the properties and performance of multiple conjugate designs before making conclusions as to the best construct for a given application. Even subtle changes in structure can have significant effects on bioconjugate performance when used for *in vivo* diagnostics or therapeutics.

Conversely, for the preparation of bioconjugates designed for more standard "tried and true" research detection methods or for use in research assays, the choices regarding the components to use and potential reaction strategies that will work are not as daunting as for those that are designed for clinical use. In fact, the rich history of bioconjugate design and applications can help guide the preparation of new conjugates that will work well for almost any intended use. The protocols provided in this book have worked to create bioconjugates of a wide variety of types. They provide viable starting points for the construction of almost any new bioconjugate designs using similar reaction strategies. In the end, however, the most viable bioconjugates are thoroughly optimized to perform best in their intended application and carefully produced to assure reproducible and robust reagents.

3. THE APPLICATIONS OF BIOCONJUGATES

Throughout this book, different bioconjugate types and strategies for making them are presented along with their principal applications for use. These applications generally can be grouped into the six major areas that are described in this section: (1) assay and quantification; (2) detection, tracking, and imaging; (3) purification, capture, and scavenging; (4) catalysis and chemical modification; (5) therapeutics and *in vivo* diagnostics; and (6) vaccines and immune modulation. It will be seen, however, that many conjugates successfully used in one application may also be applied to other areas; thus, many conjugate designs are not exclusive to a single application or method but can be used in diverse applications with equivalent success.

The following sections present an introduction to each of these application areas along with a discussion of the major bioconjugate designs that have been used for them. Each section also points the reader to the relevant chapters where additional information can be obtained on conjugate preparation and use.

3.1. Assay and Quantification

Perhaps the most prevalent use of bioconjugates is in the assay or quantification of target analytes, in which a substance to be measured is present in a complex sample mixture containing many other components. Designing an appropriate bioconjugate and assay strategy to measure such target molecules often involves first creating a two-component conjugate that consists of a specific targeting molecule attached through a covalent bond to a detection molecule. A targeting molecule can be anything that is able to discretely bind and interact with the desired target in the presence of other biological molecules. This can include antibodies, specific interacting proteins, peptides, nucleic acid sequences, substrate analogs, or other affinity ligands that exclusively bind to a

portion of the target molecule with high enough affinity to interact and stay bound under the assay conditions.

In the majority of assay applications, the targeting molecule of choice is an antibody or an antibody fragment with specificity for binding a discrete epitope on an analyte. It can also be any other biological or non-biological molecule with biospecific or chemical affinity toward the substance to be measured. Such affinity groups may include saccharides that can bind to certain lectin binding sites, metal chelates that have affinity for certain functional groups (such as His-tagged fusion proteins or phosphate groups on phosphorylated proteins), substrate analogs that are able to bind to the active site on enzymes, and organic ligands that have affinity for receptor binding sites on proteins. Examples of some of these affinity targeting molecules are shown in Figure 1.11.

However, it takes more than just a good affinity molecule to develop an assay. Most molecules with the requisite binding specificity for a target do not in and of themselves possess the needed detection characteristics for quantification. It usually takes a specialized detection molecule coupled to the targeting molecule to provide the resulting complex with sufficient detectability for measurement of the desired target. This is where bioconjugation comes into play.

Targeting molecules such as antibodies have been used for decades to form bioconjugates using detection molecules such as fluorescent labels, enzymes, and chemiluminescent compounds (Figure 1.12). An antibody bioconjugate having this type of detection component can form the basis for making powerful assay systems, which can measure almost any biological molecule in a complex mixture. The readout from these detector molecules typically involves taking a measurement using absorbance, fluorescence, or luminescence. Detection bioconjugates made from a targeting molecule coupled to an enzyme can be used to act on a substrate and convert it into a chromogenic (colored) product or a fluorescent product, or to create an excited intermediate that subsequently emits a photon of light as it decays back to its ground state. There actually are several forms of luminescence signals that can be used in assay designs. Luminescence can be a consequence of the chemical triggering of a chemiluminescent compound or enzymatic turnover of a substrate that generates chemiluminescent or bioluminescent light emission. Ultimately, all of these luminescent detection systems operate through a series of reactions to create an intermediate excited state that then emits light.

Bioconjugates Used in Heterogeneous Immunoassays

To quantify a target molecule using most detection bioconjugates, a separation step must first be performed to capture and isolate the target from all other molecules in the sample solution. Once separated, a detection bioconjugate can be used to measure the amount of target present. However, in order to capture the target, another bioconjugate is required, which consists of a second specific affinity ligand able to interact with the target, bind, and then isolate it from the rest of the sample molecules. This capture step has two important functions: it gets rid of the other non-relevant components of the sample and it enriches the target molecule to enhance the potential signal in an assay.

To make this separation step as simple and rapid as possible, the capture bioconjugate usually is comprised of the capture molecule covalently attached to an insoluble support matrix (Chapters 14 and 15). Immobilization of the appropriate affinity ligand onto an insoluble particle or surface creates a bioconjugate that can be easily separated from soluble molecules simply by washing the affinity support with buffer (Figure 1.13). Upon binding of the target to the immobilized capture molecule, the rest of the unwanted sample components can be separated and washed away, leaving only the bound target molecule. Subsequent application of a detection bioconjugate to this bound target molecule complex followed by another wash step to remove excess detection reagent thus provides the means for quantification. Finally, comparison of the signal obtained from the interaction of the detection bioconjugate with both an unknown amount of target from the sample and that of a similarly treated set of known concentration standards provides the means for an accurate measurement of the amount of target in the original sample.

In the majority of all quantitative measurements for biomolecules, at least two bioconjugates are used in a heterogeneous assay system to measure a particular target molecule. The exact format that the assay takes can be highly variable, depending on the materials available, the measurement instrumentation to be used, and whether a single target is to be measured or multiple targets are to be analyzed simultaneously (multiplexed analysis). Solid phases such as microplates, tubes, planer array surfaces, beaded chromatography supports, microparticles, nanoparticles, and membranes all have been employed to immobilize capture molecules to facilitate a separation step in an assay (Figure 1.14; see Chapters 14 and 15 for immobilization techniques). Such capture conjugates combined with the appropriate detection conjugate can create viable assays for nearly any target, including proteins, nucleic acids, other biological macromolecules, as well as a wide diversity of small organic molecules. The various types of capture and detection bioconjugates used in these assays are the most widely used reagents in life science research, and most scientists do not even think about how the bioconjugates are made when using them to run an assay. This is how common and transparent bioconjugation has become today when doing routine assay procedures.

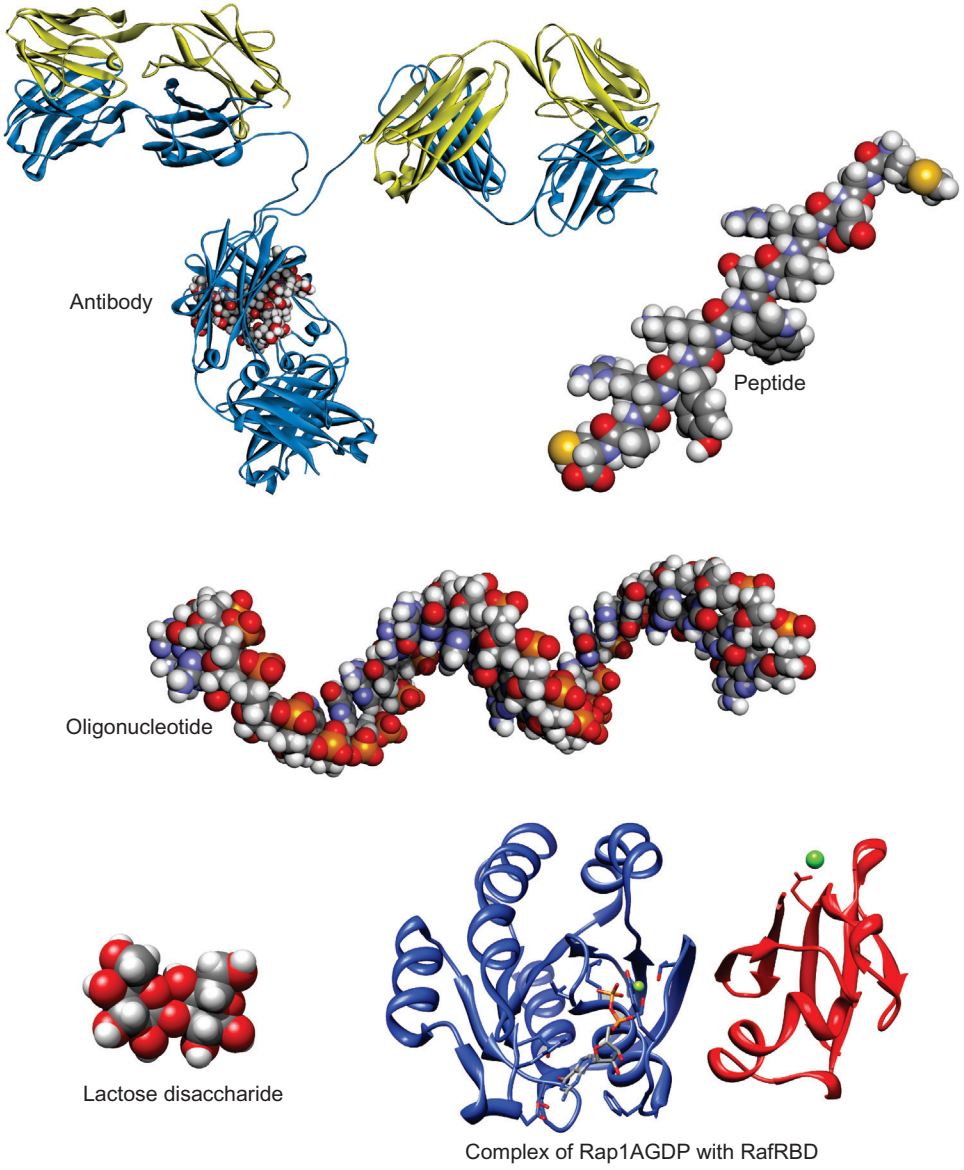

FIGURE 1.11 Affinity molecules commonly used to specifically bind to a target in an assay include the use of antibodies, peptides, oligonucleotides, saccharides or carbohydrates, and proteins that have specific interaction potential with other proteins or molecules. These targeting molecules are often used to form bioconjugates with detection molecules or other components have some specific activity desired in the final complex.

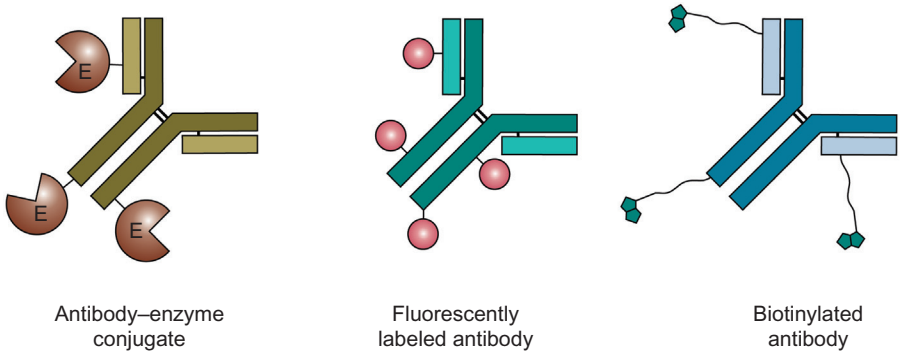

FIGURE 1.12 The most common antibody conjugates used in assays include (l to r) antibody–enzyme conjugates, fluorescently labeled antibodies, and biotinylated antibodies.

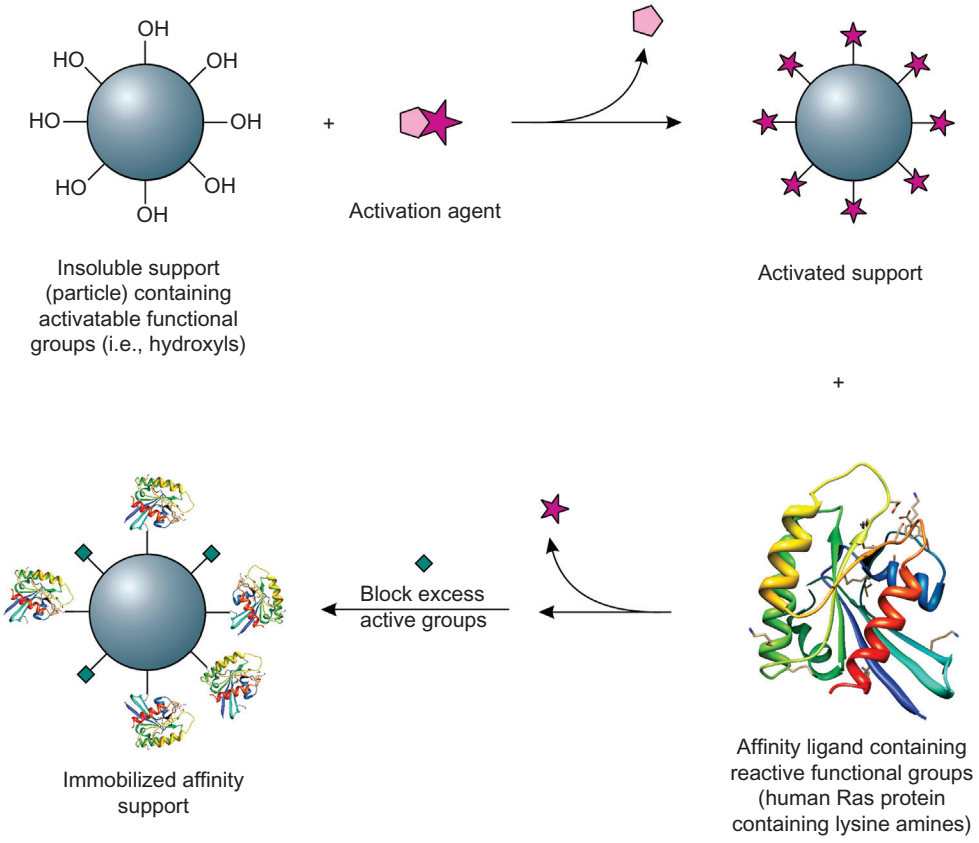

FIGURE 1.13 The immobilization of an affinity ligand onto insoluble supports typically involves activation of the support to create reactive groups and subsequent coupling of the ligand to form covalent bonds, thus linking it to the support.

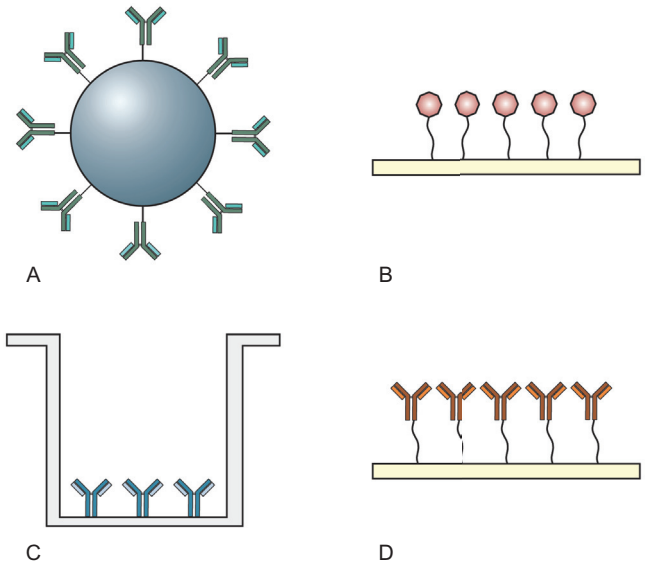

FIGURE 1.14 Some of the most common immobilized capture conjugates used in assays include (A) antibodies coupled to particles, (B) affinity ligands coupled to surfaces, (C) antibodies coated onto microwell plates, and (D) antibodies covalently linked to surfaces.

Bioconjugates for Enzyme-Linked Immunoassays

One of the more common assay designs that makes use of bioconjugates involves microplates with capture antibodies adsorbed or covalently coupled onto the surface for use in an enzyme-linked immunosorbant assay (ELISA) system (Lequin, 2005; Crowther, 2009). The assay is performed by adding samples to the wells of the capture antibody plate and allowing the target analyte (antigen) to bind (Figure 1.15). After a wash step to remove excess sample, the detection process is initiated, which often next includes the addition of an unconjugated primary antibody against the target. The immobilized capture antibody and the primary antibody can be both monoclonals directed against different epitopes on the analyte or polyclonals, or a mixture of both types. After another wash step, the detection antibody–enzyme conjugate is added, which uses a secondary antibody directed against the antibody species type used as the primary antibody. Any analyte-bound primary antibody that bound as a result of the first step will also result in the binding of the secondary antibody–enzyme conjugate. A final wash is then carried out to thoroughly remove any excess unbound detection conjugate before a substrate is added to develop the detectable product of the reaction (i.e., chromogenic, fluorescent, or luminescent signals). In the more rapid designs often used in clinical diagnostic testing, the primary antibody is a part of the detection conjugate to eliminate the extra steps of using a secondary antibody–enzyme (or streptavidin) conjugate in the assay. The only downside to the use of a direct primary antibody–enzyme conjugate is that the sensitivity and

minimum detection level of the assay are usually not quite as good as that possible when using an unconjugated primary antibody followed by the secondary antibody–enzyme conjugate. This is because a multilayering effect of binding the primary antibody plus the secondary antibody–enzyme complex allows for more detection conjugates to bind to each captured analyte than would be possible with just a single primary antibody conjugate alone docking on the analyte.

Another frequent bioconjugate strategy used in immunoassays is the use of a biotinylated primary antibody, which initially is bound to the captured analyte in the assay. To detect this binding event, typically a (strept)avidin conjugate is added that contains the enzyme used to develop the substrate. This multi-layered ELISA detection process is a very common method for assay of antigens using sandwich immunoassays, because the production of a biotinylated primary antibody is simple and the (strept)avidin–enzyme conjugate becomes a universal detection agent for all such assay designs.

Thus, for ELISA formats of all types the production of a universal detection agent like a secondary antibody–enzyme conjugate or a (stept)avidin–enzyme conjugate can provide the basis for developing virtually any analyte-specific assay. The methods for making such conjugates can be found in Chapters 11, 20, and 22.

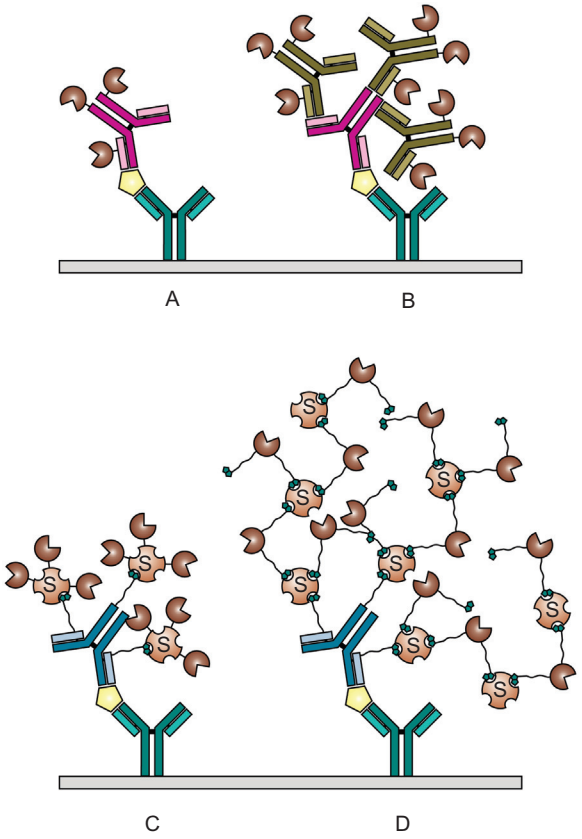

FIGURE 1.15 Typical ELISA methods using capture and detection bioconjugates. (A) a sandwich assay design using a primary antibody-enzyme conjugate, (B) a sandwich assay design using a primary antibody plus a secondary antibody–enzyme conjugate, (C) a sandwich assay using a biotinylated primary antibody and a streptavidin–enzyme conjugate, and (D) a sandwich assay using a biotinylated antibody along with a biotinylated enzyme and a streptavidin bridging molecule. Some methods of using bioconjugates in assay systems can result in better detection capability by recruiting more detection molecules at the site of the measured analyte.

Chemiluminescent Acridinium Ester Conjugates

A unique detection bioconjugate that is used in many heterogeneous diagnostic immunoassays consists of a complex between a targeting molecule such as an antibody and an organic chemiluminescent compound, such as an acridinium ester. This type of labeled conjugate can be used in assays that generate a photon of light from each acridinium modification present on the targeting molecule. A trigger solution containing hydrogen peroxide (H_2O_2) is added at the end of a typical immunoassay procedure followed by an addition of NaOH to result in highly alkaline conditions to rapidly oxidize the acridinium ester compound. This oxidation reaction forms an intermediate dioxetanone that subsequently breaks down into the singlet electron excited state (*N*-methylacridone), which then emits a photon of light when it returns to the ground state (Figure 1.16).

The detection limit of an acridinium ester-labeled antibody in an assay is typically in the low fmol range, indicating that targeted analytes can be measured with high sensitivity. One deficiency of using this detection conjugate design, however, is the short lifetime of the chemiluminescence once the label is triggered. For this reason, the trigger solution must be added within an instrument by rapid injection followed by immediate signal measurement to capture the emitted light.

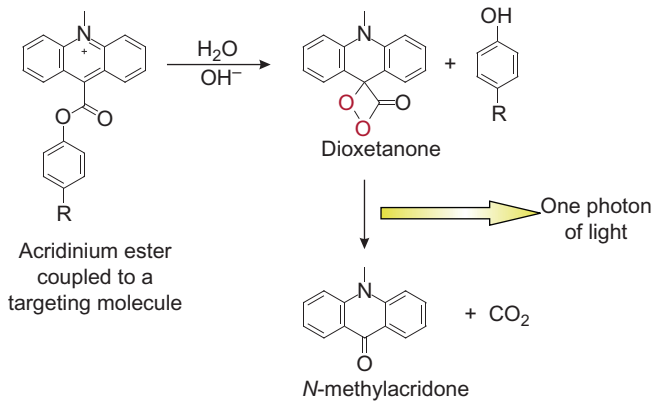

FIGURE 1.16 Acridinium ester bioconjugate and mechanism of light generation. Labeled antibodies made with acridinium esters can be used in a flash chemiluminescent assay system to detect desired antigens.

A recent alternative method of generating the chemiluminescent reaction is a continuous electrochemical production of superoxide using flavin-containing molecules, such as flavin adenine dinucleotide (FAD), flavin mononucleotide, or riboflavin (Aizawa *et al.*, 2006). Another technique uses an initial acridan ester compound, which upon electrochemical-mediated oxidation yields the reactive acridinium ester that can then be further oxidized with peroxide and base to produce light (Wilson *et al.*, 2001). These alternative electrochemical techniques eliminate the need for injection of the trigger solution and extend the overall lifetime of chemiluminescence, but they still require the auxiliary electrochemical system to generate signal.

In addition, unlike chemiluminescent systems that use enzyme–substrate reactions to produce light, the acridinium ester groups attached to the targeting molecule cannot continue to produce light catalytically. Once they are oxidized, the ester is cleaved from the targeting molecule and the acridinium degrades to an *N*-methylacridone derivative that does not get regenerated. Thus, only a single photon of light is emitted per acridinium ester group on each bioconjugate. This contrasts with conjugates made using antibodies linked to HRP or alkaline phosphatase that can use the turnover of a chemiluminescent substrate to produce an ongoing signal. For this reason, the enzyme conjugate systems are inherently more sensitive than the acridinium ester system, and therefore they may be a better choice for routine assays.

Fluorescent Oligonucleotide Probes

Bioconjugates consisting of oligonucleotides having fluorescent labels attached to them for use in hybridization methods can be employed in heterogeneous assays to detect and quantify specific target DNA or RNA sequences. These conjugates can be synthesized during solid-phase oligo synthesis using fluorescently labeled phosphoramidite monomers or the oligo probes may be labeled subsequent to synthesis using a number of reaction strategies, including enzymatic and chemical modification (Chapter 23). Once a fluorescently labeled oligo conjugate is available, it can be used to assay a complementary target sequence after the target has been captured by another oligo attached to a surface or particle. The capture oligo hybridizes to one portion of the targeted genomic DNA or RNA sequence, immobilizing it on the surface while unbound components of the sample are removed, and then a fluorescent detection oligo is added to hybridize to the other end of the targeted sequence. This assay is similar in concept to sandwich antibody assays often used in immunoassay procedures, but here two synthesized oligo conjugates are used to first capture and then detect the target instead of two antibodies (Figure 1.17).

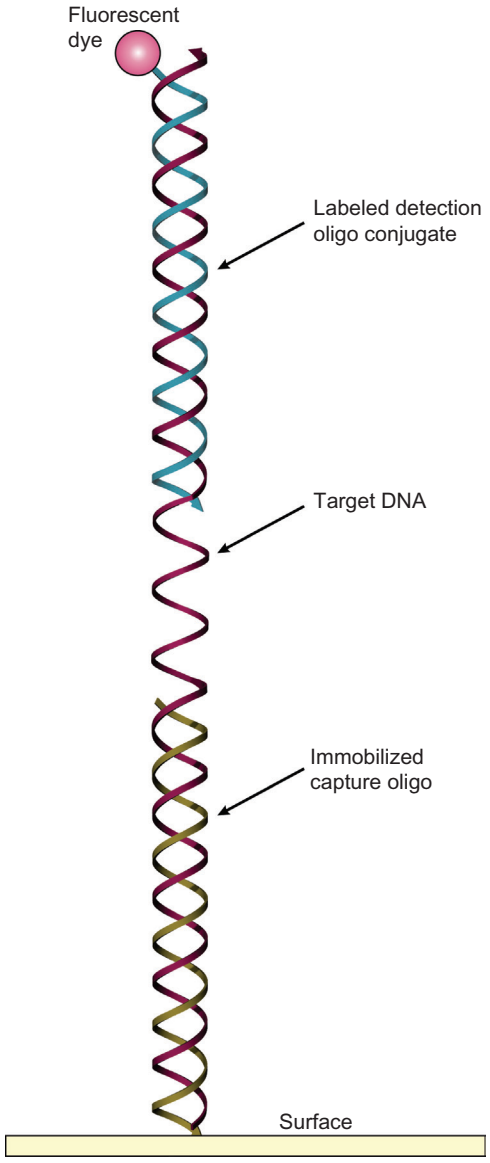

FIGURE 1.17 Fluorescently labeled oligo conjugates and capture oligo used in hybridization assays. The initial conjugate involves the attachment of the capture oligo to the surface, which binds to the targeted genomic DNA. Next a detection oligo conjugate consisting of a fluorescently labeled oligo that can bind to another region of the targeted DNA is used to provide signal for the binding event.

An alternative to the use of fluorescently labeled oligo probes is to prepare conjugates of a targeting oligo that is coupled to an enzyme. Similar to antibody–enzyme bioconjugates used in ELISA systems, the oligo serves as the affinity component that can interact with the complementary DNA- or RNA-targeted sequence and the enzyme functions as the detection component, which can act on a substrate to create a detectable signal—fluorescent, chromogenic, or chemiluminescent.

Hybridization assays can be carried out using many different heterogeneous assay formats. For instance,

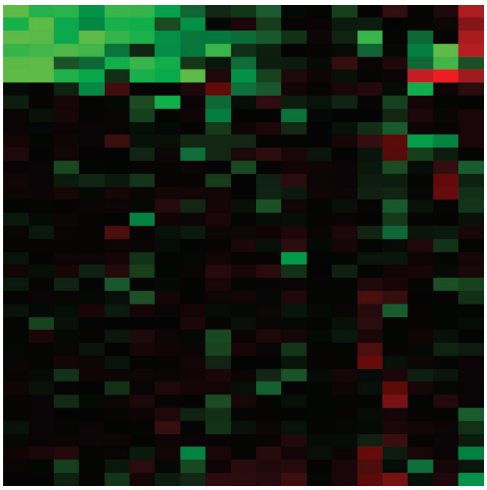

FIGURE 1.18 The fluorescent signals from an oligo array. Spots that have captured specific complementary genomic sequences are detected using a fluorescently labeled detection oligo. *The image was created by Miguel Andrade, as posted on Wikipedia from data available in the public domain at http://www.stembase.ca/ and using the public domain program Cluster from Michael Eisen, which is available from http://rana.lbl.gov/EisenSoftware.htm. FIGURE 1.19 Selected DNA sequences can be used to capture specific binding proteins in a chromatin immunoprecipitation assay (ChIP), such as the binding of transcription factors and other regulatory proteins. The binding of DNA polymerase beta to a segment of double helix is shown here.

a capture oligo can be immobilized onto the wells of a microplate, onto a microparticle surface, or onto a microchip using reactions suitable for activation of the given surface followed by coupling to an appropriate functional group on the oligo, usually put on the 3′ or 5′ termini (Chapters 14, 15, and 23).

Labeled oligos have become key bioconjugates in the development of multiplexed oligonucleotide assays, which now are used routinely to map critical gene profiles associated with disease or genetic abnormalities. Microchips containing hundreds or thousands of unique oligonucleotides have been produced to simultaneously capture multiple gene targets within microchip boundaries not much larger than a few mm^2. These chips may be probed using fluorescently labeled detection oligos to result in differential fluorescent signals emanating from the oligo array at discrete points corresponding to each captured target. Software algorithms can then be used to quantify the amount of target captured at each array point (Figure 1.18). A number of companies, such as Affymetrix and Roche NimbleGen, have commercialized high-density oligo arrays for use in profiling gene expression and in the diagnosis of disease. The market for Affymetrix products alone in 2011 was $267.5 million (Affymetrix annual report, 2011). Note that this market has been declining as the DNA sequencing market is accelerating upward, which represents a technique that also uses fluorescently labeled nucleotide probes.

Immobilized oligonucleotide probes also are being used for chromatin immunoprecipitation (ChIP) assays. Instead of probing for complementary nucleotide sequences that can bind to the immobilized oligos as in hybridization assays, these bioconjugates are used to capture proteins which specifically interact with them. For instance, transcription factors and polymerases often interact with segments of genomic DNA to turn on genes or replicate the DNA double helix (Figure 1.19). So-called "ChIP-on-chip" arrays can be used to discover the binding regions for specific transcription factors and other regulatory proteins, which interact with certain sequences on genomic DNA and function to control transcription (Buck and Lieb, 2004; Shaked *et al.*, 2008). Oligo capture probes coupled to planar surfaces or particles can be used to isolate these interacting proteins by using the solid phase as a convenient affinity support for removing the non-binding components in a sample prior to analysis (Figure 1.20). Alternatively and more commonly, the regulatory protein-DNA complexes first can be covalently captured within cells using fixation with formaldehyde or other crosslinking agents. Cell lysis is then carried out followed by

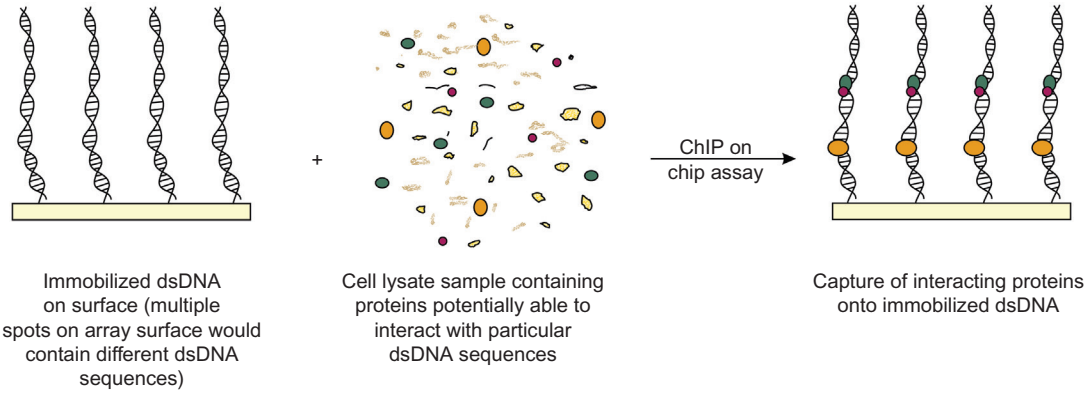

FIGURE 1.20 A ChIP-on-chip array design using immobilized dsDNA to capture interacting proteins is illustrated. A cell lysate sample containing potential binding proteins is incubated with the array and proteins are allowed to bind. These proteins can be eluted and detected by western blotting or mass spec methods.

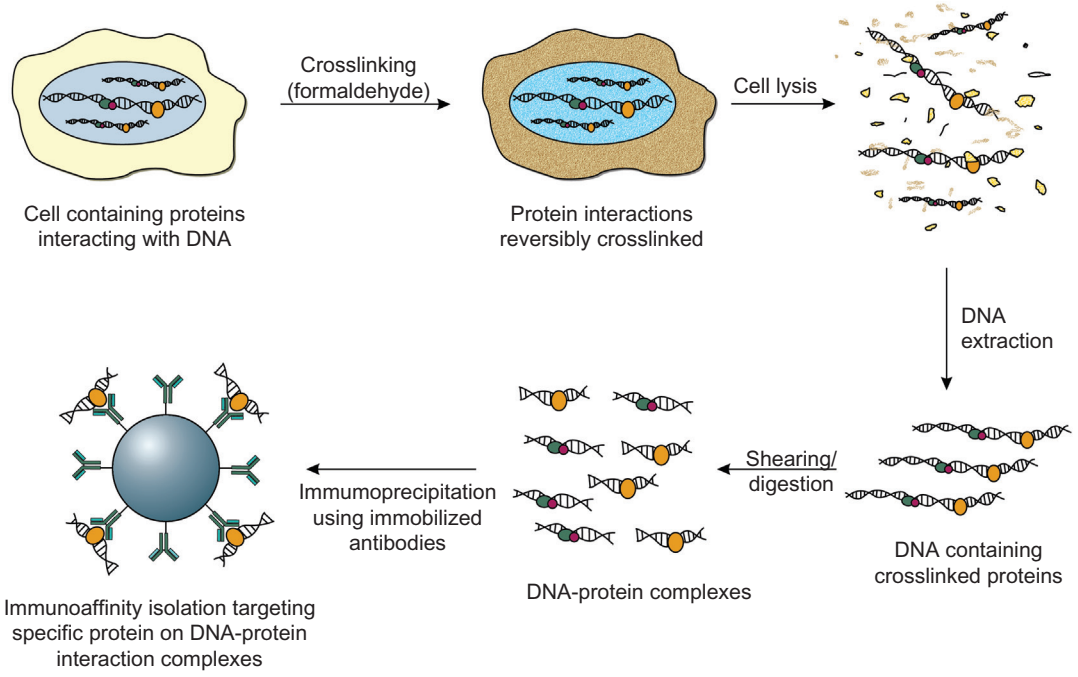

FIGURE 1.21 A ChIP assay design using immobilized antibodies can be used to capture specific interacting proteins onto particles for subsequent analysis by western blotting or mass spectrometry.

disruption of the chromatin using sonication and partial enzymatic digestion, which fragments the DNA into short sequences of 100 to 250 bp. These DNA–protein complexes can then be isolated using particles containing immobilized antibodies directed against the regulatory proteins of interest (Figure 1.21). ChIP assays can be used to study gene activation and epigenetic modifications within chromosomes that control protein expression within cells.

Another important application area for oligonucleotide bioconjugates is represented by the technique called "fluorescence *in situ* hybridization" (FISH), described by Pinkel *et al*. (1988). In this method, gene targets can be directly probed within cells or tissue sections using labeled oligo conjugates (Nath and Johnson, 2000; Liehr, 2009). The complementary oligo probes can be prepared by limited digestion of genomic DNA using DNase or made synthetically by selecting the proper sequence regions within the DNA target and synthesizing a complementary strand which will hybridize to it. However, the nucleotide probes used in FISH assays typically are longer than those probes used in hybridization arrays to ensure better specificity and faster binding to the genomic target sequence.

The oligo conjugates used for targeting in FISH can be of several varieties (Figure 1.22). They can be directly labeled with a fluorescent dye (Chapters 10 and 23) or they can first be labeled with another molecule that subsequently can be detected using a fluorescently labeled antibody (Chapter 20) or a fluorescently labeled (strept)avidin conjugate (Chapter 11). One of the more popular oligo labels for antibody targeting is to use the small organic hapten digoxigenin (DIG), which is a plant hormone found only in the leaves of certain plants (foxgloves). Antibodies of high affinity are available against DIG and since it is not found in mammalian cells DIG-labeled oligo probes can be detected within cells with high specificity and low background. An alternative to DIG labeling is to use a biotinylated oligo probe (Chapters 11 and 23), which can be detected using a fluorescently labeled (strept)avidin conjugate. Biotinylated oligonucleotides are common bioconjugates used to probe DNA and RNA sequences in a number of applications.

DIG or biotin modifications can be enzymatically incorporated into DNA probes using dUTP derivatives, typically DIG-11-dUTP or biotin-11-dUTP. These derivatives are commercially available from many suppliers and can be used in PCR labeling procedures or other enzymatic methods to add several DIG or biotin tags into an amplified segment of an oligonucleotide probe (Chapter 23). For instance, terminal transferase can be used to add DIG or biotin dUTP derivatives to the 3′ end of an oligo probe in a template independent manner (Schmitz *et al.*, 1990). This labeling method typically adds multiple copies of modified nucleotides (10–100 copies) to the 3′ end, depending on the concentration of the dUTP derivative used. Alternatively, these tags can be chemically added through conjugation of an amine-modified oligo to the NHS ester derivatives of DIG or biotin (Chapter 11 and 23) (Figure 1.23). The modification of a 5′-amino derivative of an oligonucleotide can add a single biotin handle to the end of an oligo probe, thus avoiding over labeling, which could lead to decreased hybridization efficiency.

Molecular Scaffolds to Increase Assay Sensitivity

In some strategies to further enhance the signal and sensitivity of assays, multivalent scaffolds may be used in bioconjugate construction to increase the number of detection molecules associated with a single targeting molecule. In this approach, the docking

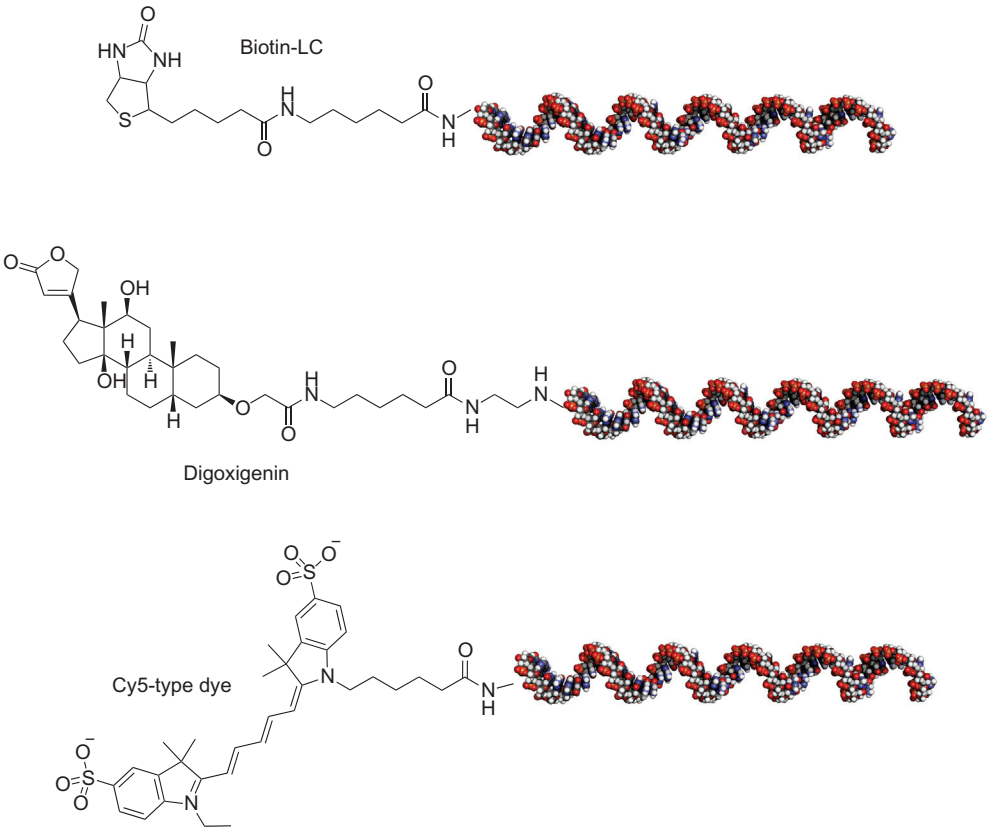

FIGURE 1.22 Fluorescent oligo conjugates typically used in FISH assays include labels such as biotin, digoxigenin, or a fluorescent dye to detect hybridization events. The biotin- and digoxigenin-modified oligos typically are used with streptavidin conjugates or antibody conjugates (DIG) for detection.

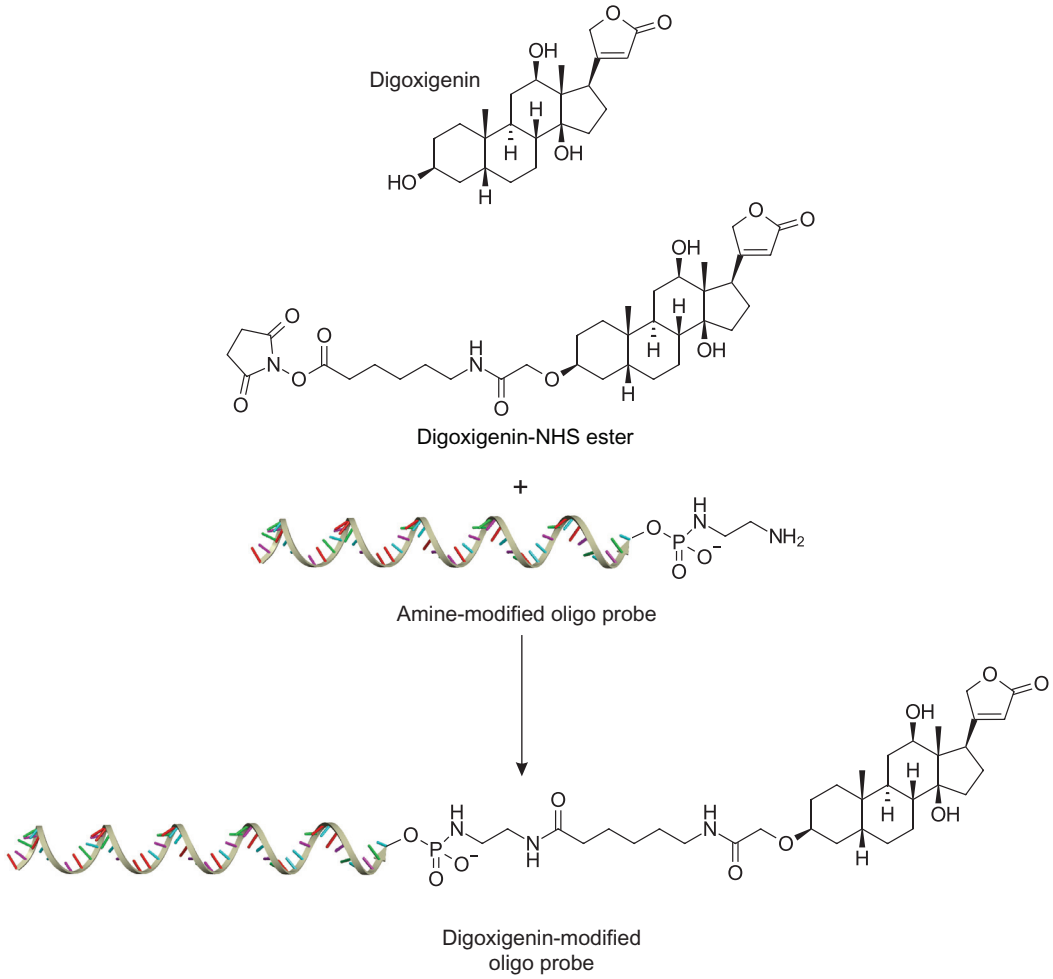

FIGURE 1.23 DIG-NHS ester modification of an amine-modified oligo to create a probe useful in hybridization assays.

of one targeting molecule on its target analyte brings with it a larger number of detection components due to the scaffold design, therefore increasing the resultant sensitivity in a particular assay. Some conjugates that are constructed in this manner to increase signal include scaffold components consisting of dendrimer polymers (Chapter 8), linear or branched polymers (Chapter 18), particles (Chapters 14 and 15), and other interacting molecules including large complexes formed from use of the biotin–(strept)avidin system (Chapter 11) (Figure 1.24). In each system, assay designs can be constructed using advanced bioconjugation techniques that can multiply the detection signal over that normally observed without the use of a scaffold. Such scaffold designs are used not because a simple bioconjugate of a labeled antibody will not work in most assays; rather, the use of auxiliary scaffolds is driven by the need to detect and measure ever decreasing concentrations of target molecules, especially when measuring very low copy numbers of proteins expressed in cells.

Bioconjugates Used in Homogeneous Assays

Specialized bioconjugates can also be developed for use in single-step or homogenous assay formats. Unlike in a heterogeneous assay system, this method involves the mixing of sample and detection reagents together in a single reaction solution and the assay result is obtained without any separation steps being done. With heterogeneous assays, the detection conjugate is bound to its target analyte on an insoluble solid phase support and any excess reagent is removed before a measurement is taken. This removes any nonspecific signal due to unbound conjugate and isolates on the solid phase only the specific signal due to the detection conjugate being bound to the target analyte. Homogeneous or single-step assays have to be designed to allow analyte detection even in the presence of excess detection conjugate. Thus, the bioconjugates used for this type of assay must create a detectable signal if and only if they are bound to their target analyte. The advantage of the homogeneous or single-step assay design is that a test can

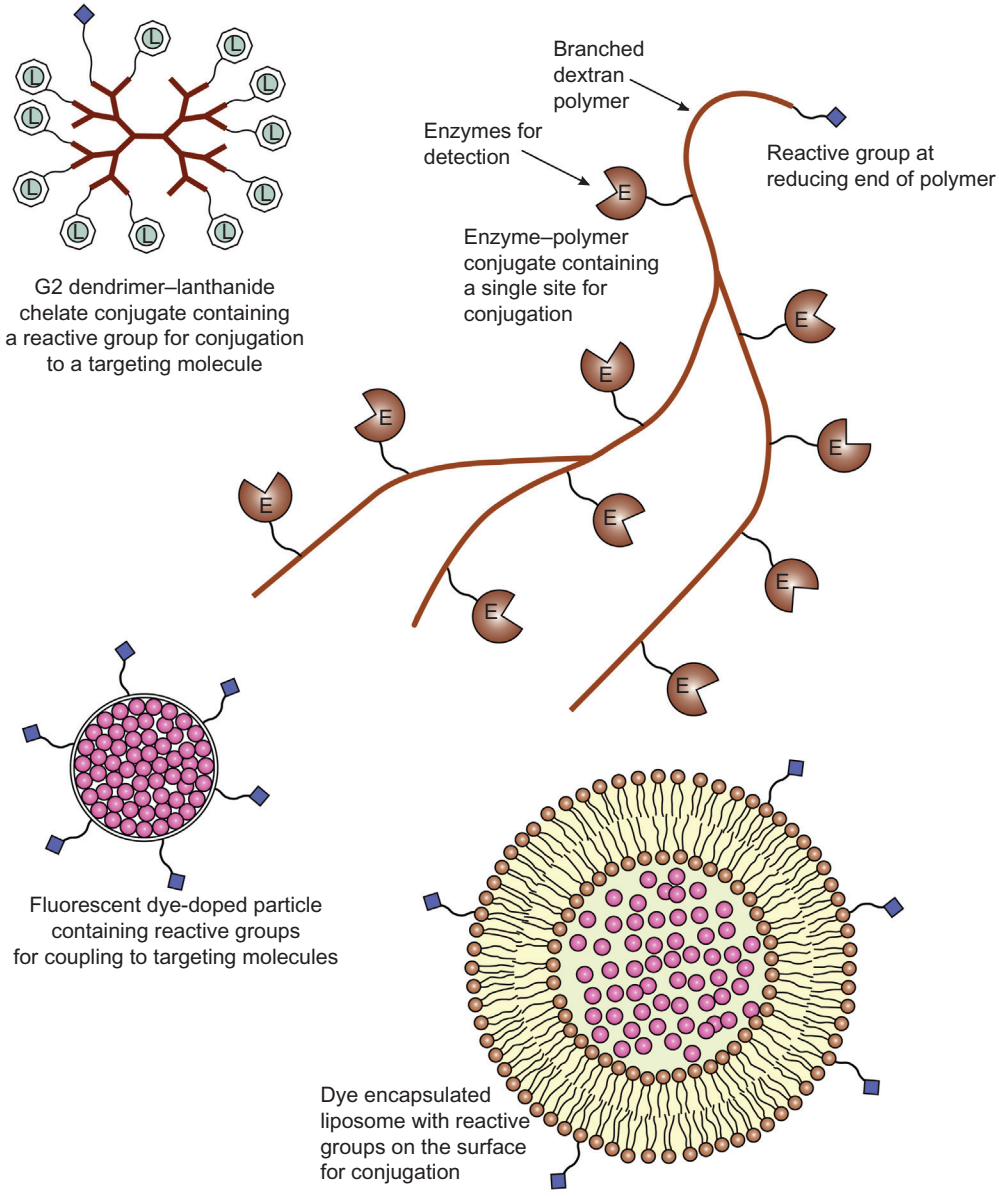

FIGURE 1.24 Scaffolds commonly used to enhance detection in assays through multivalent conjugation sites. The upper left shows a dendrimer containing multiple fluorescent lanthanide chelates for high sensitivity detection plus a reactive group for labeling a targeting molecule, such as an antibody. The upper right shows a dextran polymer linked to numerous enzyme molecules for detection using substrates and a reactive group on the polymer's reducing end for conjugation purposes. The bottom left illustrates a particle containing multiple fluorescent molecules and reactive groups on its surface for bioconjugation. Finally, on the lower right, a liposome-containing dye molecule with reactive groups on its surface for conjugation with targeting molecules is shown. Each of these scaffold designs can be used to generate greater signals in assays or in imaging methods.

be completed almost immediately after the sample and reagents are mixed, and without the need for subsequent washings, reagent additions, or lengthy incubations. As might be imagined, this format is particularly attractive for use in diagnostic testing and drug discovery screening, as both applications are sensitive to the price-per-test expense and the time it takes to complete an assay.

Bioconjugates used in homogeneous assays typically are designed to utilize one of three strategies for assay detection: (1) fluorescence resonance energy transfer (FRET); (2) bioluminescence resonance energy transfer (BRET); or (3) split reporter proteins (Figure 1.25). The first two systems involve non-radiative energy transfer between an emitter of light and an acceptor of light, wherein the acceptor can be either

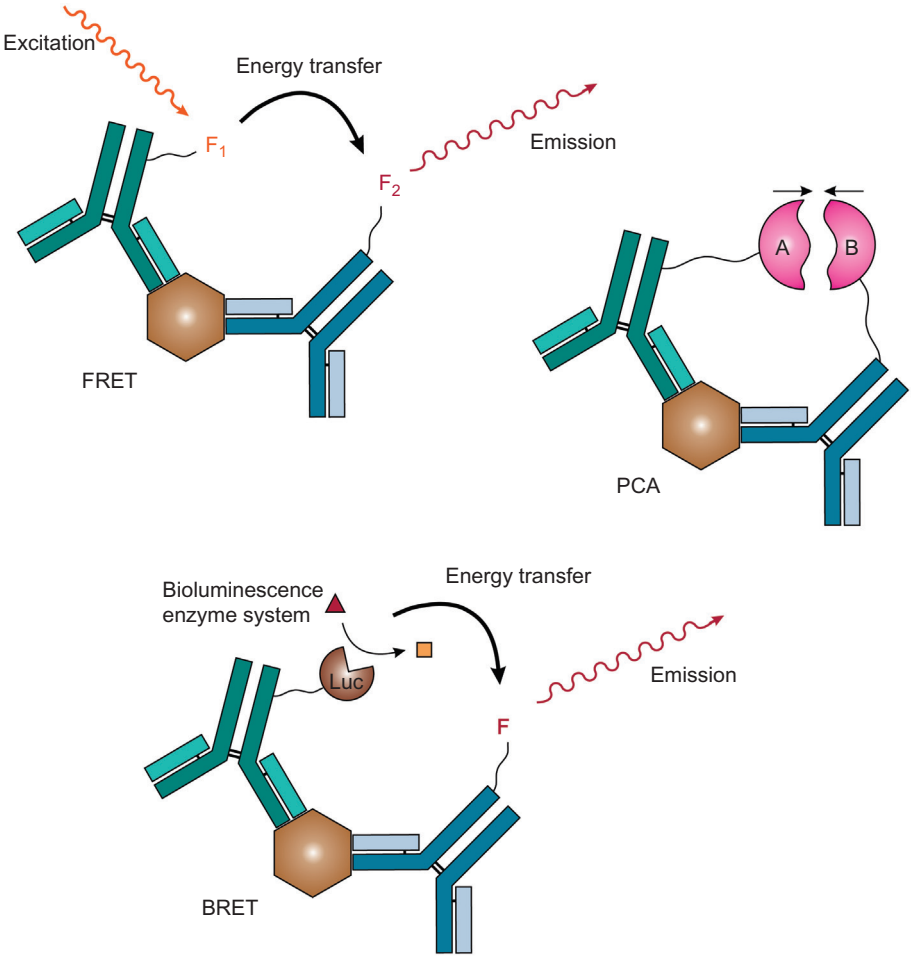

FIGURE 1.25 Basic homogeneous assay formats using bioconjugates. FRET-based systems often use antibodies labeled with two fluorescent molecules that can transfer energy between them if they are held close enough together by docking on a target protein. A protein complementation assay (PCA) uses recombinantly split enzymes or fluorescent proteins that have no activity or fluorescence unless they come together close enough to reconstitute the intact three-dimensional structure of the native protein. Bioluminescence-based systems use energy transfer between a luciferase enzyme and a nearby fluorescent dye to transfer energy from the converted luminescent substrate to the dye for emission at another wavelength. All three designs can facilitate the development of single-step or homogeneous assays without the need for separation steps to detect the specific signals.

an emitter at a different wavelength or a quencher (absorber) of the emitter's energy. Split reporter technology, also called "protein fragment complementation assays" (PCAs), involves the use of truncated portions of proteins that can bind together only when the fragments are positioned and held within an appropriate molecular distance of each other and thus result in restoration of the protein's unique detection characteristics (Michnick, 2003; Michnick *et al.*, 2007). In this system, each fragment of the split reporter produces no detection signal on its own, because it requires the other portion of the molecule to restore native structure and activity.

The strategy fundamental to most homogeneous assay systems involves the use of two different detection components that come together in molecular proximity as they are bound to the desired target. The bioconjugate designs for use in such systems should permit signals to manifest only when the detection reagents are held through tight affinity interactions onto the targeted analyte. This brings the two detectors close enough together to generate an efficient energy transfer or allows for regeneration of split reporter activity, which results in the desired signal. To ensure specificity, any excess detection conjugates that are not bound to an analyte must not contribute to any signal or the assay would have considerable background noise and low sensitivity.

Bioconjugates for FRET Assays

Bioconjugates used in a fluorescence resonance energy transfer (FRET) system are designed to contain fluorescent labels or a fluorescent label combined with a quenching label. A targeting molecule, such as a monoclonal antibody directed against an epitope on the target analyte, is conjugated with one of these molecules while a second targeting molecule, such as another monoclonal antibody against a second epitope on the target analyte, is conjugated with the appropriate complementary detection molecule. For FRET to occur with good efficiency and signal strength, the donor and acceptor detection conjugates must be brought together and held within a molecular distance of less than about 50 Å (5 nm) and preferentially at a distance of less than 20 Å (2 nm). According to the Forster equation (Chapter 10), FRET efficiency decreases with the

sixth power of the distance in which the two molecules are separated, so high-proximity assay designs result in the best signals.

Unfortunately, FRET assays using standard organic fluorescent dyes (Chapter 10) usually do not produce strong enough assay signals, because the resultant molecular distances between the fluors can easily be outside the range of efficient energy transfer. A typical IgG targeting molecule, for example, is about 11 nm in diameter (110 Å). Therefore, two fluorescently labeled antibody conjugate pairs of a FRET assay that are used simultaneously to dock on a large protein analyte may result in a complex in which the attached fluorophores are too far away from each other to generate good signals. Energy transfer in such systems usually does not occur with enough efficiency to make homogeneous assays with large analytes possible, unless the two targeting antibodies are designed to interact with target epitopes that are spatially close together.

However, this situation can be overcome for macromolecule assays by using a fluorescent lanthanide chelate label on one of the targeting antibodies (the donor) and a strongly absorbing fluorescence acceptor such as a cyanine dye or a phycobiliprotein on the second antibody. For protein assays, FRET signaling can be done at a greater distance using a lanthanide chelate, typically up to about 8 to 10 nm with good efficiency and signal strength. For instance, in a FRET-based system, a first monoclonal antibody might be conjugated with fluorescent lanthanide chelates having bound europium ions (Chapter 10, Section 9) and a second antibody might be conjugated with either a Cy5-type dye (Chapter 10, Section 8) or a phycobiliprotein, such as allophycocyanin (APC) (Chapter 10, Section 7). When these bioconjugate pairs are combined in an assay and both bind to a target analyte, the fluorescent conjugates are held in close enough proximity to allow efficient energy transfer between their fluorescent labels. Thus, excitation of the lanthanide chelate at 340 nm will cause FRET signaling to the neighboring APC molecules with concomitant emission at 660 nm. Signal emission at 660 nm occurs only in proportion to the amount of analyte present in the sample. Any excess labeled antibody conjugates that do not bind to the target will not undergo FRET signaling, and consequently they will result in no fluorescence emission at 660 nm. Unbound lanthanide conjugates still undergo excitation at 340 nm but only result in sharp signals at the europium chelate's characteristic emission wavelength of about 615 nm but no FRET signaling to the APC conjugates. In this system, a homogeneous assay can be done for a particular target that requires only the mixing of the detection bioconjugates with the sample followed by measurement of the resultant fluorescence at 660 nm, which forms a rapid and powerful system for many assays done in drug discovery (Figure 1.26).

Molecular Beacons and TaqMan Probes

Another application of organic fluorescent labels in FRET assays is their use in molecular beacon-type assays using oligonucleotide probes or peptides. In this case, the organic detection molecules of the FRET system are both attached to the same detection molecule: either an oligo or a peptide. The acceptor in such designs can be another fluorescent dye or a quencher of the first fluorophore's emission. In molecular beacon assays using oligo probes, the acceptor is often a

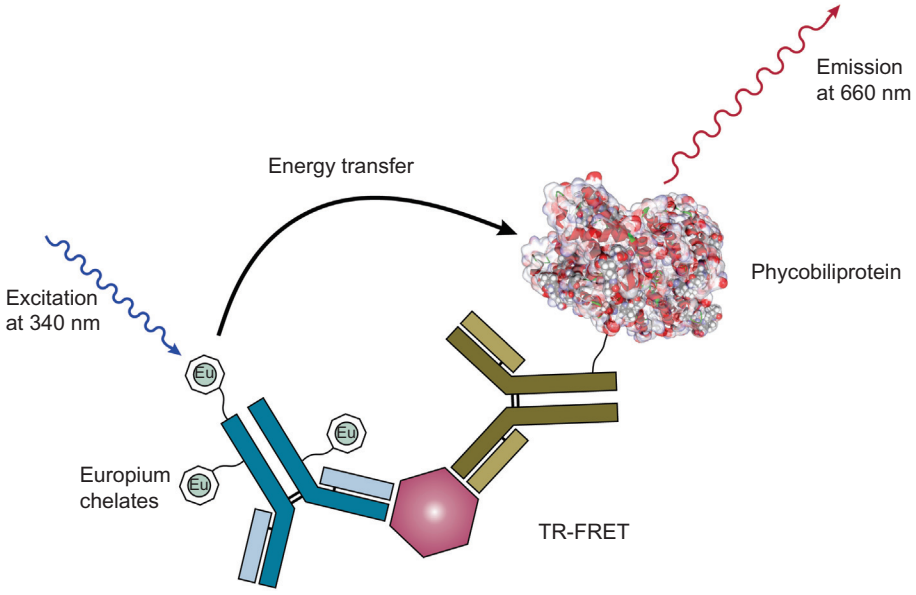

FIGURE 1.26 In a time-resolved FRET assay system (TR-FRET) an Europium chelate modified antibody is used along with a phycobiliprotein (e.g., APC) labeled antibody. Energy transfer between the lanthanide chelate fluorescent label and the fluorescent protein does not occur except when the two labeled antibodies are held close enough together by being bound to a targeted analyte. The efficiency of energy transfer using lanthanide chelates is much better than that observed using standard organic fluorescent dyes.

quencher. Both the fluor and the quencher are labeled on the probes at specific sites along the polymer—typically at the ends. An oligo probe might be labeled with one donor fluor at the 3′-nucleotide end and with the quencher at the 5′-nucleotide end of the sequence. The total length of the oligo probe is long enough to result in inefficient FRET signaling between the two labels if the oligo is stretched out linearly or hybridized to a complementary target sequence. The design of the oligonucleotide probe usually includes a hairpin configuration in which the last few nucleotides at both ends can hybridize to each other, thus bringing the donor and acceptor labels close together as the hairpin forms in solution (Chakravorty *et al.*, 2010; Krasnoperov *et al.*, 2010). In the hairpin configuration, the FRET labels will associate with each other and cause no fluorescence signal, as the fluor is completely quenched by the neighboring quencher molecule. In the presence of specific target sequences, however, the labeled oligo will hybridize to its target, breaking the hairpin structure, and pushing the FRET pairs far enough apart to lose any energy transfer potential. Hybridization to the target consequently causes a fluorescent signal to result, as the fluor-labeled end is no longer in proximity to, and quenched by, the quencher-labeled end (Figure 1.27). The more target that is present in the sample, the greater the fluorescent signal will be in the assay.

Perhaps the most popular molecular beacon-like technology is represented by the TaqMan probes (Roche, Applied Biosystems, and others) that are designed to assay specific nucleotide sequences in real time during a polymerase chain reaction (PCR) amplification process. These assays often are called real-time PCR or quantitative PCR (qPCR) tests. The sensitivity of this technology can measure target gene sequences down to a level of 10 to 100 copies and has a linear assay range of about nine orders of magnitude. There are very few technologies that can tout this degree of sensitivity and linearity in typical assays for any biomolecule. These probes do not use the hairpin structure design discussed previously but are linear oligonucleotide probes labeled at the 5′ nucleotide end by a fluorescent molecule and at the 3′ end by a quencher. The sequence is short enough to maintain nearly a quenched state of the fluor if the probe has not bound to its target genomic sequence; therefore very low background fluorescent signal results from just the probe in solution. However, if the probe binds to its amplified target during PCR, the 5′ nuclease activity of the polymerase enzyme used in the PCR process degrades the bound probe from the 5′ end, releasing the fluorescently labeled nucleotide and generating a characteristic fluorescence emission (Figure 1.28). As the PCR amplification process continues the amount of fluorescent signal increases exponentially, thus resulting in the exquisite sensitivity possible for the assay. Over one million TaqMan type assays have been developed to detect gene expression, mRNA, miRNA, or siRNA in samples from many different species.

The bioconjugate designs used for TaqMan assays have also incorporated minor groove binding molecules to enhance the initial binding to double-stranded target

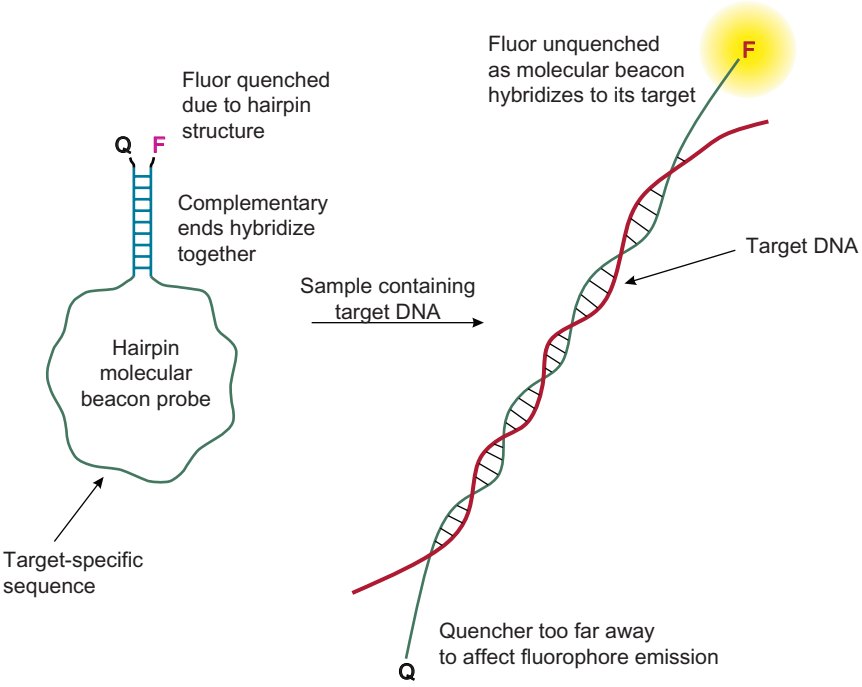

FIGURE 1.27 Oligo hairpin molecular beacon assays using fluor-quencher designs. The complementary region on the labeled probe keeps the fluorescent dye and quencher close enough in solution to eliminate fluorescence in the unbound state. However, once a targeted DNA sequence is hybridized with the probe, the hairpin is opened up and the fluor and quencher are moved apart far enough to allow fluorescence emission to occur. Such molecular beacons allow homogeneous assays to be carried out in solution in a single step.

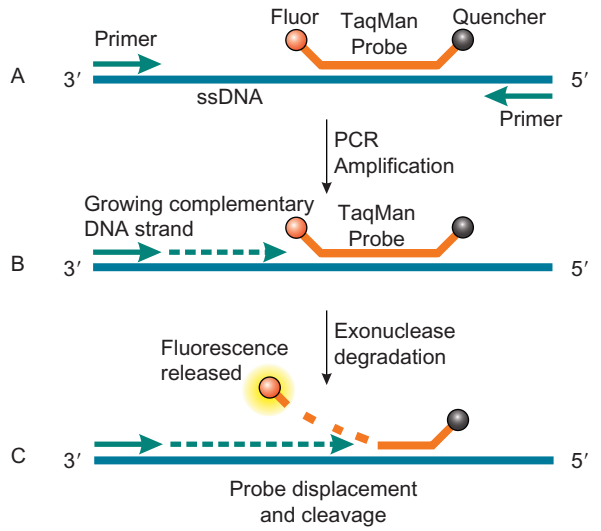

FIGURE 1.28 The TaqMan assay system design involves the use of a fluor–quencher FRET-based oligo probe that has its fluorescence quenched before and during hybridization with a target DNA sequence. Upon PCR amplification, however, the exonuclease activity of the enzyme cleaves off the nucleotides from the hybridized probe starting at the 5′ end labeled with the fluor. As the fluor molecules are released, they are able to emit fluorescence as they move away from the quencher end of the probe. An increase in fluorescence signal therefore results as the targeted DNA sequence is amplified, permitting real-time assays with high sensitivity.

sequences during PCR. Some designs have even used multiple dyes to enable multiplexed qPCR assays. In one such multiplex design, a dual-dye-labeled probe was created using a fluorescein molecule linked to a Cy5.5 dye, which was in turn used to label the 5′ end of the probe (Jothikumar *et al*., 2009). At the 3′ end, a Black Hole Quencher (BHQ-3) molecule was attached to the terminal nucleotide (Figure 1.29). In solution, the fluorescein dye could be excited by a blue LED at 470 nm resulting in FRET signaling to the Cy5.5 dye. However, due to the BHQ-3 quencher attached at the other end, the cyanine dye displays little to no fluorescence emission. Only after the polymerase enzyme has degraded the bound probe during PCR can excitation at 470 nm result in emission at the Cy5.5 wavelength of 705 nm. Along with the multiple-dye-labeled probe, a second probe labeled only with fluorescein can be used simultaneously during an assay to result in multiplexed signals at both 705 nm for the dual-fluor-labeled probe and at 530 nm for the fluorescein-labeled probe. Thus, two target sequences can be measured simultaneously in solution using these bioconjugate probes.

Molecular beacon type assays can also be designed using peptide sequences. In this case, the two FRET pairs are labeled onto the N- and C-terminal amino acid residues of a peptide. With peptide molecular beacons, a hairpin design is not possible to bring the ends together as it is with oligo probes. However, if relatively hydrophobic dye structures are used as labels, often they will have a tendency to associate together in solution, thus bringing the ends of the peptide sequence together and quenching any potential fluorescence from the donor fluor. The fluorescent molecule label and the quencher may also be sufficiently close with only a short sequence of amino acids in-between them so as to maintain good quenching characteristics. In this type of probe, the peptide sequence can be chosen to be a substrate for a particular protease of interest. In an assay, the action of the protease will cleave the peptide at a specific site in the center of the sequence and result in the fluor and the quencher being released into solution and thus becoming separated from one another. This releases the FRET quenching and allows the fluorescent molecule to emit light at its characteristic wavelength (Figure 1.30). In an assay, the more of the specific protease that is present and active in solution the greater the fluorescent signal that will be generated from separating the fluor from the quencher. Thus, using a peptide molecular beacon bioconjugate in a single-step homogeneous assay, a protease enzyme can be quantified for activity and estimated for concentration. Stefflova *et al*. (2007) describe the use of different peptide-based molecular beacons for use in cancer imaging *in vivo*.

Bioluminescence Resonance Energy Transfer (BRET)

In a BRET system, similar bioconjugates can be designed for a homogeneous assay as in FRET systems, but in this case using targeting molecules conjugated with a bioluminescent enzyme for the first conjugate and a fluorescent label for the second conjugate (Subramanian *et al*., 2006). This phenomenon is naturally seen in the sea pansy *Renilla reniformis* which has a luciferase enzyme that emits blue light, but it is associated with a green fluorescent protein (GFP) that accepts the light and re-emits it in the green region of the spectrum. For designing BRET assays, the main criterion is that the fluorescent label must be able to absorb energy emitted by the bioluminescent enzyme–substrate activity and emit it at another wavelength characteristic of the fluor. One of the main advantages of BRET-based assay systems is that they can be used *in vivo* in living cells to study protein interactions. In this design, the bioluminescent enzyme component is fused to one of the two proteins to be studied for potential interactions. The acceptor fluor in this instance consists of a fluorescent protein, such as GFP or one of another color (yellow fluorescent protein [YFP] is particularly popular for this application), which is fused to the second protein of the potential interacting pair. The advantage of this assay design is that both bioconjugates are expressed

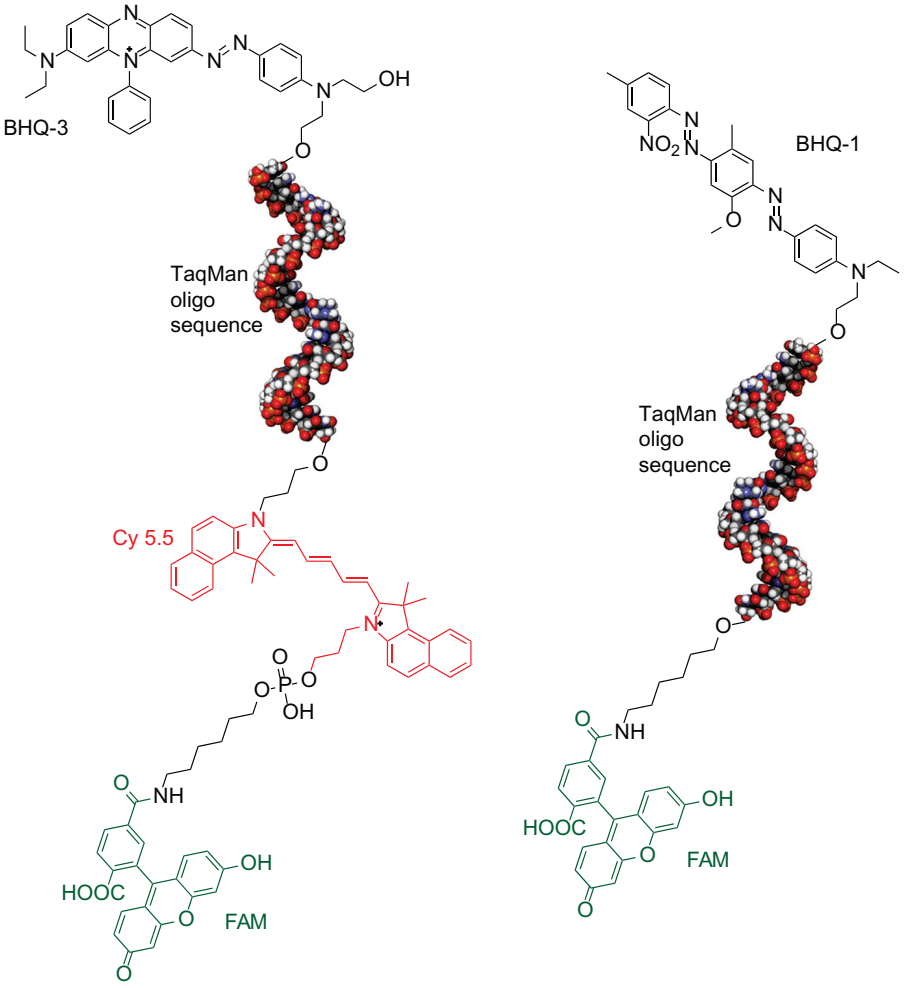

FIGURE 1.29 Multiplex TaqMan probe designs use one fluorescein-quencher probe (right) along with a second probe having a different specificity and containing a fluorescein-Cy5.5 FRET pair of dyes combined with another quencher (left). During an assay both probes can be excited at 488 nm; however the fluorescein-only probe will emit at about 520 nm whereas the fluorescein-Cy5.5 probe will emit in the far red region at the cyanine dye's emission peak due to energy transfer within the FRET system. Thus, two different DNA target sequences can be assayed simultaneously using the same laser excitation source.

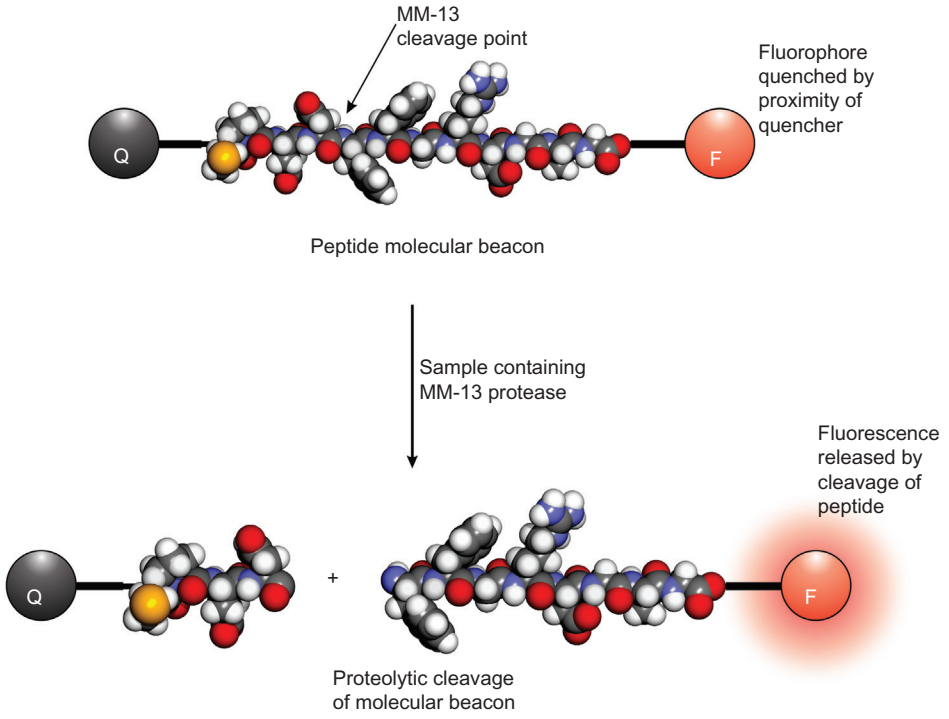

FIGURE 1.30 Peptide molecular beacon assays for protease activity typically are constructed using a specific amino acid sequence that can be cleaved by the intended enzyme target and having one end labeled with a fluorescent dye and the other end labeled with a quencher. Upon cleavage of the probe by the protease enzyme, the fluorescent dye moves far enough away from the quencher to become fluorescent. The degree of fluorescence is indicative of the amount of enzyme present in the sample.

as fusion proteins within the cell, thus poised to be assayed by the simple addition of a bioluminescent substrate. If the bioluminescent enzyme is expressed with its fusion protein partner and is able to act upon the substrate, then light will be generated from this reaction. If this fusion protein has bound with its putative interaction partner, then the fluorescent protein will be held in close enough molecular proximity to be able to accept the energy produced by the bioluminescent enzyme. Therefore, BRET signaling will only occur if the two target proteins are present and held in association from biospecific interactions. This type of assay system has advantages for use with biological systems, because it does not require external illumination to generate the signal, which could cause autofluorescence from biomolecules in the cell or inadvertent excitation of the acceptor fluorescent protein (Figure 1.31).

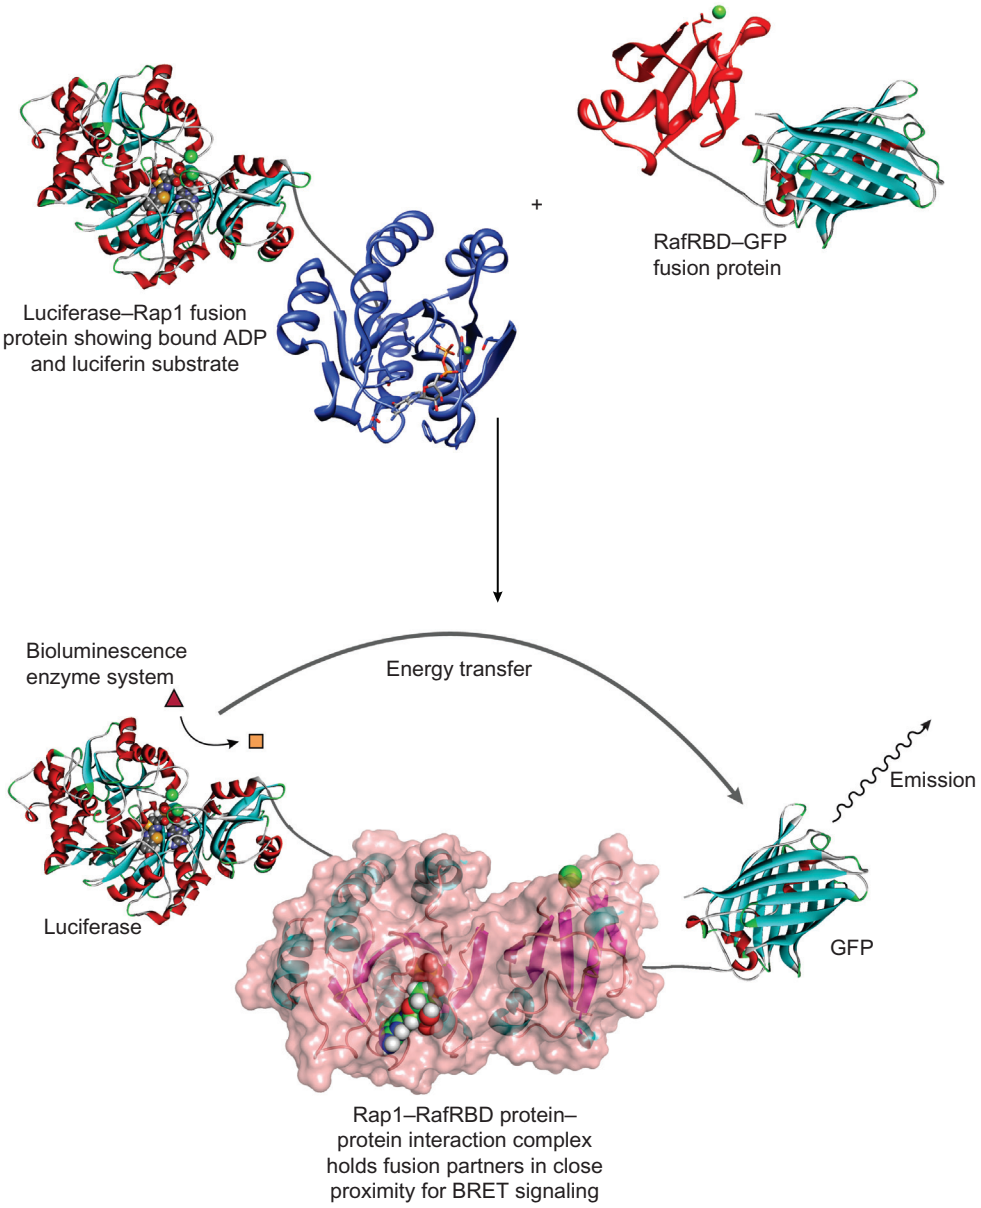

FIGURE 1.31 A bioluminescence resonance energy transfer (BRET) assay system with a bioluminescent enzyme and GFP fusion proteins. In this type of protein–protein assay one of the putative interacting proteins is fusion tagged with a bioluminescent luciferase enzyme (e.g., Rap1) and the other interacting protein (RafRBD) is tagged with a fluorescent protein (GFP). If the two target proteins interact within a cell, then the luciferase and the GFP are held close enough together to allow for the luminescence of the luciferase enzyme/substrate reaction to be transferred to the nearby GFP. If this occurs, then the complex will emit light at the emission peak of GFP and not just at the luminescence wavelength of the luciferase substrate reaction.

Protein Fragment Complementation Assays: Split Reporters

In a split reporter system used for homogeneous assays, the two components can be of several types: (1) an enzyme that acts upon a substrate to produce a chromogenic or fluorescent product; (2) a bioluminescent enzyme that transforms a substrate to produce a photon of light; or (3) a fluorescent protein with characteristic excitation and emission properties, such as the green fluorescent protein (GFP). The fragments of such reporters are designed to be stable but inactive when conjugated to targeting molecules like antibodies. However, once the targeting molecules interact with their targeted analyte in solution or on a solid phase, the coupled reporter fragments are able to interact in a complementation process that restores their native function. For example, in a split firefly luciferase reporter assay, the fragments come together as the two targeting bioconjugates dock upon the analyte and the native bioluminescence enzyme activity is then restored. Enzyme complementation results in a turnover of luciferin substrate in the assay and bioluminescence light output is measured as proportional to the amount of target molecule present in solution. Protein complementation assays (PCAs) are also used to detect interacting proteins within cells, wherein fusion protein complexes similar to the design of the BRET system, each containing a fragment of the split reporter, are detected as a specific interacting complex only if complementation occurs and the unique detection activity of the reporter is restored (Gambhir and Paulmurugan, 2005). Figure 1.32 illustrates the design and function of a split GFP PCA system wherein two labeled antibodies bind to a target protein, resulting in the GFP fragments coming together and restoring fluorescence activity.

Mass Tags for Quantitative Mass Spectrometry

Bioconjugation reagents incorporating stable isotope-labeled structures are becoming common for the quantitative analysis of protein expression using mass spectrometry. Chapter 12, Section 3, describes the major types of mass tags and their protocols for use, including isotopic and isobaric constructs. Mass

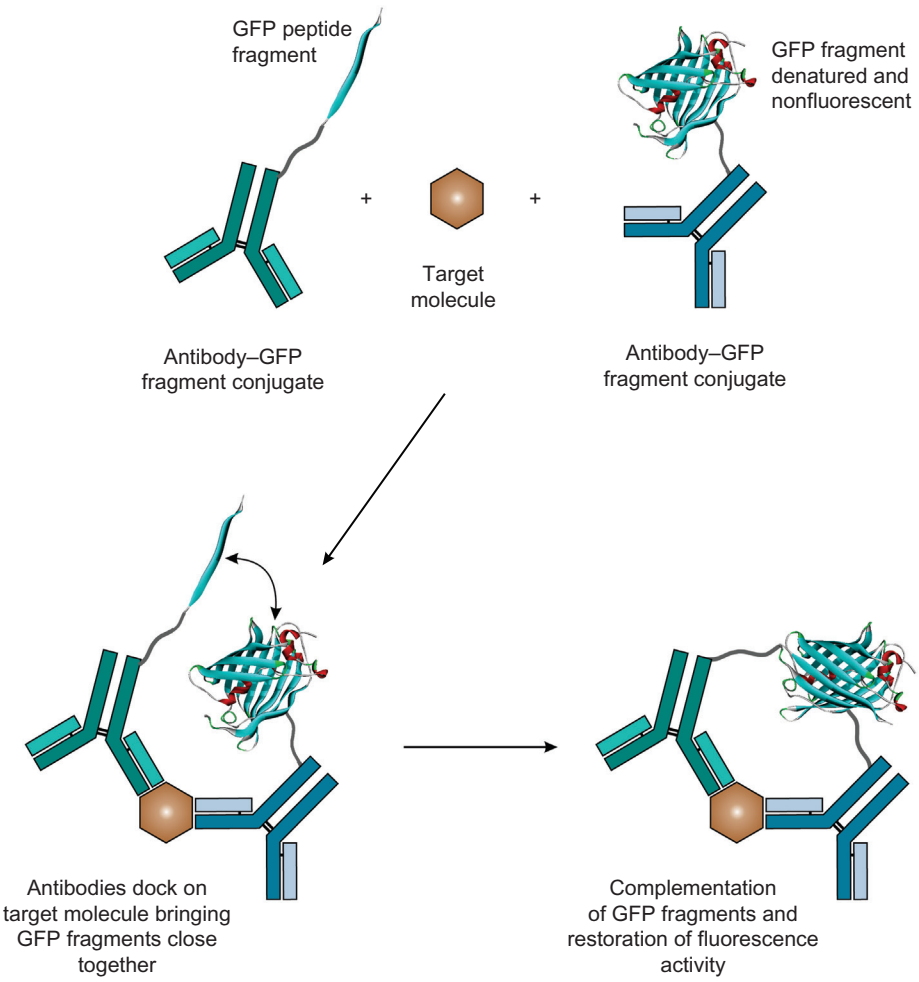

FIGURE 1.32 A protein complementation assay (PCA) can be designed using a recombinantly split GFP. If one antibody is tagged with a fragment of GFP and another antibody is conjugated with the other part of GFP, then bringing the two antibodies together onto a targeted protein will allow the two fragments to recombine and reconstitute its fluorescent properties. This same concept can be used with recombinant fusion proteins to detect protein–protein interactions in cells.

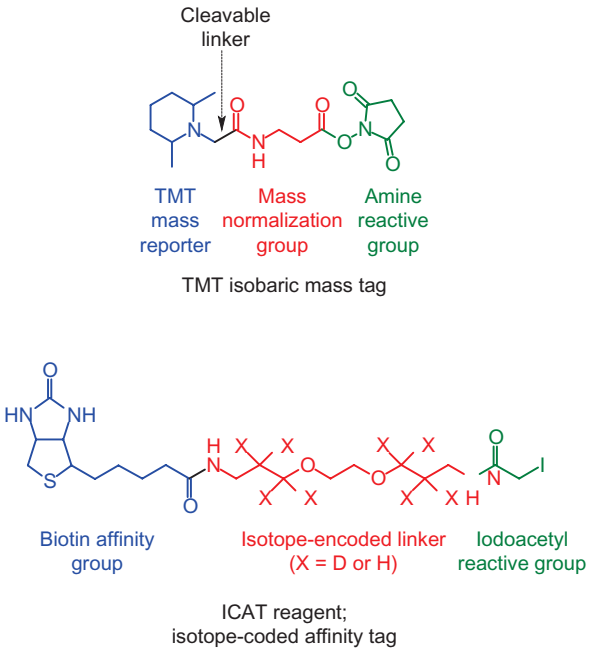

FIGURE 1.33 Examples of isotopic and isobaric mass tag designs. The isobaric mass tag uses a reporter group and a balancing group (mass normalization) to maintain the same total mass within the tag. A set of different isotopically labeled tags can be designed that all have different reporter group masses but the same overall mass. Peptides labeled with these reagents will all elute at the same point during the chromatographic separation, but upon mass spec analysis the different reporter masses can be correlated to different samples, thus allowing multiplexed analysis. An isotope-coded affinity tag, by contrast, has an isotope label region but does not have the properties of the isobaric mass tags. The biotin group allows for enrichment prior to mass spec analysis of labeled peptides.

tags can be used to analyze the expression levels of multiple proteins from a cell sample, from just a few at a time to global proteomic changes across a number of samples simultaneously (Bantscheff *et al.*, 2007). Modification reagents used as mass tags typically contain a mass reporter unit, a spacer, and a reactive group useful for modifying specific sites on peptides or proteins. The mass reporter typically is one of two types, either (1) a simple isotopically labeled compound containing, for instance, deuterium, ^{14}C, or ^{15}N in place of the normal isotopes for hydrogen, carbon, or nitrogen (Zhou *et al.*, 2002); or (2) a more complex isobaric design, wherein there is a mass reporter group that is next to a mass balancing group (Figure 1.33). For simple isotopic mass tags, two samples can be run simultaneously with one sample being modified with the normal isotopic tag and the other sample modified using a tag containing stable heavy isotopes.

In the isobaric form of these reagents, any isotopic changes made to the reporter group are counterbalanced with opposite changes to the balancing unit, thus maintaining the same overall molecular weight of the entire mass tag molecule (Gingras *et al.*, 2007). Isobaric tags allow the labeling of multiple samples using designs with different reporter unit masses, but the same total mass signature. These samples can be mixed in equal ratios prior to mass spec analysis to obtain the relative expression levels for particular proteins within all the samples. Identical peptides labeled with the isobaric tags from different samples will all be contained in the same peak in the first dimension of MS separation; however, in MS^2 where peptide fragmentation occurs to identify the amino acid sequence of each peptide, the reporter groups are also released and used as an identifying mass signature to correlate the peptide sequence to the appropriate sample number. Thus, multiplexed analysis of protein expression is enabled by use of an isobaric mass tag bioconjugation reagent.

Isotopic or isobaric mass tags are used to covalently modify peptides in a protein sample before undergoing mass spec analysis. The mass tag can be designed to contain an amine-reactive, thiol-reactive, or carbonyl-reactive group for covalent modification of peptides at known sites. Each modified protein can then be identified by its combined peptide-plus-tag molecular mass as detected by the mass spectrometer. The tags can also be used to derivatize post-translational modifications on proteins or other biological molecules through specific functional groups. For instance, aminoxy-containing isotopic tags have been used to detect oxidative damage in proteins by reacting with carbonyl groups that are produced on amino acid side chains (Whetstone *et al.*, 2003; Meares *et al.*, 2007).

Mass tags that facilitate relative protein expression analysis between multiple samples can be combined with isotopically labeled peptide standards to permit quantitative analysis of expression levels (Yan and Chen, 2005; Lange *et al.*, 2008). The labeled peptide standard creates a mass spec peak from a known initial concentration added to the sample solution. Comparing the standard peak area to the sample peak area from the same peptide (which is from a known protein) makes possible multiplexed quantitative MS analysis.

Limiting Nonspecificity in Bioconjugate Designs

Another important factor in assay design is to limit the nonspecificity of the bioconjugate as much as possible in the desired application. Many strategies for removing nonspecific binding or background signals include adding components to the assay buffers that can block sites of potential nonspecificity on the immobilized capture support, thus reducing the potential for the detection bioconjugate to bind and generate false signals. Proteins such as BSA, casein, serum, non-fat

dried milk, and a host of other proteins or polymers have been used extensively to block nonspecific binding on microplates, membranes, particles, and other assay surfaces.

However, in addition to introducing blocking agents or excipients to solutions, the actual design of the capture or detection bioconjugates may also be altered to limit nonspecificity and improve assay performance. For instance, the use of discrete PEG-based crosslinkers in the formation of the bioconjugates instead of aliphatic-based crosslinkers can dramatically affect assay performance by lowering the potential for nonspecific binding. During modification and conjugation processes, PEG linkers create an extremely hydrophilic surface due to the ethylene oxide spacers on each molecule, which in turn reduces the potential for nonspecific interactions of the conjugate with other molecules. Conjugates designed using hydrophilic instead of hydrophobic crosslinking strategies can improve signal-to-noise ratios in many assay applications. Chapter 18 discusses the reagents and methods used to create such conjugates, which can benefit not only assays but other applications as well.

In forming a typical protein–protein bioconjugate, it is common to have intermediate derivatives prepared that modify and activate both proteins for the subsequent conjugation reaction. For instance, in the preparation of an antibody–enzyme conjugate, often one of the molecules is activated with a heterobifunctional crosslinker, while the other protein is modified to contain an appropriate functional group to couple with the modified first protein. In many traditional bioconjugation procedures this could take the form of reacting the antibody with an aliphatic NHS ester–maleimide crosslinker, such as SMCC. In this reaction, SMCC couples with the amines on the antibody to create amide bonds while the other end of the crosslinker creates thiol reactive sites on the molecule, thus producing terminal maleimide groups sticking out from the surface of the protein (Chapter 20). However, using this approach, the resultant derivatized antibody also contains a number of hydrophobic aliphatic components sticking off its surface (Figure 1.34) and potentially creating sites for nonspecific interactions.

In a secondary reaction, the enzyme molecule typically is modified with an aliphatic thiolation reagent prior to crosslinking with the SMCC-activated antibody. Modification agents such as Traut's reagent or SATA (Chapter 2, Section 4.1) form aliphatic protrusions on the surface of the enzyme to create thiols just as the SMCC modifications made on the antibody create thiol-reactive groups. Figure 1.34 illustrates both the SMCC- modified antibody and an alkaline phosphatase enzyme that is modified using SATA to create terminal thiol groups after deprotection (note: the structure shows the deprotected enzyme with exposed thiol groups). After mixing the SMCC-activated antibody with the thiolated enzyme, the conjugate that is formed may have relative ratios of enzyme-to-antibody of perhaps 2:1 or 3:1, depending on the molar ratio of the components added to the initial reaction

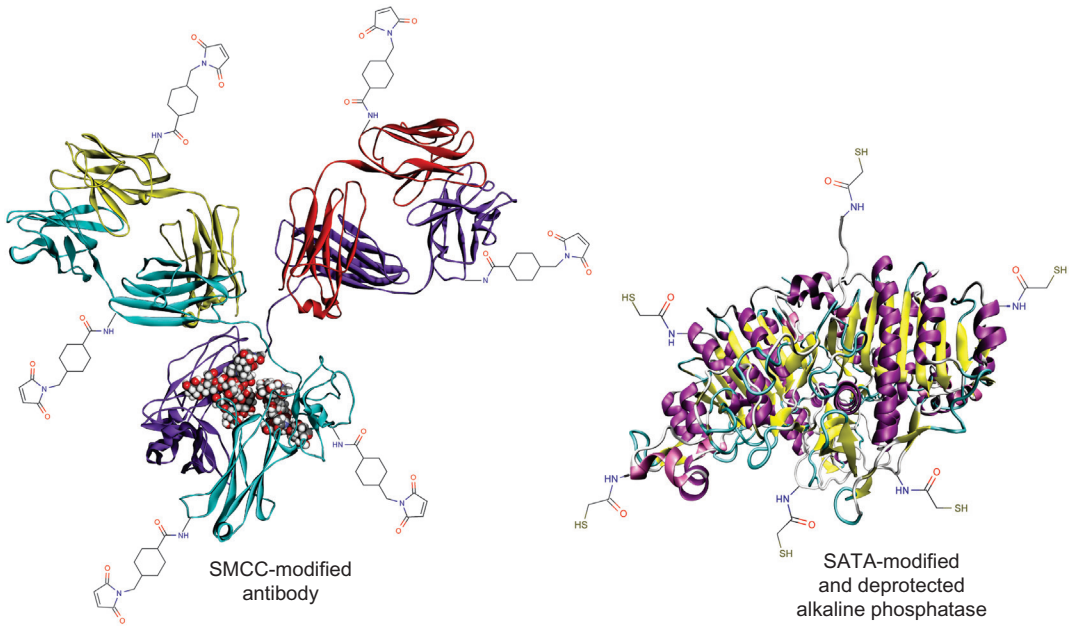

FIGURE 1.34 An antibody modified with aliphatic SMCC linkers and alkaline phosphatase modified with SATA create aliphatic modification sites sticking out of both molecules.

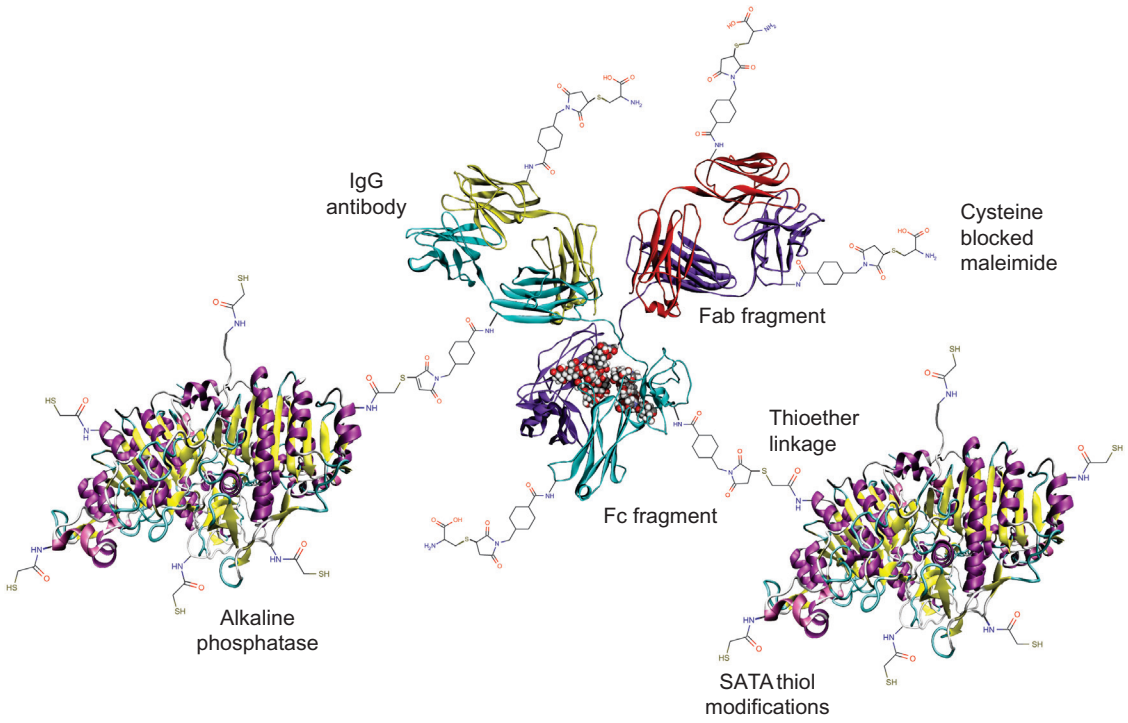

FIGURE 1.35 An antibody–alkaline phosphatase conjugate made using SMCC and SATA. The final conjugate has numerous dead-end linkers sticking out of both components, which can cause nonspecific binding in assays or aggregation of the conjugate in solution.

media. However, after the conjugation reaction is complete many of the modification sites on the antibody and enzyme remain unused. This leaves unreacted SMCC or thiolation modifications on both the antibody and the enzyme protruding off the final conjugate and forming hydrophobic interaction sites (Figure 1.35). Though the reactive groups on the ends of these reagents usually are blocked to prevent subsequent unwanted covalent reactions, the aliphatic groups sticking out from the conjugate remain.

The use of discrete PEG-based crosslinkers and thiolation reagents in place of the standard aliphatic compounds can create a completely different situation. The modification of an antibody with an NHS-$(PEG)_n$-maleimide compound forms a thiol-reactive intermediate that contains hydrophilic PEG-based spacers. This intermediate actually is more water soluble than the initial antibody, especially when using PEG chains of equal length or longer than PEG_4. Similarly, the modification of the enzyme component with a PEG-based thiolation reagent forms an intermediate containing hydrophilic PEG spacers sticking off the enzyme. Once the activated antibody is mixed with the thiolated enzyme to form the final bioconjugate, the excess modification sites sticking off both components of the complex are all hydrophilic, not hydrophobic. Thus, bioconjugates made from discrete PEG-based reagents end up being more water soluble and less likely to interact nonspecifically with surfaces in assays or bind nonspecifically with other biomolecules present in samples.

3.2. Detection, Tracking, and Imaging

A second major application area for bioconjugate techniques is in the detection, tracking, and imaging of biomolecules. In many ways, this area is closely related to the use of bioconjugates for assay and quantification, but in this case the purpose is to reveal the presence or location of a target molecule, not necessarily to quantify it. Methods in this area typically involve the identification of biomolecules within cells, tissues, or in organisms using bioconjugates composed of a targeting component conjugated to a detection component. It also includes semi-quantitative analysis of specific biomolecules after electrophoretic separation and blotting, such as in the chemiluminescent detection of proteins on western blots using antibody–enzyme conjugates. Bioconjugates used in detection, tracking, and imaging have driven the rapid growth of techniques like immunochemical staining, fluorescence microscopy, and high content analysis (HCA), which have become crucial for advancing an understanding of cellular biology. They also form the most important new technology platforms for performing *in vivo* imaging for diagnostics or therapeutics, which are a significant part of the overall medical imaging market estimated to be close to $6 billion worldwide

(Bergin, 2009). The specific applications of bioconjugates for therapeutics and immune modulation will be discussed in greater detail in Section 2.4 of this chapter.

The most frequently used targeting molecule for detection, tracking, or imaging is an antibody or antibody fragment with specificity toward a desired target molecule in a cell or tissue. Tens of thousands of antibodies now are commercially available with defined specificity and many of them have validated data that prove their utility for a particular application. Conjugation of such antibodies with the appropriate detector molecule can facilitate its use in specific imaging techniques (Chapters 10 and 20). Often, however, the primary antibody is available in quantities too small and at price points too high to economically prepare a conjugate from it. In this case, a secondary antibody conjugate can be used to detect the primary antibody in an imaging application. Another convenient alternative to making a primary antibody conjugate is the use of a biotinylated primary antibody, which can then be detected using a labeled streptavidin conjugate (Chapter 11). The use of secondary antibody conjugates or streptavidin conjugates is the most popular strategy for detecting a primary antibody in detection, tracking, and imaging applications.

In addition to antibodies, targeting molecules can consist of synthetic or small biological affinity binding molecules such as peptides or aptamers as well as active-site probes for enzymes or ligands that are able to interact with certain receptors. Some targeting agents can be molecules that are naturally taken up by cells, such as transferrin, which is taken up more readily by tumor cells than normal cells due to the cells' rapid growth characteristics. Some bioconjugates designed for use in cells have been labeled with short peptide sequences that facilitate rapid uptake by cells, such as trafficking molecules, which shuttle other attached molecules to specific cellular organelles or locations (Morris *et al.*, 2008). Also, certain small molecule drugs with known intracellular targets can be used to deliver a detection reagent to a specific site within a cell (Figure 1.36).

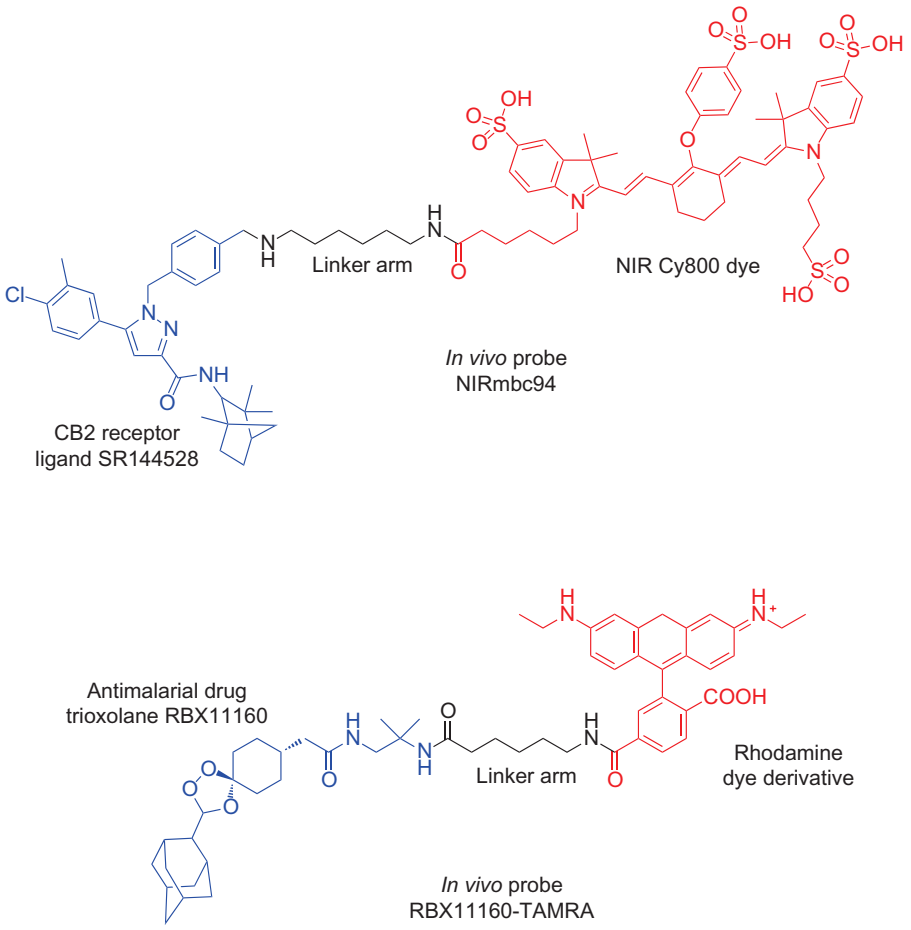

FIGURE 1.36 Two examples of bioconjugates designed for NIR fluorescence *in vivo* imaging. The reagent on the top contains a CB2 receptor affinity ligand that will bind to the receptor sites on cell surfaces and a carbocyanine 800-nm dye with absorbance and emission characteristics well within the NIR region of the spectrum. The probe on the bottom contains an antimalarial drug as the targeting component and a rhodamine dye, which emits within the red region of the spectrum.

Fluorescently labeled pharmacophores represent a novel method for imaging cellular compartments or locals through known drug–target interactions (Uhlemann *et al.*, 2007; Leopoldo *et al.*, 2009). Often, drug candidates have been studied for their mode of action by fluorescently labeling the drug and observing the site of interaction *in vivo*. Using established drug–target interactions is an excellent way of delivering fluorescent signatures directly to specific locations within cells.

The detection module conjugated to detection, tracking, or imaging probes can consist of many different traceable components, such as fluorescent labels, enzymes, radiolabels, high-contrast agents, nanoparticles, intermediary biotin–(strept)avidin reagents, synthetic scaffolds such as dendrimers or fullerenes, carbon nanotubes, or fluorescent fusion proteins (Figure 1.37). Some of these detection modules are identical to those used in bioconjugates for applications in assay and quantification, but some traceable components are unique to the imaging field. For instance, gold-labeled targeting molecules (Chapter 14, Section 6) can be used as high-contrast agents to visualize antigen locations in tissue sections or cells. Detection of such nanoparticle gold conjugates is particularly effective by electron microscopy, as precise locations of each particle can be imaged. Similarly, nanoparticle quantum dots (QDs) (Chapter 10, Section 10) can be used to label a targeting molecule and provide stable and intense fluorescent signals of target molecule locations within cells. QD-labeled antibodies are becoming a popular choice for detection and probing of western blots, because several different conjugates can be used simultaneously to image different protein targets. Each antibody–QD conjugate used in this type of system has its own unique fluorescence emission signature, thus ensuring that each target can be determined independently of the other probes and targets.

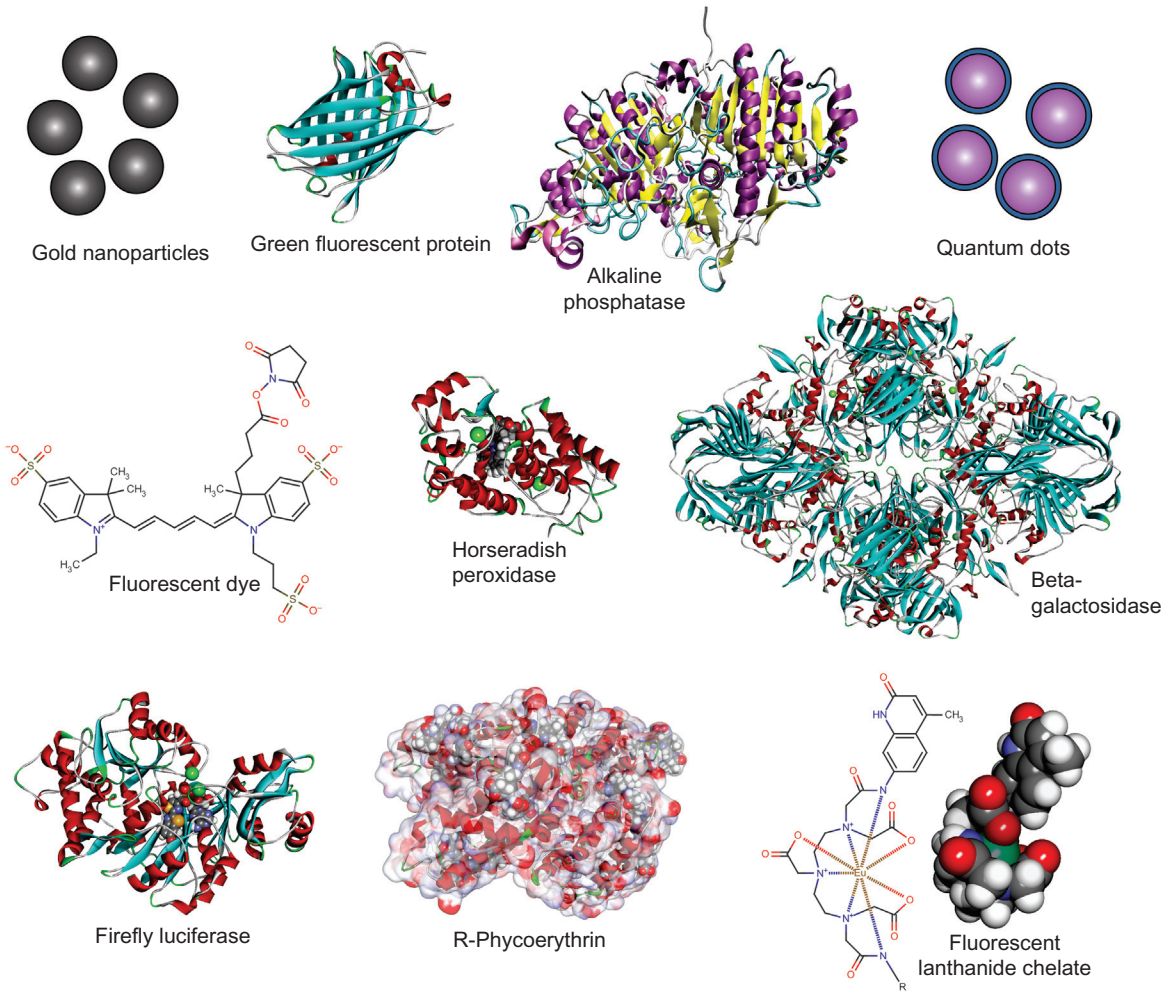

FIGURE 1.37 Common detection agents used in bioconjugates include gold nanoparticles, fluorescent proteins such as GFP, alkaline phosphatase, quantum dot nanocrystals, fluorescent dyes, horseradish peroxidase, beta-galactosidase, luciferase bioluminescence, phycobiliproteins, and fluorescent lanthanide chelates.

Fluorescently Labeled Antibodies and Streptavidin

Perhaps the most common bioconjugate used for cellular imaging is a fluorescently labeled antibody. Fluorescence microscopy has become a standard technique for studying cell biology, and the use of fluor–antibody bioconjugates is an essential tool in this process. Fluorescence detection and the reagents associated with this technique are discussed in Chapter 10. Fluorescent labels consisting of organic molecules, metal chelates, or nanoparticles are able to provide sensitive detection for imaging specific antigen targets within cells (Figure 1.38). A bright fluorescent label conjugated with a highly specific targeting agent, such as an antibody, can yield pertinent information on the biological state of a cell, including expression levels, post-translational modifications on proteins, cellular trafficking (translocation), morphology, and phenotype. The most common antibody used for

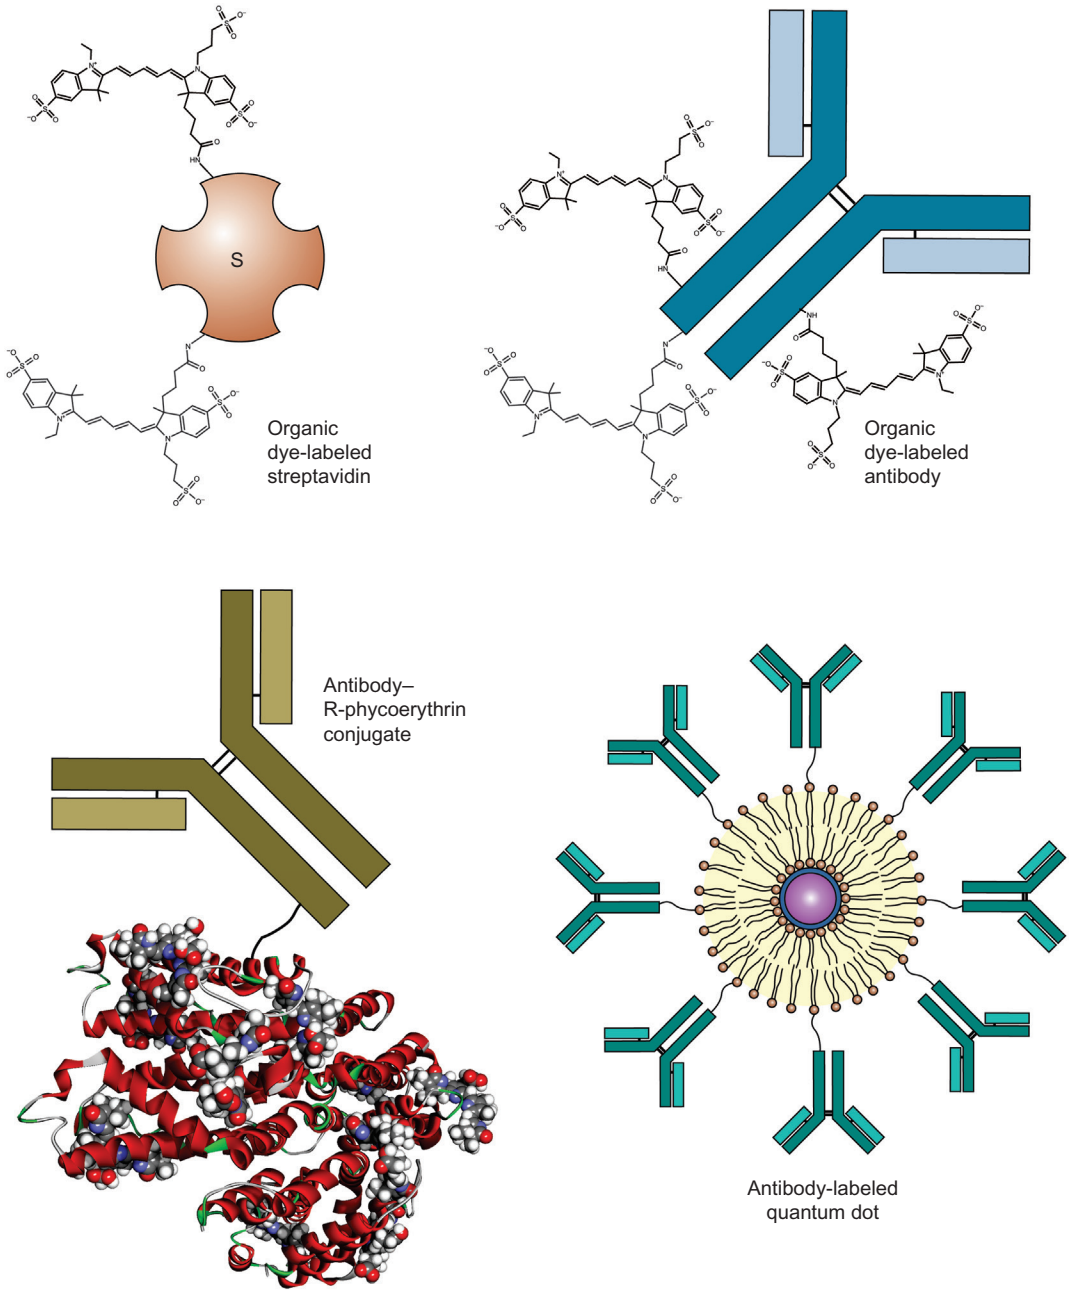

FIGURE 1.38 Fluorescent bioconjugate reagents are among the most common detection constructs used for cellular imaging. Popular conjugates include fluorescently labeled streptavidin, fluorescently labeled antibodies, antibody–phycobiliprotein conjugates, and quantum dot conjugates with specific antibodies attached.

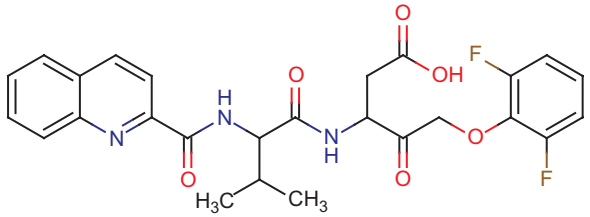
these techniques is a secondary antibody, which can target a primary antibody that has bound to a cellular target. Alternatively, a fluorescently labeled streptavidin bioconjugate can be used to target biotinylated primary antibodies. The use of secondary antibodies or streptavidin conjugates avoids the expense of having to purchase or prepare a fluorescently labeled primary antibody. This layered detection approach using a primary antibody followed by a fluorescently labeled secondary reagent also provides greater fluorescent signal than a primary labeled reagent alone in cellular imaging applications. In practice, most of these fluorescently labeled reagents are used to probe fixed and permeabilized cells and through the permeabilizing treatment are able to accommodate the molecular size of the fluorescent bioconjugate to access virtually any areas within the cells. The only exception to this perhaps involves some antibody–nanoparticle conjugates, which can have diameters greater than 50 nm and thus may have limited access to some small intracellular spaces.



FRET Based Protease Probes

Bioconjugate imaging agents have also been developed to assess the activity of proteases within cells, including the use of molecular beacons (see Section 1.1, this chapter). These are typically fluorescently labeled at one end and labeled with a quencher molecule at the other end, and contain a protease-specific peptide sequence in the middle. These probes generate a fluorescent signal only if the cell has a protease active which has specificity for cleaving the peptide sequence. For instance, the peptide might consist of a caspase-specific sequence containing an aspartic acid cleavage point. This type of bioconjugate probe can be used to determine if a cell is undergoing apoptosis and therefore if caspases are activated (Edgington *et al*., 2009). Before it encounters a caspase enzyme, the probe essentially is nonfluorescent due to the presence of the quencher molecule attached to the other end of the peptide (FRET quenching). However, as the activated caspases of the apoptotic cascade cleave the labeled peptide probe, the fluor and the quencher are separated and released into the surrounding cytoplasmic solution, and the FRET quenching process no longer occurs. The result is the generation of a fluorescent signal proportional to the amount of caspase enzymes activated within the cell or tissue. This type of molecular beacon assay is a powerful indicator of programmed cell death.

Caspase bioconjugate probes can also be designed with a fluorescent tag, a short peptide recognition sequence for binding to the enzyme, and a reactive warhead end, which covalently couples to the active site upon binding (Ekert, 1999; Amstad, 2000; Bedner, 2000; Smolewski, 2001). This type of bioconjugate has been made using NIR dyes to image tumor cells *in vivo* that are undergoing apoptosis after drug treatment (Griffin *et al*., 2007; Cursio *et al*., 2008, 2009; Delgado-Martín *et al*., 2009; Erman *et al*., 2009). Other fluorescent dyes can also be incorporated into the probes for use in cell-based imaging or flow cytometry applications. The reactive warhead end of the probe can consist of a fluoromethyl ketone (FMK) group that is highly efficient at covalent coupling to the thiol in the active site of the large subunit of the caspase heterodimer. The warhead end may also be made of a 2,6-difluorophenoxy-methyl ketone group, which has been shown to have even greater binding potential with the active site thiol of caspases (Melnikov *et al*., 2002; Southerland *et al*., 2010) (Figure 1.39). Unlike caspase molecular beacon probes, these types of active site conjugation probes do not catalytically generate a fluorescent species due to enzyme cleavage of a peptide, but in this case a fluorescent active site binder stays within the cells while excess probe is removed either by washing (for cell-based imaging) or through removal by the kidneys or liver (for *in vivo* imaging). Animal imaging studies have resulted in excellent tumor cell localization using NIR imaging at wavelengths from 680 to 900 nm, which penetrates tissue to at least several centimeters to excite the bound fluorescent probe.

Interacting Proteins or Domains

Another targeting component that can be used for specific cellular targeting is an interacting protein or a peptide domain, which is able to bind to another protein through native biospecific interactions (Pawson and Nash, 2003). This can also include an interacting protein that only binds to the activated state of the target protein, such as after a phosphorylation event has occurred. Proteins within cellular pathways have specific interacting partners and one of these proteins can be used in this manner to detect its partner. An example of this type of bioconjugate is the use of a fluorescently labeled Src homology 2 (SH2) domain, which is able to recognize and bind to certain phosphotyrosine sites in receptor tyrosine kinases (Hanke and Mann, 2009; Major *et al*., 2009). In addition, downstream effector molecules or domains have been used to target activated GTPases, such as the Raf1 binding domain that binds to activated Ras or the Pak1 p21 binding domain, which binds to activated Rho (Smith *et al*., 2008). Using a labeled bioconjugate of an interacting protein can reveal the precise locations of the activated target within the cell and yield information regarding the differences between a diseased cell and a normal one or a treated cell *versus* an untreated one. Yaoi *et al*. (2006) developed a fluorescent bead-based assay using a library of different SH2 domains that can target

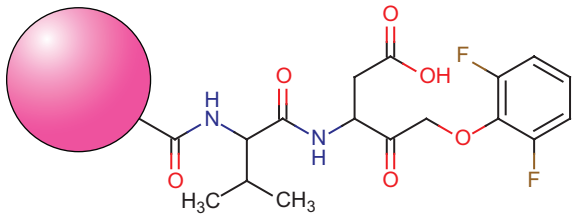


FIGURE 1.39 Two fluorescent warhead probes designed to detect caspase enzymes include a quinoline-labeled valine–aspartic acid (VD) probe, which can bind to the active site on caspases and covalently link to it by reaction of the difluorophenoxy-methyl ketone group. This type of probe can be designed to include NIR fluorescent tags for better signal penetration through tissue.

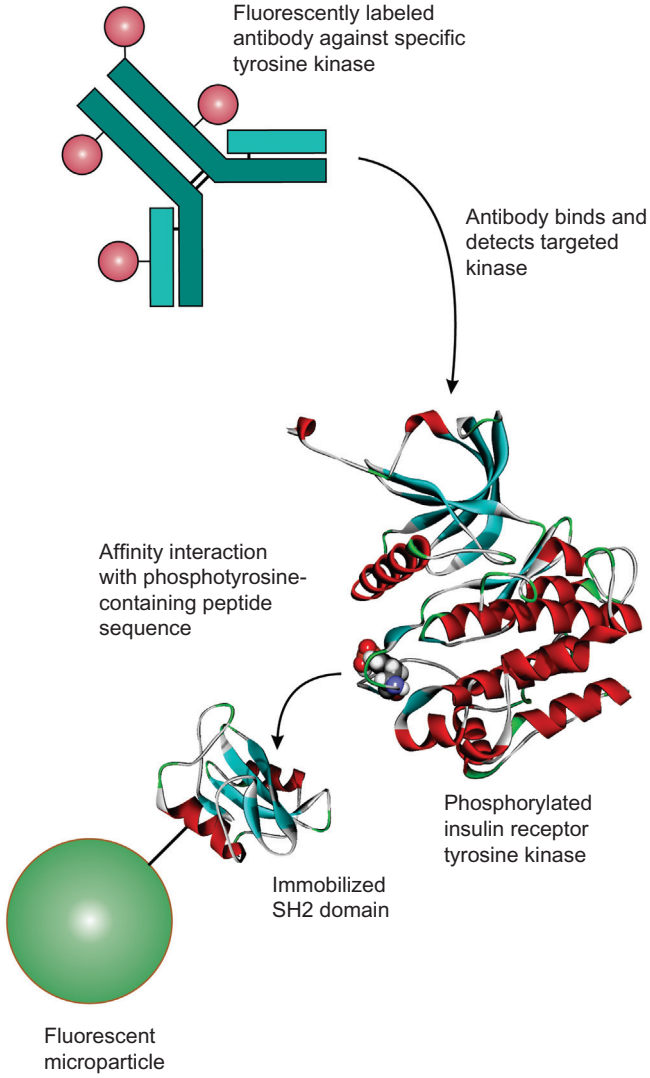

FIGURE 1.40 A fluorescent bead-based affinity assay can be designed using an immobilized protein or protein domain, in this case SH2 domains, to specifically capture phosphorylated tyrosine kinases and detect them using a fluorescently labeled antibody directed against the kinase enzyme.

specific activated tyrosine kinases. This system was able to globally profile tyrosine kinase pathway activation in cell extracts (Figure 1.40).

Probing by Chemoselective Ligation

A recent conjugation strategy that is highly suitable for real-time detection within living cells is the use of *in vivo* labeled proteins or carbohydrates using non-natural amino acid or sugar derivatives (Codelli *et al.*, 2008; Laughlin *et al.*, 2008; de Graaf *et al.*, 2009). These amino acid analogs contain unique reactive groups that can facilitate subsequent bioconjugation with detection or affinity components. Certain amino acids and sugars can be derivatized to contain relatively small functional groups that still allow them to be used with the intracellular translational machinery or carbohydrate biosynthesis enzymes, thus placing these modified residues within newly synthesized proteins or glycans. Cells grown in the presence of a limiting amount of the non-natural amino acid or sugar derivatives will slowly begin incorporating such modifications into proteins, carbohydrates, and glycans. However, an important criteria for success using this strategy is that the reactive groups appended onto the amino acids must be nonreactive with other biological molecules and also be non-toxic to the cells; otherwise, they would react and covalently attach to biomolecules or affect cell viability and potentially cause cell death. Some examples of non-natural amino acids and sugars are shown in Figure 1.41 and include groups such as azides, alkynes, or aryl ketones modified onto the side chains or derivatized off one of the carbon atoms of a monosaccharide. Many other amino acid and sugar derivatives can be used for this purpose; for an excellent review, see Sletten and Bertozzi (2009).

Proteins or glycans containing these non-natural amino acids or sugars can be targeted for detection using reagents containing another reactive group that will only conjugate with the functionality on the

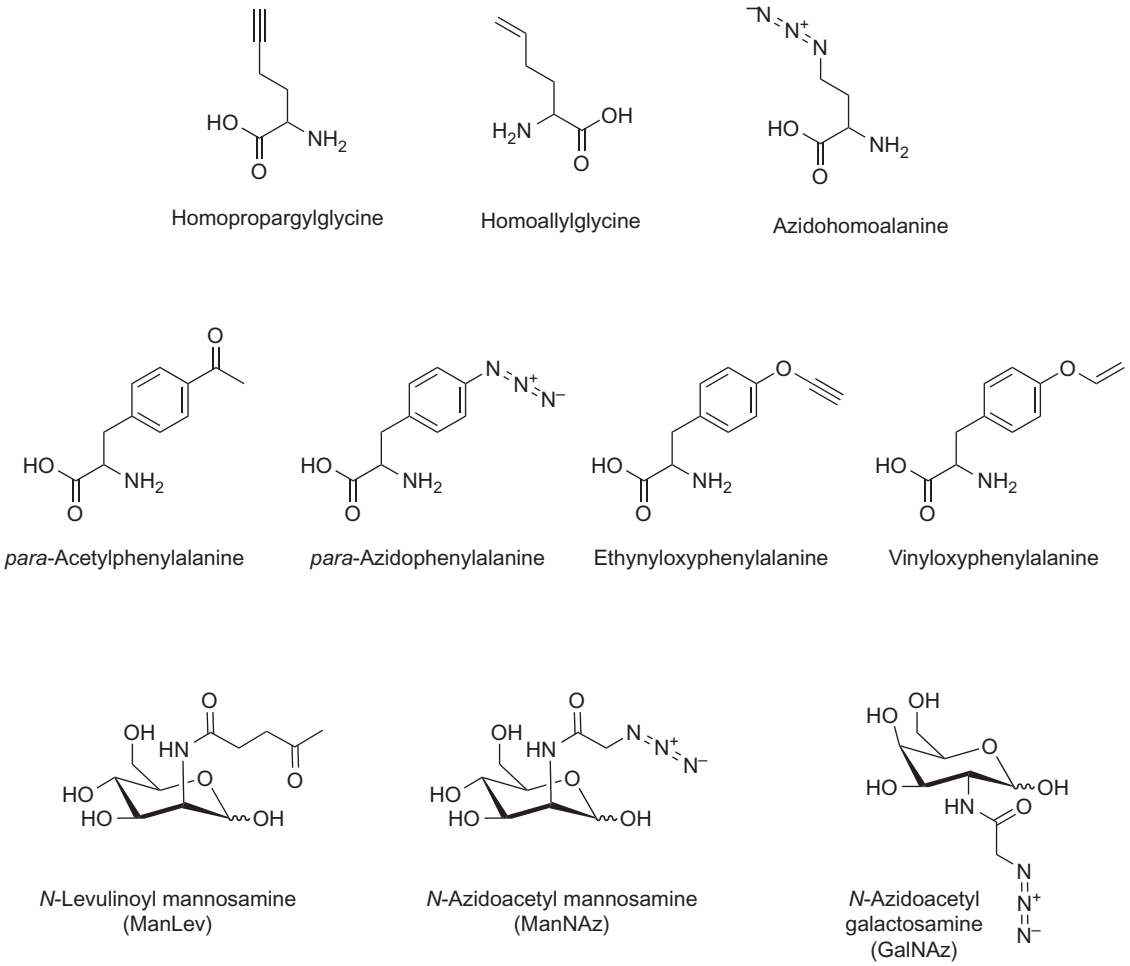

FIGURE 1.41 A number of amino acid and sugar derivatives have been synthesized to contain functional groups able to participate in a chemoselective ligation reaction with a detection reagent. For example, the alkyne-containing amino acids can be used as additives in depleted media to grow cells and incorporate these analogs into proteins within the cells. The alkynes can then be reacted with azide-containing detection reagents to covalent link to these sites by forming a triazole ring. Alternatively, the azide-containing compounds may be incorporated similarly into proteins or carbohydrate components of cells and reacted with an alkyne-containing reagent in a click chemistry reaction or a phosphine derivative in a Staudinger ligation reaction to specifically label the proteins or glycans containing the azido groups.

non-natural component. Such "bioorthogonal" reactions (see Chapter 17) can be used to create bioconjugates within the complex milieu of a cell or a cell lysate without cross-reactivity with other biological components. In this manner, modified glycoproteins have been targeted and imaged using fluorescent dyes containing a complementary bioorthogonal reactive group (Baskin *et al*., 2007).

There are a number of bioorthogonal reactions that can be used for detection, tracking, and imaging purposes. These include click chemistry, Staudinger ligation, hydrazide–aldehyde reactions, aminoxy–aldehyde reactions, and others (Chapter 17). For detection within live cells, the copper-free click chemistry option is perhaps the best choice, because of its rapid reaction kinetics and the components are relatively nontoxic to cells. The only deficiency of the cyclooctyne chemistry is the potential of the triple bond to react with other nucleophiles within biomolecules, especially free thiols. However, the copper-catalyzed click reaction with an alkyne group can be used to fluorescently label azido amino acids or azido sugars with greater specificity, as long as cell viability is not an issue. Figure 1.42 illustrates the use of a fluorescent rhodamine–alkyne probe to detect azido-labeled glycans on cell surfaces. This particular alkyne compound was originally synthesized by Beatty (2008) and used to image azido amino acids within cells. For imaging within fixed and permeabilized cells, a broad spectrum of other bioorthogonal chemistry approaches may also be used, since cell viability is not an issue.

Proximity Ligation Assays

Detection and imaging within fixed cells can also be done with extraordinarily high sensitivity using unique

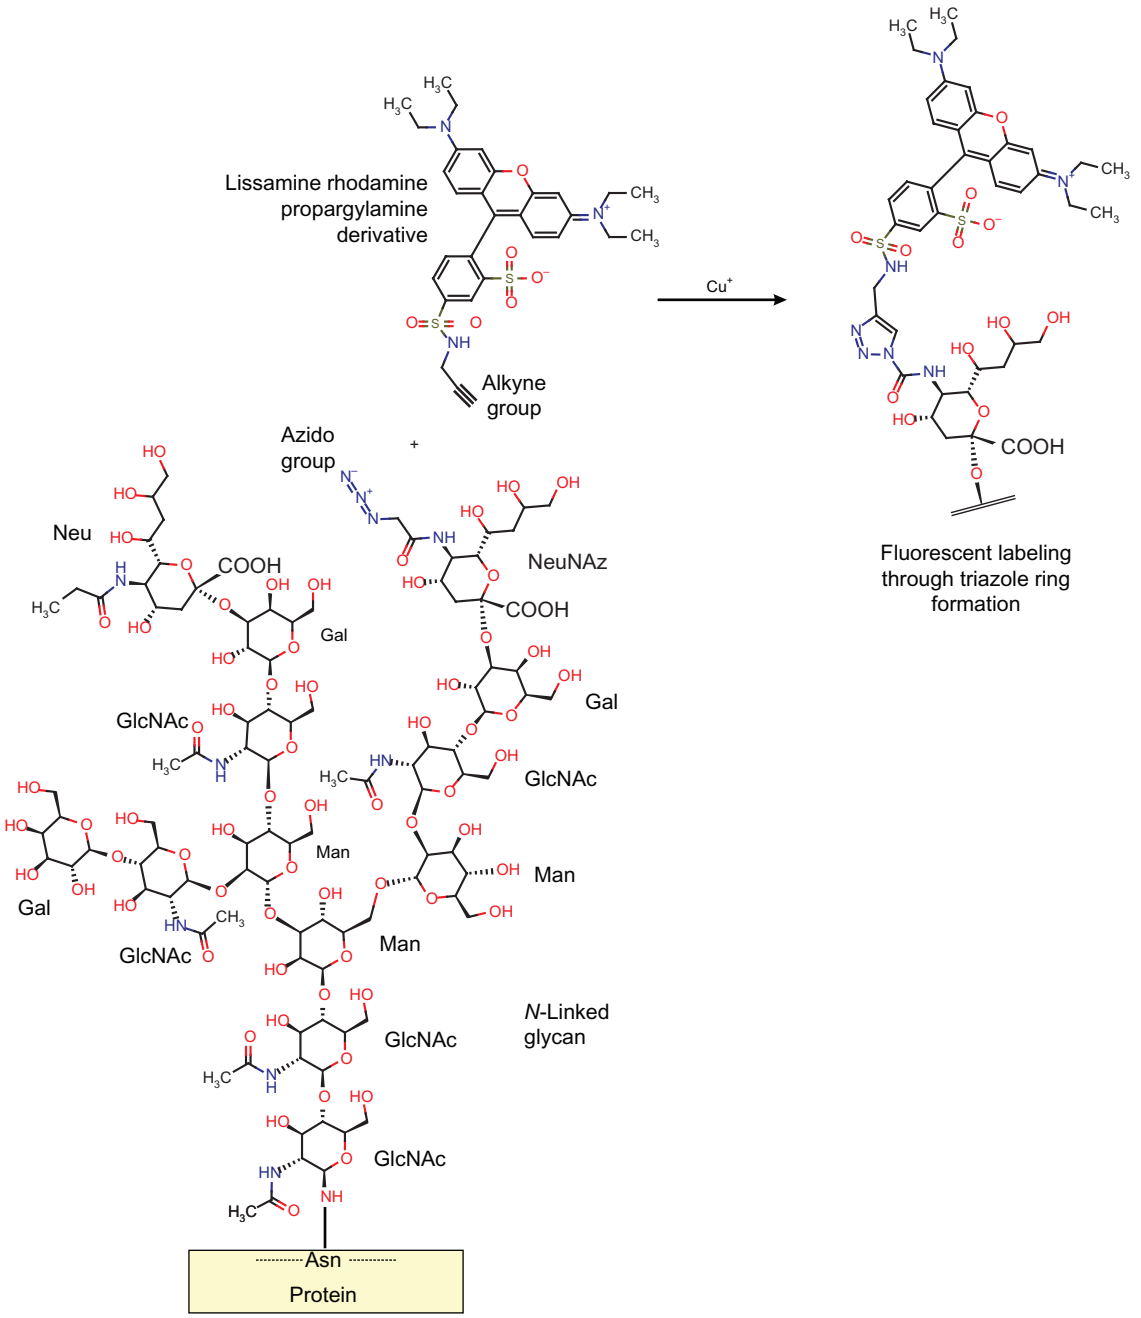

FIGURE 1.42 An illustration of the labeling of an azide-containing glycan on a cell surface glycoprotein or glycolipid with an alkynyl–rhodamine derivative to fluorescently tag the modified carbohydrates.

oligonucleotide bioconjugates in a process called a "proximity ligation assay" (PLA) (Fredricksson *et al.*, 2002; Gullberg *et al.*, 2004; Jarvius *et al.*, 2006; Söderberg *et al.*, 2006). The bioconjugates used in this detection method are capable of visualizing individual cellular events such as discrete protein–protein interactions or the activation of a particular protein through phosphorylation (Jarvius *et al.*, 2007). The reagents used for PLA consist of two main conjugates, each containing a targeting molecule attached to a tether consisting of a terminal synthetic oligonucleotide, which acts as the reporter (Olink Bioscience). The targeting molecules typically are two different secondary antibodies directed against two different primary antibody types (species specific). The primary antibodies that are chosen for an assay are directed against two different targets or epitopes within the cell and can consist of antibodies that are able to bind to particular proteins or interact with any other cellular components desired to be detected. In addition, PLA targeting molecules can

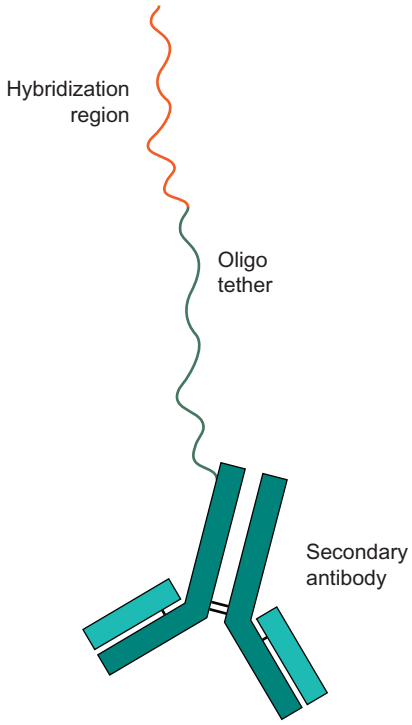

FIGURE 1.43 A proximity ligation assay (PLA) conjugate can be created by covalently linking an oligo tether containing a uniquely designed hybridization region to an antibody specific for a particular target molecule. Secondary antibodies may also be used as part of the bioconjugate to make more universal detection reagents for any appropriate primary antibody.

also be specific oligonucleotide probes that can bind to target DNA or RNA sequences within the cells. Figure 1.43 illustrates the components of a PLA bioconjugate for antibody-based reagents.

The PLA method first involves the binding of the targeting bioconjugates containing the attached oligo tethers with their targets within a cell. If the binding events occur in sufficient proximity, such as in the binding of labeled primary antibodies to a protein within a cell (Figure 1.44), then the oligo tethers on each conjugate are maintained within molecular distance of one another. A second set of synthetic oligos is added to the assay that are able to hybridize with the ends of the oligo tethers and form a circular DNA structure containing some double-stranded features at the points in which they interact with the tethers. The circle that is created is ligated together by adding ligase enzyme and then amplified using polymerase enzyme and deoxynucleotide triphosphates in an isobaric rolling circle amplification process that forms a long repeating complementary oligonucleotide sequence in the immediate vicinity where the initial binding event took place. This amplified piece of DNA is finally detected by adding a third bioconjugate consisting of a fluorescently labeled short oligonucleotide, which is able to hybridize repeatedly along this long amplified strand. The fluorescent signal generated by this detection process is produced through multiple fluor–oligo bioconjugates docking at the site of the targeted molecules, thus resulting in an intensely bright signal of high sensitivity. The resultant fluorescent spots created within a cellular image are about 500 nm in diameter and effectively localize the targeted molecule or interacting proteins with highly discrete signals.

PLA detection methods thus can result in the imaging of individual events within a cell, and the fluorescence signals produced in cell-based imaging amount to numerous discrete spots associated with the amplified DNA at the site of each targeted molecule. Unlike the diffuse signals obtained when using fluorescently labeled antibodies to detect targets within cells, the PLA process produces dots of fluorescence, which can dramatically improve imaging, localizing, and tracking of biomolecules (Figure 1.45). It is likely that this technique permits sensitive assays down to the single molecule detection level for cellular imaging.

Staining with Antibody–Enzyme Conjugates

One of the oldest methods for detecting markers within cells and tissues involves specific immunohistochemical (IHC) staining using antibody–enzyme conjugates. Bioconjugate reagents for IHC were among the first developed for imaging disease from biopsies within thin tissue sections mounted on microscope slides. The pathology market that still extensively uses these bioconjugates for diagnostic testing is crucial for assessing the presence of cancer and other diseases within millions of patients worldwide. The bioconjugates designed for this purpose are constructed virtually the same as those used for ELISA or western blotting applications. The typical targeting components are antibodies, but they must be validated for activity and specificity toward the target of interest. It often takes a trained pathologist to validate the specificity of IHC reagents for targeting and staining the proper antigens within a tissue section. The enzymes usually used for detection are horseradish peroxidase (HRP), alkaline phosphatase, or β-galactosidase, which can all form chromogenic or fluorescent products from turnover of specific substrates. In addition, since the initial substrate is added to the IHC process as a soluble molecule in a buffered solution, the detectable product of the enzyme reaction must be insoluble or it would diffuse away from the site of target interaction. The result of a positive signal in IHC type bioconjugate assays is a dark colorimetric stain or a bright fluorescent signal marking the sites of antigen targets within the tissue section. Figure 1.46 illustrates the use of antibody–enzyme bioconjugates in an IHC staining process.

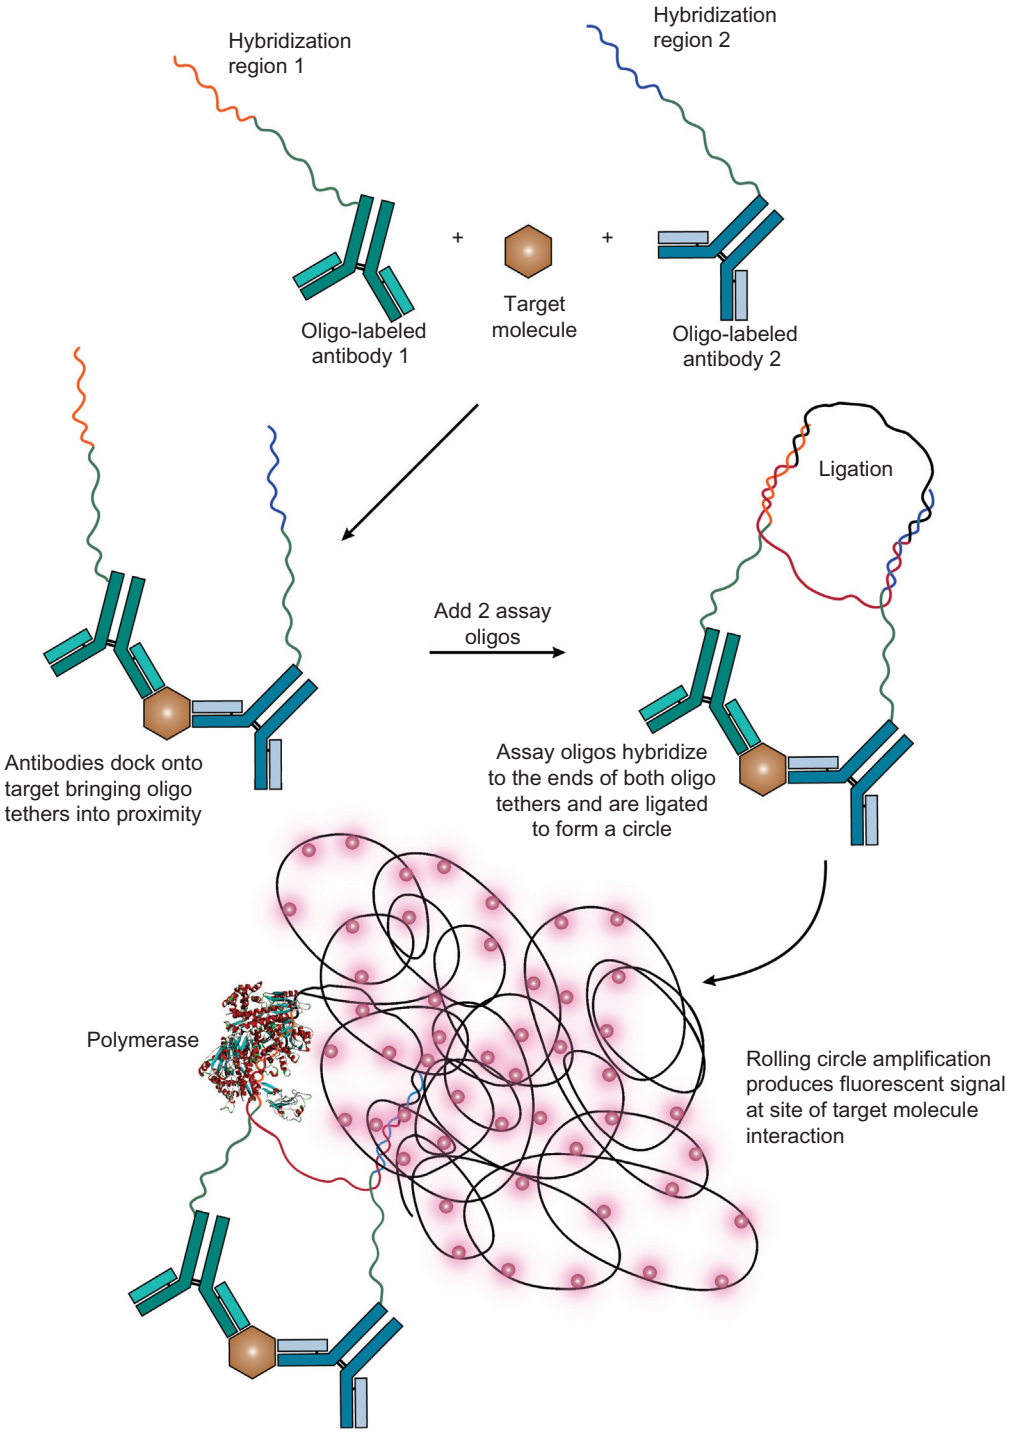

FIGURE 1.44 A proximity ligation assay (PLA) can be done using two oligo-labeled antibodies directed against two separate regions of a target protein (or against two different proteins interacting together). The antibody conjugates are mixed with a sample containing the target and allowed to bind. Assay ligation oligos are then added that are capable of hybridizing to selected regions on the oligo tethers on each antibody. If both antibodies have bound to their target, then the oligo tethers are held in proximity and the ligation oligos can be ligated together to form a circle. At this stage, a polymerase enzyme is added along with the appropriate deoxynucleotide triphosphate molecules to perform an isobaric rolling circle amplification reaction, which replicates the complementary sequence to the circular DNA strand over and over again. Finally, fluorescently labeled detection oligos are added that can hybridize to the amplified DNA and create an intense fluorescent signal at the site of the targeted protein.

Bioconjugates for Western Blot Detection

In an immunoassay detection procedure similar to IHC staining, western blots can be specifically probed using antibody–enzyme bioconjugates with subsequent highly sensitive chemiluminescent detection. Secondary antibody–enzyme conjugates and streptavidin–enzyme conjugates are the two most common reagents for developing western blots. In this application, a protein sample is separated by molecular weight using SDS polyacrylamide gel electrophoresis (PAGE) and the separated proteins are then transferred from the gel to a membrane for immunochemical probing. The combination of protein separation by mass combined with specific protein targeting and detection using antibodies provides a powerful confirmation for the presence of a particular target.

Typically, a primary antibody is used to initially bind the target protein on the blot. After washing off excess antibody, the secondary antibody–enzyme conjugate is added for the detection process. Alternatively, if the primary antibody is biotinylated, then a streptavidin–enzyme conjugate can be used for detection; however, if the primary antibody is not biotinylated, then a secondary antibody–enzyme conjugate is used. After another thorough wash step, a substrate solution is then added to develop a signal at the site of antibody binding (Figure 1.47). The substrate used for this process is usually one of two types: a precipitating substrate or one that creates a chemiluminescent signal as the result of enzyme turnover. Enzymatic chemiluminescence is by far the most widely used detection scheme in western blotting.

The antibody–enzyme or streptavidin–enzyme bioconjugates used to detect proteins in western blots can be prepared using direct conjugation of the two molecules together (zero length crosslinking) or they can be made with bifunctional crosslinking agents. Zero length conjugation is particularly suitable for conjugations made with HRP, as the carbohydrate on the glycoprotein can be oxidized to contain reactive aldehyde groups, which can then be coupled to the targeting molecule using a reductive amination process (Chapter 4, Section 4, and Chapter 20, Section 1.3). Bioconjugation using crosslinkers can also be done effectively using a number of reactive compounds (Chapters 5 and 6). However, the most effective crosslinkers are heterobifunctional reagents, such as the popular sulfo-SMCC (Chapter 6, Section 1.3), and even better are the hydrophilic PEG-based analogs to this compound (Chapter 18, Section 1.2). For increased sensitivity in western blotting applications, an intermediate scaffold can be used in preparing the detection conjugate, which functions to attach a greater number of enzymes onto each targeting antibody (see previous discussion on scaffold molecules).

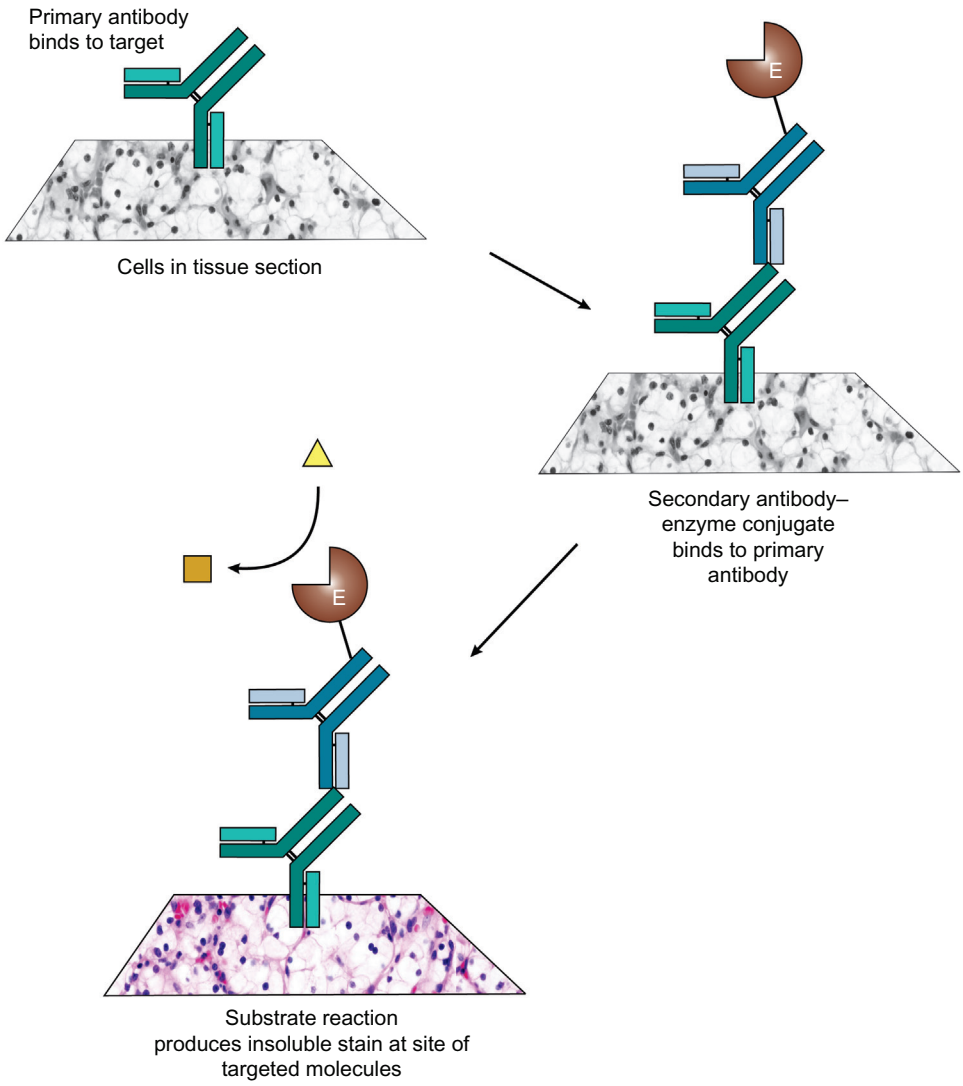

FIGURE 1.46 A secondary antibody-enzyme bioconjugate can be used to detect specific antigenic targets within tissue sections. Immunohistochemical (IHC) staining typically involves the binding of a primary antibody to a given target protein within a tissue section. An antibody–enzyme conjugate is then added that contains an antibody able to bind to the antibody type used as the primary antibody, for instance a goat-anti-mouse antibody used to bind to a mouse monoclonal primary antibody. The enzyme part of the conjugate can be used to develop a specific detectable signal by a substrate reaction, such as a chromogenic or fluorescent product at the site of the primary antibody binding event.

Bioconjugates for Super Resolution Microscopy

Some recent exciting developments in imaging are represented by the super resolution microscopy techniques that use specialized bioconjugates containing fluorescent labels. The fluorophores used in these conjugates typically are switchable from an off to an on state and sometimes back again. The technology behind this revolution in resolving ever smaller cellular components actually allow structures to be resolved that would not be possible using simple light microscopy. At one time, it was believed that due to the diffraction limit of light, the fine macromolecular structures within a cell would never be imaged below about half the wavelength of light used. However, a combination of fluorescence technology and software innovation has now made possible the resolution of cellular structures down to the 20- to 50-nm level and sometimes even within the 2- to 20-nm range (Betzig *et al.*, 2006; Chi, 2009; Huang *et al.*, 2009).

The evolution to super resolution imaging occurred through research into single-molecule fluorescence analysis of biomolecules, which are techniques that isolate a single discrete fluorescent conjugate bound to its target from all other bound fluorescent conjugates in the sample (Klar *et al.*, 2000; Kapanidis and Weiss, 2002). It has now been demonstrated that the position of a single fluorescent conjugate can be determined to extremely high accuracy, provided there are enough photons collected

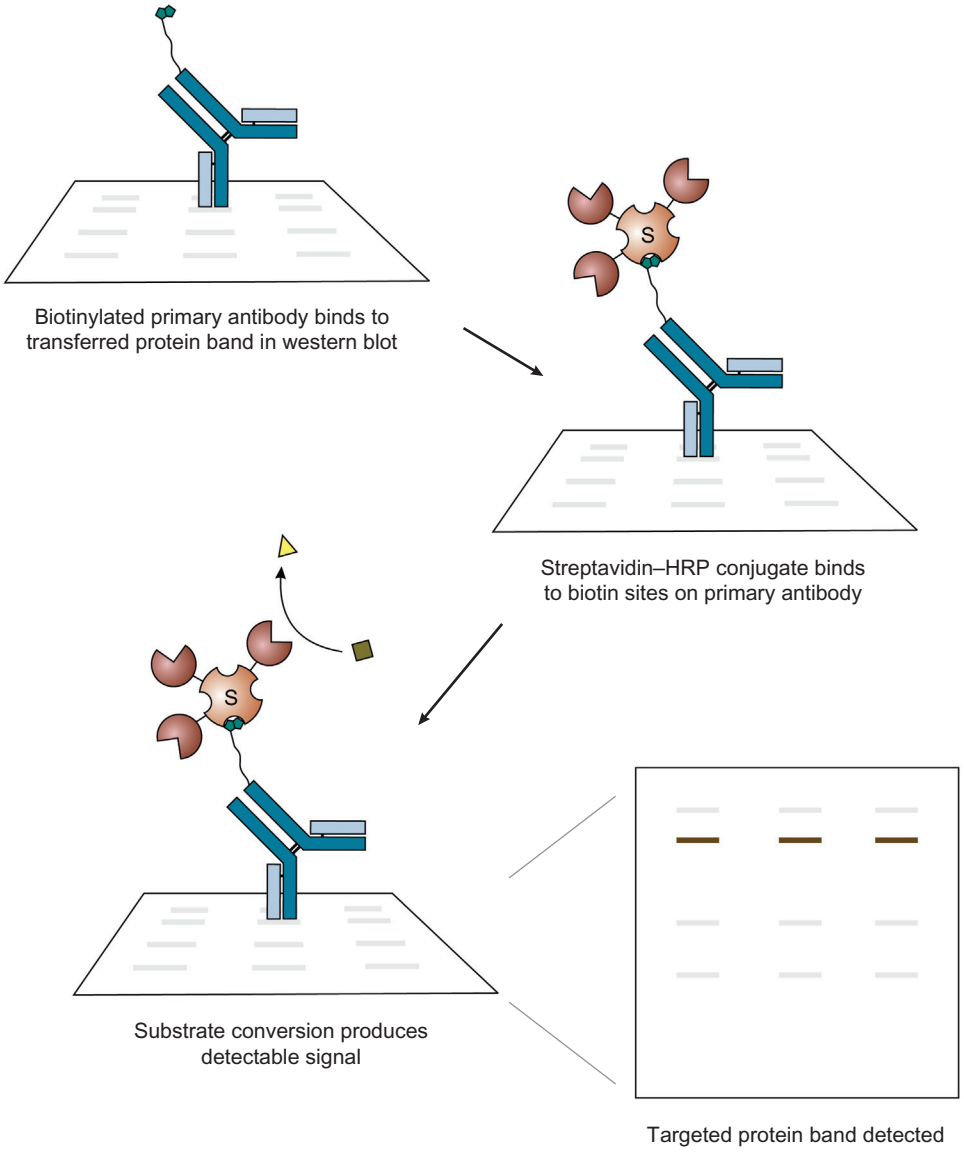

FIGURE 1.47 Bioconjugates used for western blotting purposes are among the most common reagents used in everyday laboratory experiments involving biological research. Proteins are separated by SDS polyacrylamide gel electrophoresis and then blotted over onto a membrane, typically nitrocellulose or PVDF. The transferred proteins can be probed using a biotinylated primary antibody specific for the protein of interest. Next, a streptavidin–enzyme conjugate is added that binds to the biotin groups on the primary antibody. Then a substrate reaction is used to develop a detectable signal at the site of the targeted protein, which can be chromogenic, fluorescent, or chemiluminescent in nature. The most common detection method involves the use of the enzyme HRP in the streptavidin conjugate along with a chemiluminescent reaction using a luminol or acridinium substrate system.

from a precise site of emission (van Oijen *et al*., 1998; Thompson *et al*., 2002; Yildiz *et al*., 2003). Using this technique, an extremely high-resolution image of cellular components can then be constructed from repeated localization of individual fluorescent probes.

There are a number of methods used for super resolution microscopy and each one uses unique bioconjugate designs to make optical imaging at the molecular level possible. Some of the more popular techniques include *fluorescence photoactivated localization microscopy* (FPALM or just PALM), *interferometer photoactivated localization microscopy* (iPALM), and *stochastic optical reconstruction microscopy* (STORM). The FPALM, PALM, and STORM techniques are based on nearly identical principles and were developed simultaneously by Rust *et al*. (2006), Hess *et al*. (2006), and Betzig *et al*. (2006).

FPALM, PALM, and iPALM often use bioconjugates containing photoactivatable fluorescent labels that can be switched from a dark state to a bright emission state by exposure to particular wavelengths of light (Heilemann *et al*., 2005; Betzig *et al*., 2006; Hess *et al*., 2006). The fluorescent molecules used for PALM have

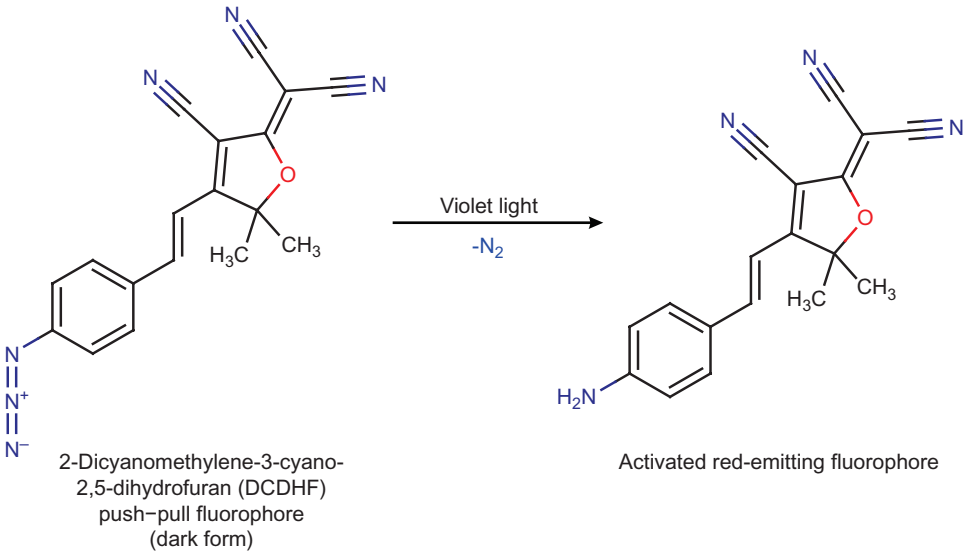

FIGURE 1.48 The photolysis of DCDHF dyes using violet light results in the degradation of the azido phenyl group to form an amine, which creates a red fluorescent dye that can be used to selectively activate bound probe conjugates within a cell for super-high resolution microscopy.

included fluorescent proteins, fluorescent organic dyes (Chapter 10, Sections 1–8), and more recently fluorescent quantum dots (Chapter 10, Section 10) (Pinaud *et al.*, 2010). Initially a probed sample may be completely dark, containing bound labeled conjugates, but none of them capable of fluorescence emission unless activated. In some cases, fluorescent fusion proteins are used that can be switched from a bright to a dark state and back on again. The dark fluorescent labels used in designing bioconjugates for PALM include organic molecules that are quenched by the presence of an azide group attached on an aromatic ring associated with the π-conjugated system of the fluorophore.

One dye family particularly useful for photoactivation and PALM imaging is based on a push–pull design containing an amine donor group on one end and a 2-dicyanomethylene-3-cyano-2,5-dihydrofuran (DCDHF) acceptor group on the other end, which are separated by an electron rich π-conjugated system (Lord *et al.*, 2008, 2009a). The amine group pushes electrons toward the conjugated system, while the cyano groups pull them away at the other end. The electron-withdrawing properties of an azide in place of the amine disrupt the conjugated system and quench the fluorescence while also causing a blue shift in the absorbance spectrum of the dye. The size of the intermediate π system determines the absorption and emission characteristics of the activated fluorescent dye. In super resolution microscopy, the quenched form of DCDHF dyes is relieved when the molecule is irradiated at 407 nm, which results in photolysis of the azide and conversion into the amine (Figure 1.48). This phenylazide group does not ring expand to the dehydroazepine as some other photoreactive phenylazides do, because of the electron withdrawing properties of the cyano groups, which stabilize the intermediate nitrene (Chapter 6, Section 3) (Lord *et al.*, 2008). However, it is possible during nitrene formation that photo-insertion may take place resulting in covalent attachment into C-H or C-C bonds in neighboring biomolecules. This reaction can be used to advantage, as DCDHF dyes could be used to design photoaffinity labeling (PAL) agents that could target a particular active site and become covalently attached and fluorescent upon photoactivation (Lord *et al.*, 2009b). Thus, the fluorescence form of the DCDHF dyes can be revealed with discrete laser pulses at precise locations within a cell during imaging, allowing detection at the single molecule or near single molecule level for highly accurate localization of signals.

The STORM method (Rust *et al.*, 2006), uses fluorescent dye conjugates with targeting molecules (e.g., antibodies), wherein the fluorophores can be switched on and off using exposure to light at particular wavelengths. Unique to this method is the use of dual-labeled conjugates that have two fluorescent probes attached to a single targeting molecule, which are able to initiate a FRET signal between them due to their proximity. It was discovered that certain dyes, for instance the two cyanine dyes Cy3 and Cy5, are able to be turned on and off for dozens of cycles without photobleaching (Figure 1.49). The equivalent dyes that represent more hydrophilic Cy3 and Cy5 derivatives containing additional sulfonate groups may also be used in this type of bioconjugate to decrease nonspecific binding of the dyes to biomolecule structures within cells.

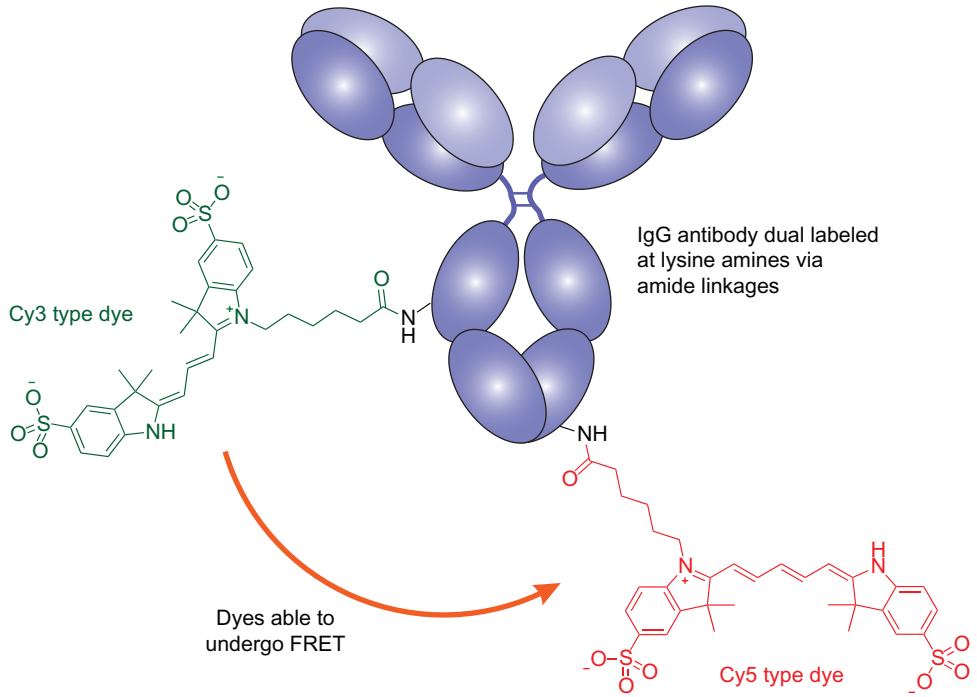

FIGURE 1.49 Dual-labeled antibody conjugates can be constructed to allow FRET signaling between the two carbocyanine dyes attached to a single antibody. This permits on and off switching of the fluorescent emission for use in super resolution microscopy techniques.

The cycling of the emission from dark to bright in such dual-labeled conjugates is essential for isolating one or at most a very limited number of labeled molecules bound to their targets within a cell. Under normal fluorescence imaging conditions using dye-labeled antibodies, the conjugates bound to targets are all excited in mass and what is observed is the average fluorescence signal from many conjugates emitting in combination. In order to determine the position of a single fluorescent probe without interference from other ones, it is necessary to have methods of turning on only a single fluorescent conjugate in the presence of many other conjugates; otherwise, the combined signals would all bleed together and reconstructing their exact positions would be impossible. The dual-labeled conjugates of STORM imaging make this possible by turning on and off the acceptor dye through selective irradiation at certain wavelengths.

In a dual-labeled fluorescent targeting bioconjugate, the acceptor dyes of the FRET pair (e.g., the Cy5-type dye) can be switched to a nonfluorescent state by excitation under non-oxygen-containing conditions in the presence of a thiol. Upon continued excitation at the acceptor dyes' excitation wavelengths, the dyes undergo a reaction to add the thiol compound at a carbon within the polymethine bridge, thus forming a thioether derivative (Figure 1.50). This addition reaction to the double bond reduces a site in the conjugated electron system of each dye to an aliphatic derivative, thus interrupting the conjugated double-bond system and effectively destroying the fluorescence character of the molecules. The Cy5 dyes are therefore no longer able to emit light upon excitation at their normal absorption band and they become dark. However, it was discovered that if the FRET donor dye (e.g., the Cy3-type dye) is excited at its normal excitation peak, it will transfer its energy to the Cy5 dye and restore the acceptor dye's fluorescence characteristics by cleaving off the thiol compound and restoring the original polymethine structure of the dye (Rust *et al.*, 2006). This selective rescue of the acceptor dye fluorescence is the property needed for discrete imaging of single molecule fluorescent conjugates in super resolution microscopy. A discretely focused laser can target and restore fluorescence to dual-labeled conjugates in only a very small area in a cell image, thus ensuring that only one or just a small number of FRET conjugates become fluorescent at a time.

3.3. Purification, Capture, and Scavenging

Another set of important applications where specialized bioconjugates are used involves affinity-mediated enrichment, purification, or scavenging of biomolecules. The immobilization of biospecific affinity ligands onto insoluble resins or other solid support materials makes possible the separation of target molecules from complex solutions, often in a single step (Figure 1.51). Immobilization technology and affinity chromatography originated in the 1960s and '70s using classical

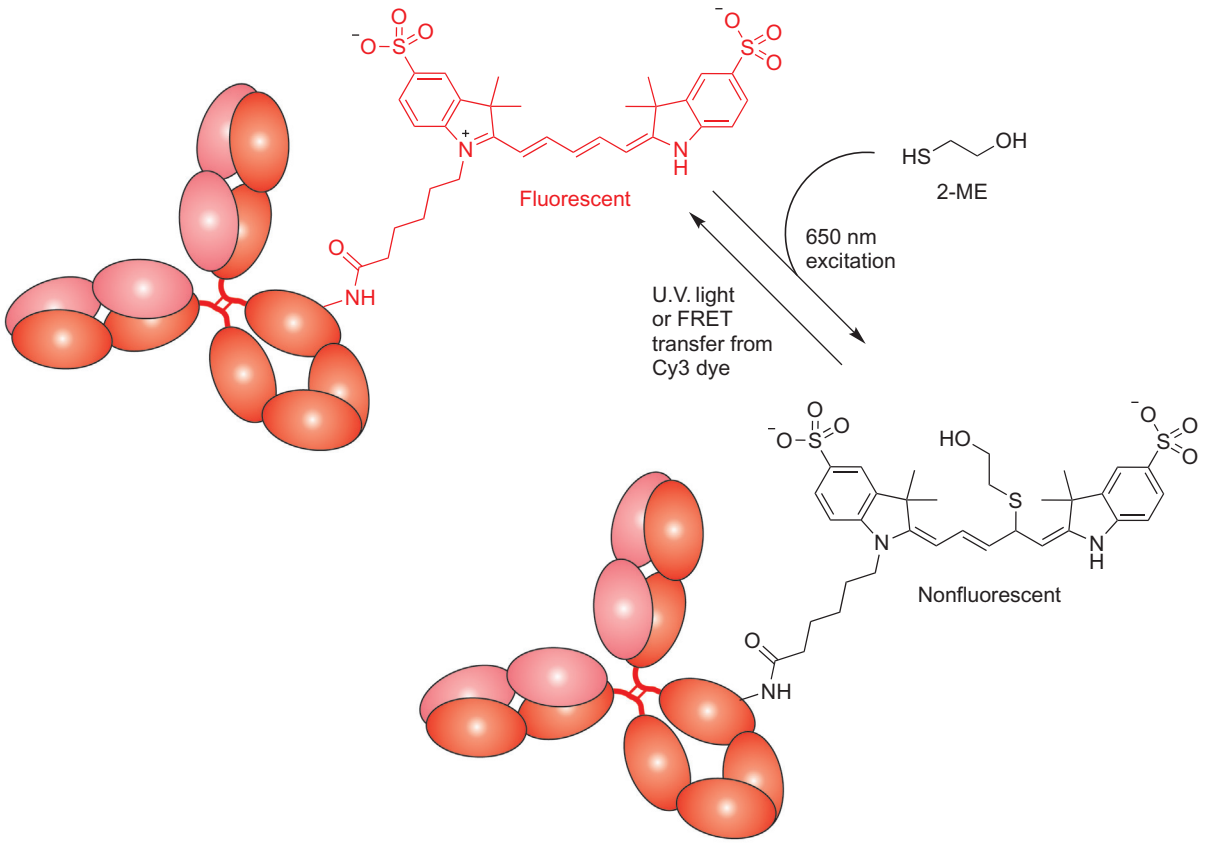

FIGURE 1.50 An antibody labeled with a Cy5-type carbocyanine dye can be switched from an on state to an off state in the presence of a thiol compound, such as 2-mercaptoethanol. Exposure to 650-nm excitation light in the presence of the thiol forms an addition product to the central polymethine bridge, thus interrupting the conjugated electron system and eliminating the fluorescent signal. Subsequent exposure to ultraviolet light causes the thiol to be removed and restores the fluorescence.

porous chromatography supports to purify proteins and other biological molecules by interaction with affinity ligands (Cuatrecasas, 1970; Hermanson *et al.*, 1992; Hage, 1999). The immobilized ligand may be a natural bioaffinity molecule or a synthetic molecule chosen to bind the desired target molecule reversibly so that the affinity support can capture and release the target for isolation. The appropriate affinity ligand typically is covalently attached to the insoluble matrix using immobilization reactions that are similar or identical to those methods used to form soluble bioconjugates in solution (Chapters 14 and 15). Alternatively, affinity ligands can be noncovalently immobilized using an intermediary high-affinity biological interacting pair, an example of which is the streptavidin–biotin interaction. In this technique, a biotinylated molecule or protein (Chapter 15, Section 2.5) is allowed to interact with an immobilized streptavidin support, thus attaching the ligand to the support through the biotin modifications.

Affinity molecules can be immobilized onto a wide range of insoluble support materials, including porous resins and nonporous particles of all shapes and sizes, as well as magnetic particles, planar surfaces, microplates, inside tubes or microfluidic channels, membranes, and porous monolithic structures. The affinity matrix thus obtained can be used to capture out of solution virtually any target molecule in a biological sample, provided the appropriate ligand is immobilized onto it. Today, immobilized affinity ligands are applied in chromatographic separations ranging in scale from microliter quantities of resin used to purify microgram quantities of target molecules to hundreds of liters of resin used in bioprocess purifications to produce kilogram quantities of therapeutic proteins.

Affinity chromatography has also become a vital tool for many proteomics studies investigating the expression, activity, structure, and function of proteins. For instance, an affinity support can be used to enrich low copy target proteins from a cell or tissue lysate to permit detection or characterization by mass spectrometry or other techniques (Zhang *et al.*, 2007; Kota *et al.*, 2009). The appropriate affinity support can be designed that can specifically capture phosphoproteins or phosphopeptides, enrich the glycoprotein fraction from nonglycosylated proteins, isolate peptides containing thiols or disulfides, purify proteins with ubiquitin or other

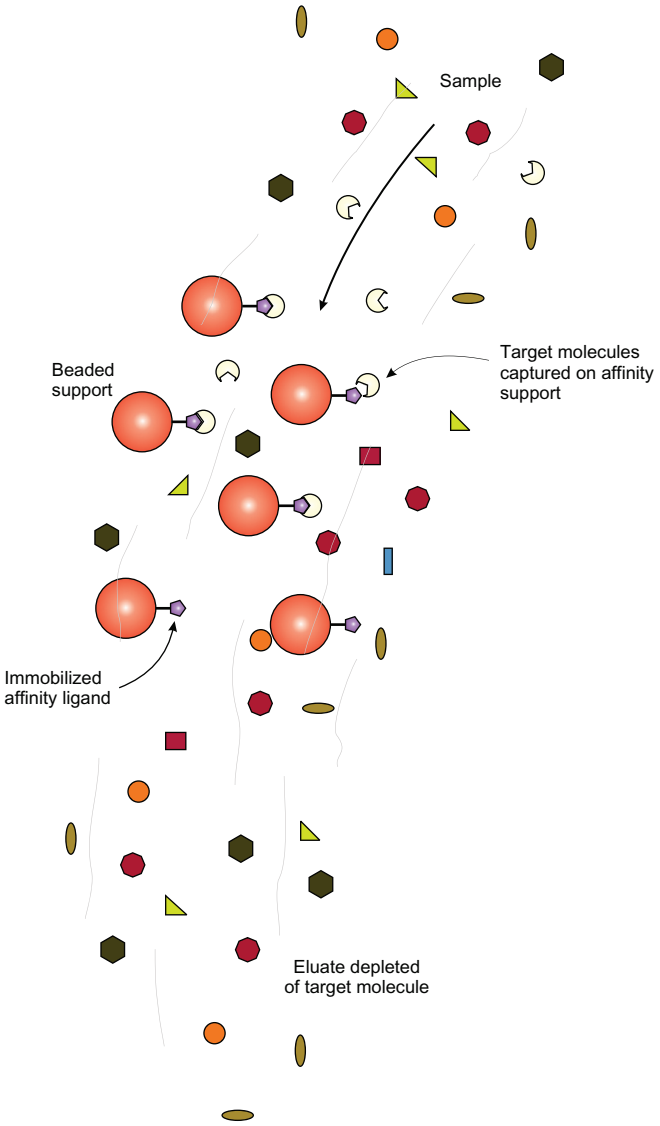

FIGURE 1.51 The principle of affinity chromatography involves the use of an immobilized affinity ligand attached to an insoluble matrix, typically a porous beaded resin that can interact with and capture a desired target molecule from a complex sample. After binding the target, the support is washed free of excess unbound sample and the captured target can then be eluted and isolated in an essentially pure state.

post-translational modifications, or pull out of solution proteins having particular active sites or binding sites able to interact with the immobilized ligand (Azarkana *et al*., 2007; Patricelli *et al*., 2007; Wissing *et al*., 2007; Cravatt *et al*., 2008).

Purification using Immobilized Affinity Ligands

Biological macromolecules (such as proteins), smaller bioaffinity ligands (such as short peptides, nucleic acids, or carbohydrates), or even synthetic organic molecules (such as substrate analogs or drugs) can be covalently coupled to an insoluble surface or particle to create an affinity matrix for the purpose of specifically binding and interacting with a target molecule in a biological solution. The major use of immobilized affinity ligands is to capture and purify a target biomolecule from an extract, for example a lysate or homogenate. Affinity chromatography has become the primary purification method of choice for isolating biological targets from complex solutions. Auxillary chromatographic methods may also be employed to clean up a biomolecule preparation, but the most powerful specific techniques are separations using immobilized affinity ligands. In fact, the biotechnology and pharmaceutical industries have invested heavily in the purification of biotherapeutic proteins in scales ranging from multi-gram quantities required during clinical trials to tens or hundreds of kilos needed for full production, if a major protein drug candidate is successful and enters the market.

The protein most often targeted for purification using an immobilized affinity ligand is an antibody. At scales appropriate for research separations, µg or mg quantities of IgG are routinely purified from immune serum, mammalian cell culture supernatant, recombinant bacterial fermentation broth, or ascites fluid to isolate a particular antibody having specificity for the desired target. There are several basic types of immobilized affinity supports that can be used for antibody isolation: (1) an immobilized antigen with precise binding specificity for the antibody being isolated; (2) an immobilized immunoglobulin binding protein which is able to bind to the general class of antibody being produced; or (3) an immobilized organic pseudo-affinity ligand having binding characteristics for the antibody type in general (Figure 1.52) (Vljayalakshmi, 1998).

The coupling of an antigen to an insoluble support usually involves conjugation through a functional group on the molecule to a reactive group on the matrix. If the antibody was produced to have specificity for a particular protein (which represents the most common type of antibody specificity), then to create an immobilized affinity support the target protein is simply coupled to the matrix using its available amines, thiols, or occasionally through its carbohydrate. This works especially well if the protein antigen is available in quantities suitable for immobilization and use as a purification tool. Chapter 15 describes the reactions useful in coupling proteins to insoluble support materials and Chapter 20 discusses particular conjugation strategies for use with antibodies, the methods of which are appropriate for both solution-phase conjugation and immobilization to a solid phase.

Purification of specific antibodies from antiserum or from media that may contain other non-relevant IgG molecules usually involves the use of an immobilized antigen column, because this ensures that the antibody of correct specificity is isolated from antibodies having other specificities. However, if the desired antibody is

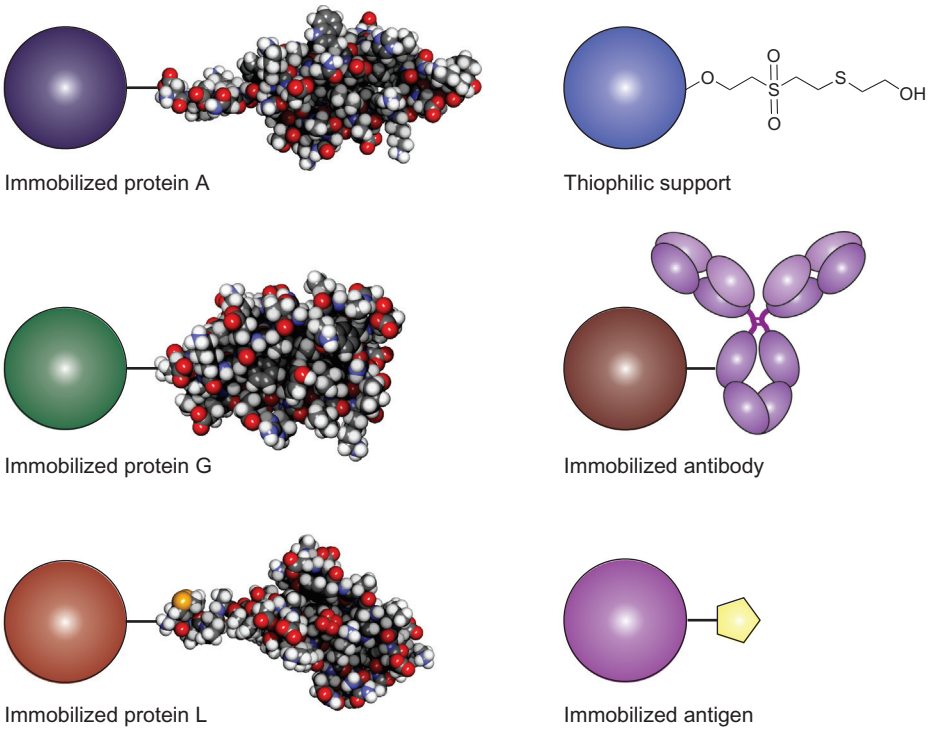

FIGURE 1.52 The most common affinity chromatography supports designed to purify antibody molecules. The immunoglobulin binding proteins protein A and protein G typically are used to purify intact antibodies containing an Fc region, whereas protein L is used with Fab fragments that contain kappa light chains. A thiophilic support binds with high affinity to the Fc region of antibodies in the presence of a lyotropic salt and can be eluted by removing the salt. Immobilized antibodies can be used to purify secondary antibodies in high purity, for instance in the use of an immobilized mouse IgG to purify a goat-anti-mouse antibody. Finally, immobilized antigens are often used to highly purify specific antibodies having discrete antigen binding activity.

present in a solution that contains no other antibodies, such as is typical of ascites fluid when making monoclonal antibodies or of bacterial production of recombinant antibodies, then an immobilized immunoglobulin binding support may be used that can isolate antibodies through its affinity to the Fc or Fab regions of IgG, and not through specific antigen binding site interactions.

For decades, affinity supports prepared using immobilized protein A, protein G, or protein A/G have been used to isolate and purify antibodies from culture supernatants and ascites (Huse *et al.*, 2002; Roque *et al.*, 2007; Bergmann-Leitner *et al.*, 2008). Recombinant protein A in particular has become the most popular immobilized affinity ligand for purification of IgG antibodies in process scale at biopharmaceutical companies. Today, many thousands of liters of immobilized protein A are produced under cGMP conditions to supply the needs of antibody therapeutic production processes worldwide. These quantities will only increase in coming years as many more antibody-based biotherapeutics are making their way through clinical trials.

A third option for the purification of antibodies using an immobilized affinity ligand is the use of a synthetic organic binding molecule. For example, the unique thiophilic support developed in the late 1980s is an affinity

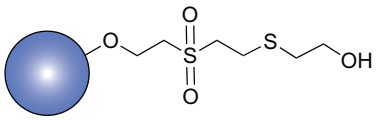

FIGURE 1.53 A thiophilic affinity support can be prepared by the reaction of 2-mercaptoethanol with a support activated with vinyl sulfone groups. This creates a thioether next to a sulfone group, which is a feature of thiophilic supports having affinity for binding antibody molecules.

matrix having high capacity for binding immunoglobulins (Belew *et al.*, 1987). It was discovered that an affinity ligand containing a thioether group next to a sulfone is able to bind to antibodies in the presence of a lyotropic salt, such as 0.5 *M* potassium sulfate (Figure 1.53). The binding presumably occurs in the region of the Fc domains and may involve hydrophobic interactions. A thiophilic support made on an agarose chromatography resin has high capacity for binding IgG at levels of 20 to 50 mg/ml, depending on ligand density. This type of thiophilic support, however, has relatively little binding potential with other proteins that may be present

in the antibody solution. Elution of bound antibody is simply accomplished by removing the high salt from the binding buffer, thus eliminating the interaction of the thiophilic groups with the antibody molecules. The only disadvantage of this method is the quantity of salt that must be used to purify large amounts of antibody, therefore creating a disposal issue for biotech companies thinking of using this support in process separations.

Other small organic molecules have been developed to interact with immunoglobulins and mimic the affinity binding of protein A to the Fc region. Some short peptide sequences have been identified using peptide libraries, such as the multimeric ligand TG19318, that are able to interact with IgG in similar fashion to that of protein A (Fassina *et al*., 1996, 1998; Fassina, 2000). In addition, certain small organic compounds, such as 2-(3-aminophenol)-6-(4-amino-1-naphthol)-4-chloro-*s*-triazine, have been discovered and immobilized on agarose that mimic protein A and have binding characteristics toward immunoglobulins (Lowe *et al*., 1986; Li *et al*., 1998; Teng *et al*., 2000).

Separations using immobilized affinity ligands can be employed to purify many more biological molecules than just antibodies. For instance, immobilized saccharides, carbohydrates, or complex glycans can be used to isolate proteins with binding specificity toward the sugar or sugar sequence of interest. This can permit isolation of lectins and cell–cell interacting proteins, which bind to certain glycan structures (Horlacher and Seeberger, 2006). It can also be used to isolate and characterize cell populations for their ability to interact with specific sugars (El-Boubbou *et al*., 2010). Intact glycans can be released from glycoproteins or other glycoconjugates using enzymatic or chemical means and subsequently immobilized through their reducing ends to surfaces or particles for analysis of interacting proteins (Kim *et al*., 2008). Glycan arrays have been produced on a variety of surfaces or particles to allow multiplexed analysis of carbohydrate-interacting proteins from a cell or tissue lysate (Taylor and Drickamer, 2009). The glycan binding properties of the *Arabidopsis* PP2-A1 phloem lectin was studied in this way, using a glycan array for identification of the lectin's carbohydrate specificity (Beneteau *et al*., 2010). Chapter 15, Section 2.4, describes the reactions of labeling or immobilizing glycans through their reducing ends, which involves coupling to amine-, hydrazide-, or aminoxy-containing compounds to create secondary amine, hydrazone, or oxime linkages, respectively. Figure 1.54 illustrates some of these immobilized saccharide bioconjugates for the capture of interacting proteins.

Conversely, immobilized lectins can be used to isolate certain carbohydrates or glycoproteins based on the specific sugars contained in the target molecule. Many dozens of lectins have been identified having

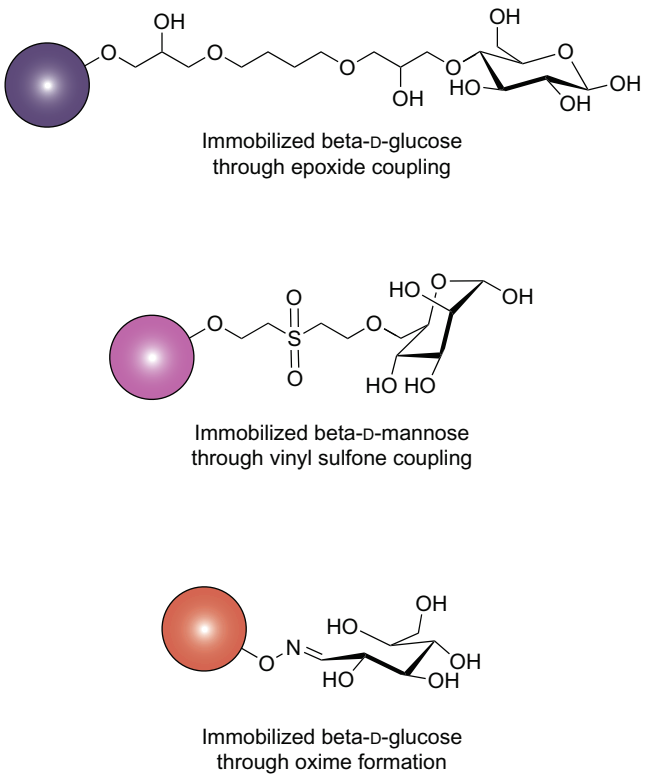

FIGURE 1.54 Immobilized sugars can be created using an epoxy activated or vinyl sulfone activated support to link to hydroxyl groups via ether bonds. In addition, reducing sugars can be coupled to supports using an aminooxy group, which forms an oxime bond with the aldehyde groups.

precise saccharide-binding characteristics, any number of which can be immobilized to separate and enrich the portion of the glycome having the requisite carbohydrate structure for interaction (Tateno *et al*., 2007). In addition, immobilized *m*-aminophenyl boronic acid (Figure 1.55) has been used to bind diol-containing molecules, such as those present in many sugars contained in carbohydrates and glycans (Olajos *et al*., 2010). The boronic acid affinity ligand coordinates with the adjacent hydroxyl groups to form a covalent cyclic linkage with the carbohydrate, thus capturing sugar-modified biomolecules from solution. Unlike lectin binding, boronate-containing supports are not selective to sugar sequences, but interact with any molecules having glycols or an amine adjacent to a hydroxyl. Immobilized *m*-aminophenyl boronic acid on agarose has been used to isolate glycated hemoglobin in diagnostic testing of diabetics for long-term glucose monitoring (Mallia *et al*., 1981; Klenk *et al*., 1982; Frolov and Hoffmann, 2010).

Small molecule substrate analogs or inhibitors have also been used as immobilized affinity ligands to capture or purify certain enzymes from biological solutions. For instance, biomimetic affinity ligands, including immobilized dyes or inhibitors like

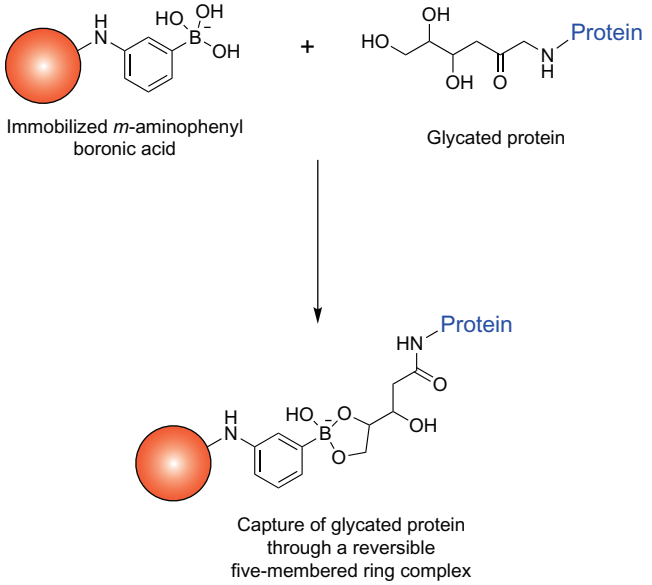

FIGURE 1.55 Immobilized *m*-aminophenyl boronic acid can be used to capture glycated proteins that are the product of non-enzymatic modification caused by glucose, which is present in high amounts in diabetic patients. The boronate group complexes with the glycated protein by forming a ring structure with the diols present in the glucose modification.

benzamidine, an inhibitor of trypsin-like proteases, have been used to isolate these enzymes, including the pharmaceutically important tissue plasminogen activator (t-PA) (Wu and Yu, 2007).

Small molecule biomimetics have been designed to bind selectively to certain proteins or other biomolecules and then immobilized for use as affinity supports in capture and purification of their specific targets (Lowe *et al*., 2001). In particular, triazine dye molecules or their derivatives have often been used to mimic natural ligands, such as nucleotides, and bind to active sites on enzymes for efficient purification (Clonis *et al*., 2000). Tsopelas *et al*. (2010) used customized biomimetic affinity chromatography columns to isolate selenium-containing molecules from biological samples, including selenomethionine, selenocystine, selenocystamine, selenourea, dimethyl selenide, and dimethyl diselenide. Gautam (2010) describes peptide biomimetic sequences that are effective in isolating IgM antibodies and also summarizes the history of peptide mimetics for protein purification. Many other proteins or biological targets can be isolated by the appropriately designed biomimetic affinity support, whether the ligand is designed based upon a synthetic organic motif, a biomolecule fragment, or a peptide sequence (Figure 1.56).

Immunoprecipitation Techniques

One of the more popular research applications using immobilized affinity ligands involves antibody-mediated immunoprecipitation. The specificity and bivalent nature of antibodies allows direct targeting through immunoaffinity interactions of proteins and other molecules from biological samples, effectively precipitating them out of the sample solution in an immune complex. If an antibody is coupled to an insoluble support, the resultant bioconjugate can also be used to capture the target molecule and remove the remaining components simply by washing (Figure 1.57). Although it is not strictly immunoprecipitation in the immunological sense, immunoaffinity chromatography on an insoluble support essentially accomplishes the same effect of precipitating the target antigen out of solution.

Polyclonal or monoclonal antibodies can be made for nearly any target protein or biomolecule and used in immunoprecipitation techniques to capture these targets. In practice, there typically are two strategies used to prepare an immunoaffinity support: (1) direct immobilization of the antibody onto the resin or solid phase; or (2) use of an intermediary high-affinity interacting pair, such as the streptavidin–biotin interaction, to capture an antibody after it has interacted with its specific target antigen. The first procedure, direct conjugation, is usually carried out if there is sufficient quantity of the antibody for immobilization, which often is the case with polyclonals. The indirect method of immobilization is sometimes carried out to orient the antigen binding sites for better interaction with the target—in other words, to direct the Fab ends away from the particle or surface—or, alternatively, because the amount of antibody that is available is limited and the price per mg is expensive (Sissona and Castor, 1990).

Direct antibody coupling to an activated support can be done using a number of reactive chemistries that can covalently link to amines, thiols, or even to the carbohydrate portion of an immunoglobulin (Chapters 15 and 20) (Figure 1.58). Immobilization through amines is the most common route and results in a fairly random orientation of the antibodies on the surface of the support. Coupling through antibody thiol groups (Chapter 15, Section 2.2) can also be done to make the attachment point near the hinge region of the antibody. This is particularly useful for immobilization of $F(ab')_2$ fragments to insoluble supports after their disulfides are reduced to prepare Fab′ fragments. This strategy ensures that every conjugation reaction to the matrix with the antibody occurs at the opposite end of the antigen binding site on each monovalent fragment. Finally, polyclonal antibodies and some monoclonals are glycosylated in the Fc region, which can be targeted to facilitate coupling by reductive amination using amine-, hydrazide-, or aminooxy-containing supports, after the carbohydrate has been periodate oxidized to create aldehyde groups (Chapter 15, Section 2.4). This method certainly avoids any coupling to the antibody peptide structure,

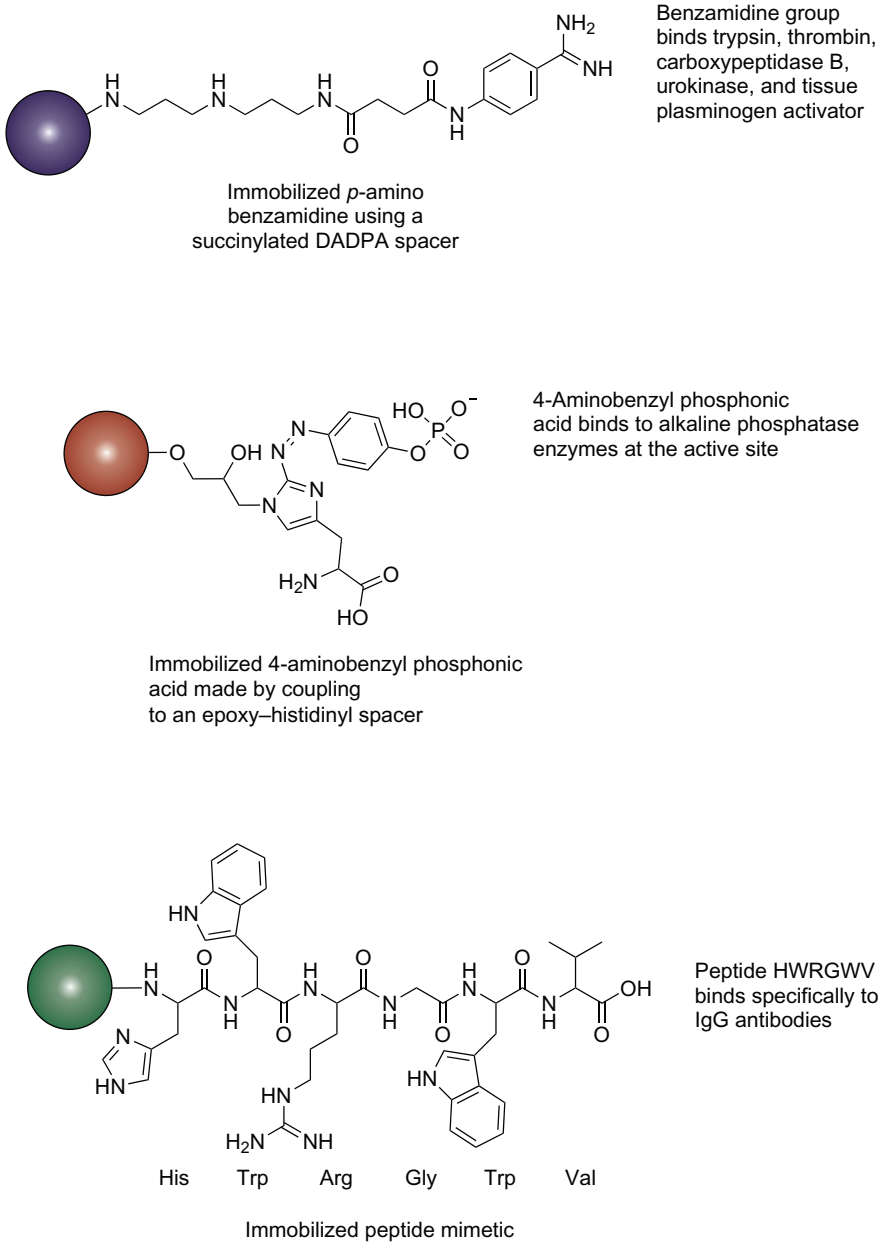

FIGURE 1.56 Immobilized enzyme inhibitors and biomimetic affinity ligands can be used to target the active sites of specific enzymes or other proteins in biological samples.

thus avoiding the binding sites; however, some carbohydrate-specific antibodies are known to be glycosylated near the antigen binding sites and may even participate in antigen binding through hydrogen bonding (Wright *et al*., 1991). Thus, immobilization of IgG molecules through their glycans might not be the best strategy in all cases.

All of these methods work well to immobilize antibodies on solid supports through the creation of direct covalent bonds, but coupling through amines may be the simplest strategy, and it almost always results in an antigen binding affinity matrix for immunoprecipitation applications with high activity for capturing target molecules. Chapters 14, 15, and 20 discuss antibody conjugation methods and immobilization reactions that can be used to couple antibodies to solid supports.

Another strategy for performing immunoprecipitation separations is to use immobilized streptavidin as the affinity support and then use biotinylated antibodies in solution to capture targeted antigens (Figure 1.59). This method is convenient in that the streptavidin matrix functions as a universal support for doing virtually any immunoprecipitation procedure using any available biotinylated antibody conjugate. In this case, only one

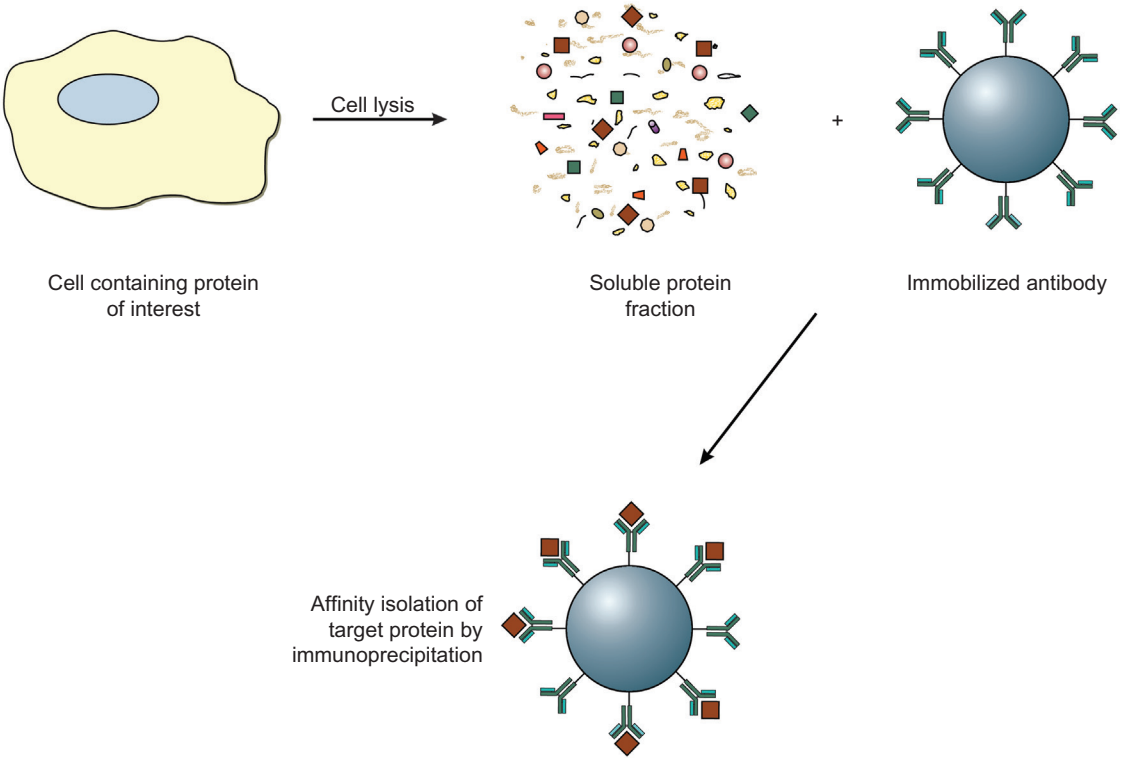

FIGURE 1.57 Immunoprecipitation can be used with an immobilized antibody to capture a specific target protein from a complex sample, such as a cell lysate.

affinity support is needed, immobilized streptavidin, while obtaining or making the desired biotinylated antibodies for use with it is relatively trivial. In addition, the amount of biotinylated antibody required to do an immunoprecipitation assay using this method is minuscule compared to the amount of antibody that would be needed to prepare an affinity support of reasonable capacity by direct immobilization of the antibody.

Another alternative option for the preparation of immobilized antibodies for immunoprecipitation applications is to use immobilized immunoglobulin binding proteins, such as protein A, protein G, or protein A/G, which are bacterial proteins that have affinity for binding IgG primarily through its Fc region. In this approach, an immobilized immunoglobulin binding support is used to capture the primary antibody through its Fc region, thus orienting the IgG molecules with their antigen binding sites free to interact with a targeted antigen (Figure 1.60). Next, this affinity complex is covalently crosslinked using a homobifunctional crosslinking agent to permanently stabilize the interaction. Schneider *et al*. (1982) first used this technique to prepare immobilized antibodies using the crosslinker DNP (Chapter 15, Section 2.6) for immunoprecipitation applications. Since that time, this technique has grown in popularity and evolved to use better crosslinking agents with much better long-term stability. However, the direct immobilization of a primary antibody may still be the best option, because it avoids the potential nonspecificity that can result from having another protein present on the affinity support.

Bioconjugates used for immunoprecipitation techniques can consist of many different solid-phase matrices, such as planar arrays, the wells of microplates, porous chromatography supports like agarose (Chapter 15), or nonporous particles such as latex beads or paramagnetic particles (Chapter 14). Figure 1.61 illustrates some of these bioconjugate types and shows both direct immobilization of an IgG as well as the use of streptavidin or an immunoglobulin-binding protein as intermediaries to immobilize the antibody.

Affinity Capture of Post-Translational Modifications

Affinity supports can be used for enrichment of the proteomic fraction of samples having specific post-translational modifications. The affinity ligand can be designed to target and bind to the modification through a number of different interactions. For instance, one of the principal signaling modifications that occur within cells is phosphorylation. The enzymatic addition of a phosphate group to serine, threonine, and tyrosine -OH groups by specific kinases facilitates activation of particular proteins within dozens of signaling pathways in cells. These

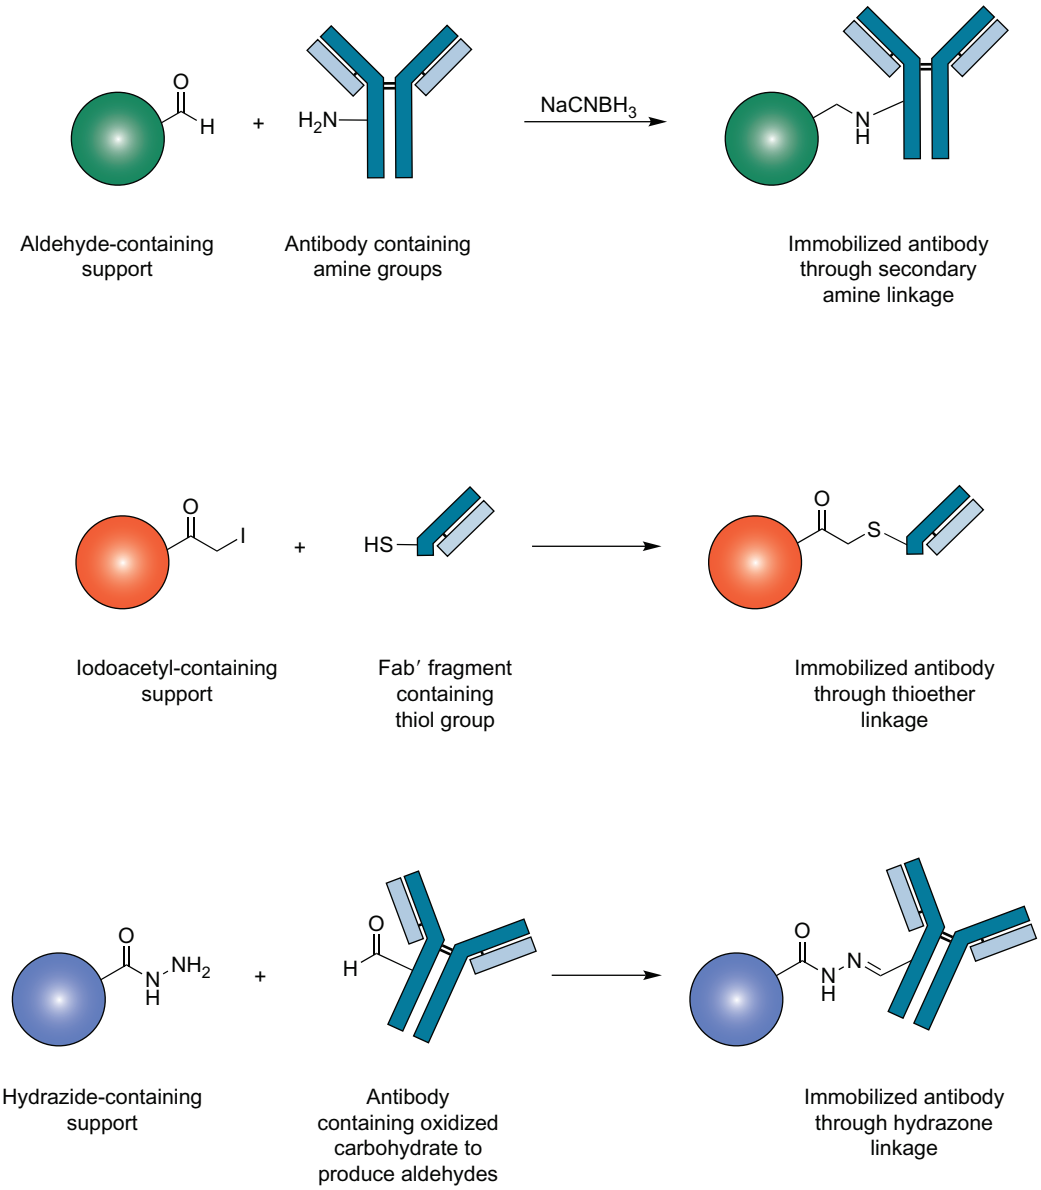

FIGURE 1.58 Three common methods to immobilize antibodies include: (1) the reductive amination coupling of the amines on an antibody to an aldehyde-containing support, such as periodate-oxidized agarose; (2) coupling to thiols on reduced antibodies or antibody fragments with an iodoacetyl-containing support, which binds thiols through a thioether linkage; or (3) using a hydrazide-containing support to couple with antibodies through their carbohydrate after periodate oxidation to create aldehydes.

phosphorylation events can be captured for study by affinity isolation of phosphorylated proteins or peptides using selective affinity matrices able to bind to the amino acid–phosphate modification sites.

There are two main approaches for affinity purification of the phospho-proteome: (1) immunoaffinity chromatography using antibodies with specificity for the phosphopeptide sequence or the phospho–amino acid modification site; or (2) immobilized metal affinity chromatography (IMAC), which selectively coordinates with the phosphate modifications. Immunoaffinity separations have a tendency to work well when using anti-phosphotyrosine antibodies (particularly the monoclonal antibody known as pY20), but the specificity of anti-phosphoserine and anti-phosphothreonine antibodies is not that good. However, some phospho-specific antibodies have specificity for a particular peptide sequence surrounding the phosphorylation site; thus, these antibodies can be used not only to enrich for phosphopeptides in general, but also to capture a unique phosphopeptide representing a phosphorylation event that occurred on a specific protein having that sequence.

Most of the phosphorylation site-specific antibodies available on the market are rather expensive, and for

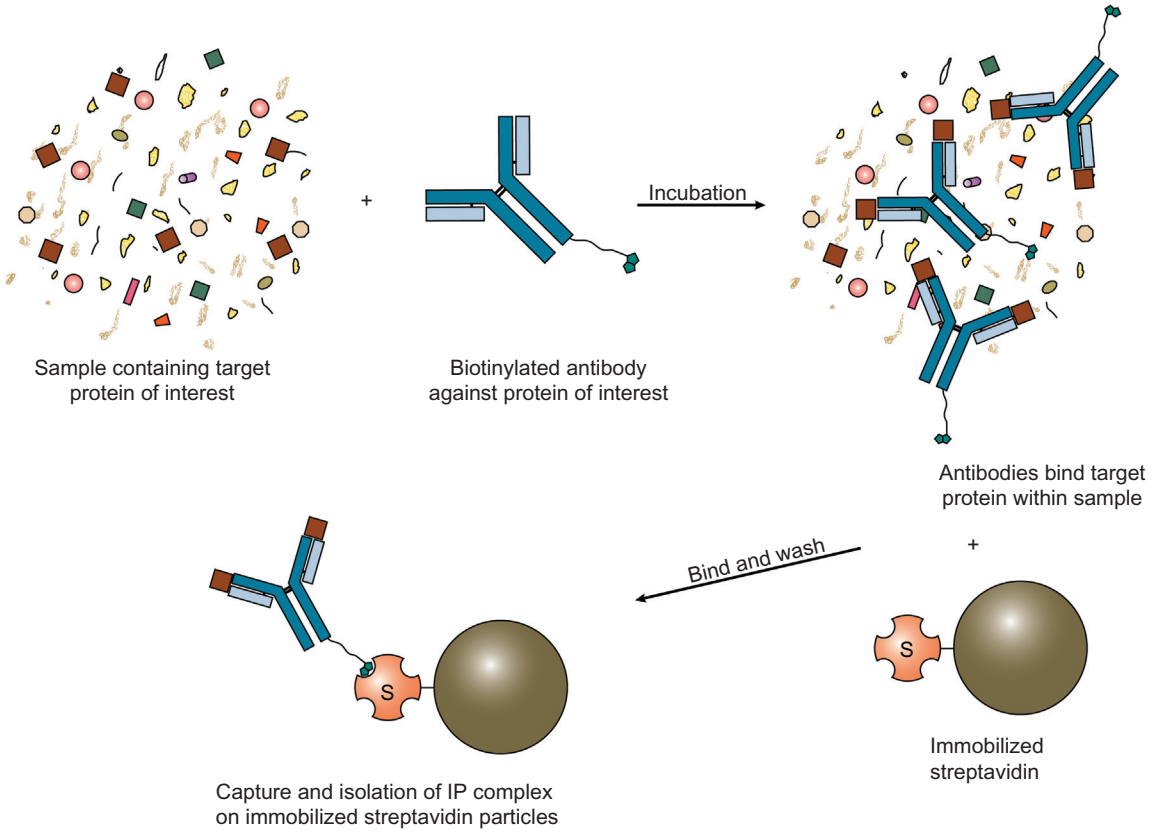

FIGURE 1.59 Immobilized streptavidin can be used in an immunoprecipitation procedure to capture a biotinylated primary antibody that has bound to a target protein in a complex sample. In this procedure, the immobilized streptavidin can be used with any biotinylated antibody and thus becomes a universal reagent for carrying out IP separations.

this reason they are often used in a biotinylated form to interact with a phosphopeptide in solution and then the complex is captured on an immobilized streptavidin column for recovery of the phosphorylated peptide or protein (Figure 1.62).

Serine and threonine phosphorylation can also be targeted for analysis using bioconjugate techniques involving a two-step chemical modification followed by affinity capture (Leitner and Lindner, 2009). Phosphoserine and phosphothreonine groups can be dephosphorylated in the first step of this technique through a beta-elimination reaction that leaves behind a carbon–carbon double bond. This double bond can be substituted in a second reaction with thiol-containing molecules to create a conjugate useful in subsequent detection or isolation procedures. A common strategy in beta-elimination is to label the dephosphorylated peptides with a dithiol derivative, which adds to the double bond to form a thioether linkage. Tags subsequently attached to the free thiol end of the dithiol compound are thus covalently coupled to only phosphorylated peptides, which can then be useful for affinity capture or detection. A common modification technique involves the addition of a biotinylation reagent to the free thiol to modify every phosphopeptide at the point of Ser or Thr phosphorylation (Oda *et al.*, 2001). In this method, each peptide containing a phosphorylation site gets tagged with a biotin group. Enrichment of the biotinylated peptides can then be done on an immobilized streptavidin support to analyze this fraction of the phosphoproteome by mass spec (Figure 1.63). In addition, other tags can be added to the dephosphorylated double bond of serine or threonine to provide fluorescent detection or enhanced ionization properties for mass spec separations. Note, however, that phosphotyrosine does not participate in the beta-elimination reaction and therefore cannot be modified using this strategy. Nevertheless, phosphotyrosine can usually be effectively captured or detected using antibodies, as discussed in the previous paragraphs.

Some limitations of the beta-elimination technique include the combined inefficiency of the dephosphorylation reaction and the subsequent modification of the double bond with a thiol compound as well as the potential for side reactions (Karty and Reilly, 2005; Tinette *et al.*, 2006). None of the reactions provides 100% yields, and under some conditions even nonphosphorylated serine and threonine hydroxyls can

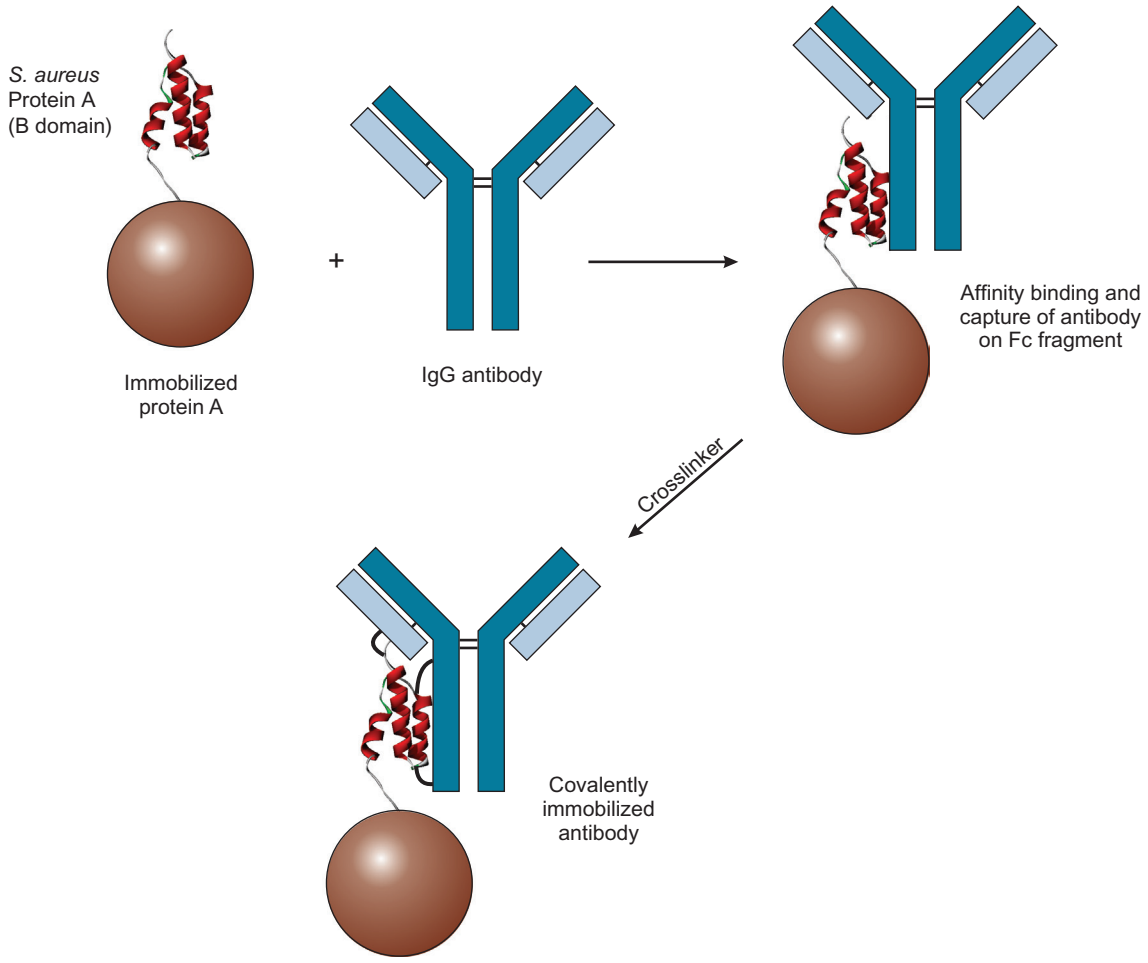

FIGURE 1.60 Immobilized protein A can be used to immobilize an antibody for immunoaffinity chromatography or immunoprecipitation applications by first orienting it with its antigen binding sites pointing outward from the matrix. To stabilize the protein A–antibody interaction a crosslinker is added to create covalent linkages, thus preventing leaching of the antibody during use.

undergo elimination and be modified inadvertently (Li *et al.*, 2003). Therefore, obtaining quantitative information about serine or threonine phosphorylation through beta-elimination is sometimes difficult unless conditions are carefully controlled.

Covalent modification of phospho-amino acid groups in phosphorylated peptides has also been done using diazo compounds (Lansdell and Tepe, 2004; Tepe and Pinnavaia, 2008; Frawley Cass *et al.*, 2009). Diazo carbonyl groups will react with an acidic phosphate group to liberate N_2 and create a phosphoester bond with a phosphopeptide. To avoid side reactions and coupling to carboxylate groups on peptides, a protein digest is first treated with a methanolic HCl solution to block all carboxylic acids and transform them into methyl esters. The subsequent use of an immobilized diazo derivative can function to enrich the phosphorylated proteome through covalent chromatography, specifically coupling to the phospho groups and allowing all other non-phosphorylated peptides to pass through the gel unretarded. This is also called "covalent chromatography," since the target molecule is captured through a covalent linkage. Once phosphopeptides have been isolated, they can be released from the resin for mass spec analysis using acid hydrolysis of the phosphoester linkages (Figure 1.64).

Another powerful way of enriching the phosphoproteome is the use of IMAC with certain chelated metal ions. Porath pioneered the method of metal chelate affinity interactions in the 1970s using immobilized organic metal chelating groups, which can coordinate and hold a metal ion for chromatography (Porath *et al.*, 1975). IMAC supports can be used as pseudo affinity ligands, that is, not truly biospecific but having interaction potential for certain functional groups or amino acid side chains in proteins (for review, see Block *et al.*, 2009). Electron-rich groups that are able to coordinate with the unoccupied sites on the chelated metal ion can bind to the IMAC support and be isolated from the rest of the proteins and

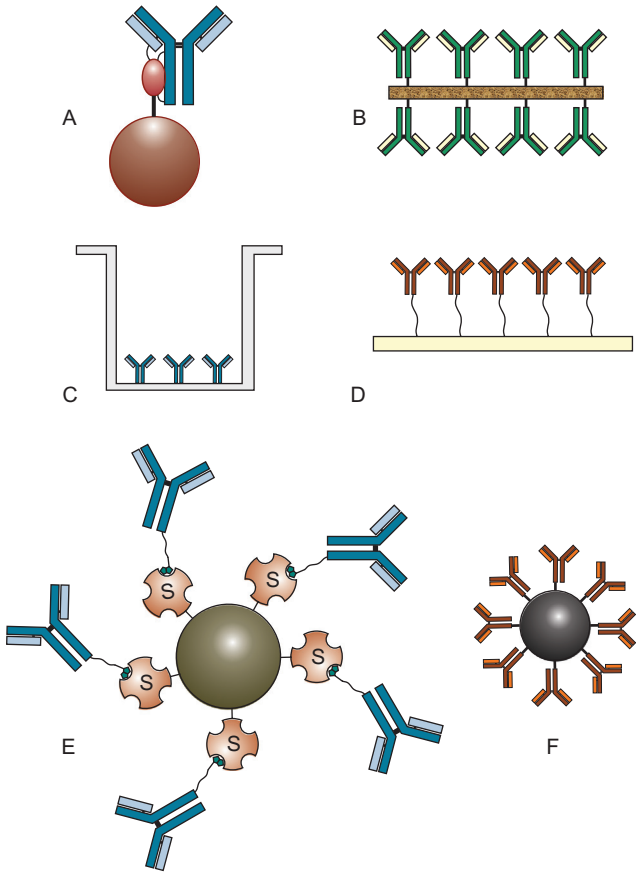

FIGURE 1.61 Solid-phase supports and strategies that are commonly used for the immobilization of antibody molecules include (A) indirectly coupled to a beaded support using an immobilized immunoglobulin binding protein, (B) covalently coupled to a membrane or monolithic support, (C) passive adsorption onto a microwell plate or surface, (D) covalently tethered to a surface via a linker arm, (E) through the use of immobilized streptavidin on particles to couple biotinylated antibodies, and (F) through direct immobilization onto porous and nonporous particles.

other molecules in a sample. Elution of bound proteins is typically done by using a buffer pH shift or through the addition of a counter-ligand, such as imidazole, which can compete for binding to the metal chelate and thus release the bound molecules. Alternatively, the addition of a chelating compound, such as EDTA, can be done to strip off the metal ions from the IMAC resin and elute the bound protein.

IMAC supports containing chelated gallium (Ga III) or iron (Fe III) are particularly useful in the enrichment of the phosphoproteome (Collins *et al*., 2005; Cantin *et al*., 2008; Ye *et al*., 2010). This method is used extensively to isolate phosphopeptides prior to mass spec analysis, a technique which was pioneered by Neville *et al*. in 1997 (Figure 1.65). Since even gallium- or iron-mediated IMAC is not absolutely specific for binding phosphorylation sites on proteins, other amino acid groups can also interact with the support, such as on peptides having an abundance of the acidic residues like aspartic and glutamic acids. For this reason, the bound proteins or peptides are said to be enriched for phosphorylated molecules, but they are not completely purified to homogeneity.

Another major post-translational protein modification that can be targeted for purification using immobilized affinity ligands is glycosylation. Glycomics, or the study of glycoconjugate modification, is perhaps the second most active area in post-translational research today, following phosphorylation. Glycoproteins contain complex carbohydrate structures coupled to certain amino acid sites in either an *N*-glycosidic (asparagine) or an *O*-glycosidic (serine, threonine, or hydroxylysine) linkage (Chapter 2, Section 2). The sugar structure making up the glycan typically is branched and can vary depending on the function of the glycoprotein and the cell of origin. Glycan synthesis is under enzymatic regulatory control in the ER and Golgi apparatus within cells (Varki *et al*., 2008). Aberrant glycosylation can often occur in disease states, such as cancer, creating tumor markers that are targets for drug discovery and therapeutic development (Brockhausen *et al*., 1995; Kim *et al*., 2009). Certain carbohydrate structures containing specific sugar residues can be recognized by carbohydrate-binding proteins (e.g., lectins, selectins, galectins, receptors, many CD cell surface antigens) (Cummings and Smith, 2005; Sakaguchia *et al*., 2006; Shoseyov *et al*., 2006; Sharon, 2007). For this reason, lectin bioconjugates have been used as probes of glycan structure or in an immobilized form, to purify glycoproteins (Ueda *et al*., 2009).

Bioconjugates consisting of immobilized lectins coupled to resins or surfaces can be used to capture carbohydrates and glycans containing the proper sugar sequence, which are able to interact with the lectin binding sites through biospecific affinity contacts (Hirabayashi, 2008). Mixed-bed affinity chromatography supports containing a library of immobilized lectins have also been used to enrich the total glycome from cell or tissue lysates for subsequent analysis by mass spec or other methods (Cummings, 2005). In addition, the immobilization of glycan structures on array surfaces has also been done to assay and study the carbohydrate binding proteins present in samples (Figure 1.66) (Blixt *et al*., 2004; Smith and Cummings, 2009).

Another important post-translational modification that can be targeted using bioconjugate techniques is nitrosylation. *S*-Nitrosylation occurs when nitric oxide (NO) synthase acts to generate this highly reactive radical gas, which then covalently modifies cysteine thiols in a protein (and the SH group in glutathione) to form a nitrosothiol group (S-NO) (Gaston *et al*., 2003). This modification is a significant cell signaling event that has downstream effects on a variety of proteins, including

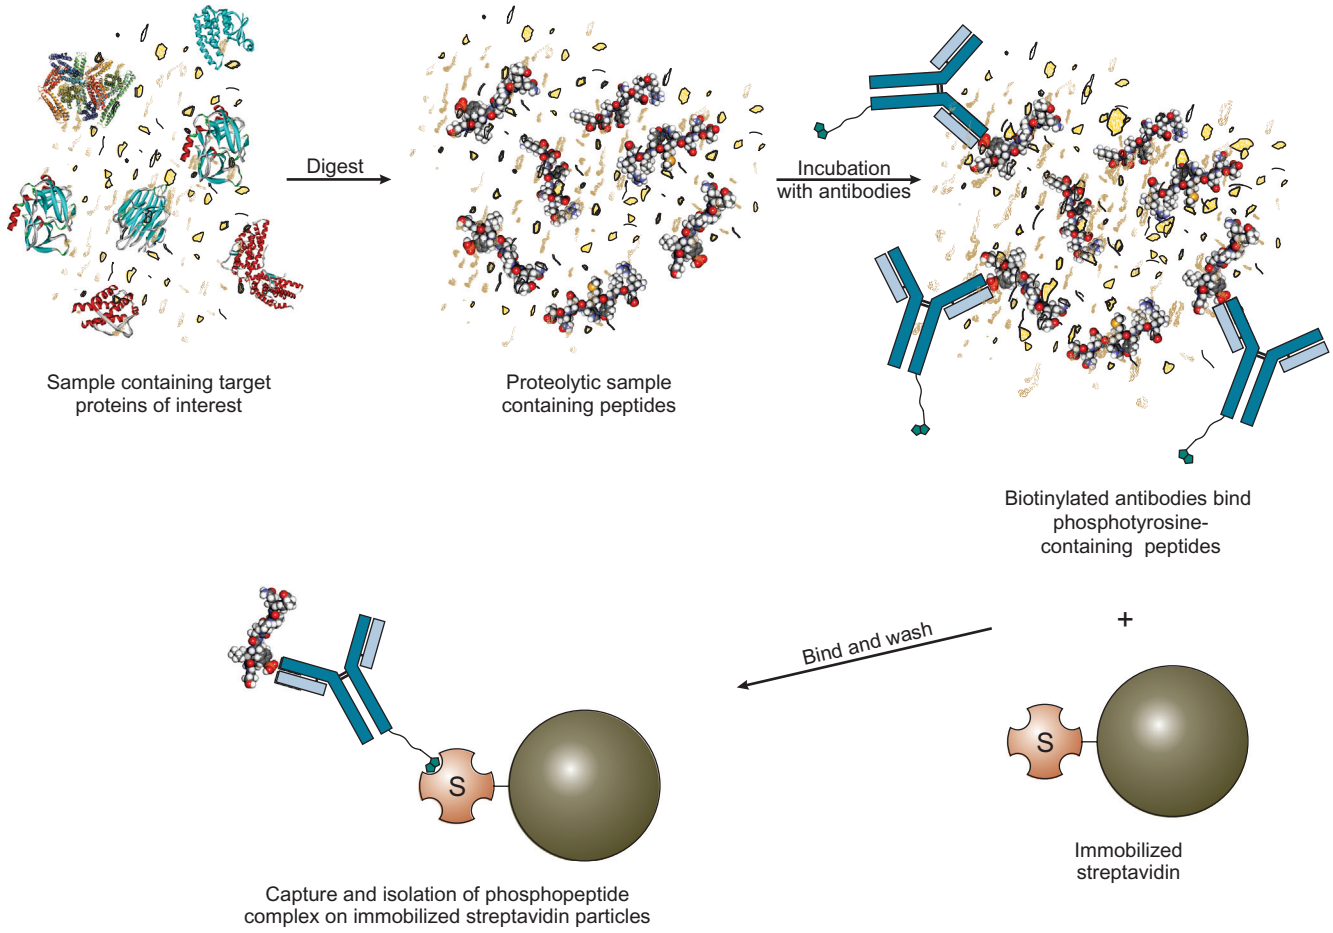

FIGURE 1.62 The enrichment of phosphopeptides in a proteomics workflow can be carried out by digesting a sample containing proteins with a protease (e.g., trypsin) to create peptides, including potentially phosphorylated peptides, incubating the mixture with a biotinylated antibody specific for the phosphopeptide of interest, and then binding the complex to an immobilized streptavidin resin, which captures the biotinylated antibody along with any phosphopeptides it has interacted with.

the control of regulatory proteins in the nucleus, structural and cytoskeletal proteins, signaling proteins, and ion channel proteins in cellular membranes (Stamler *et al.*, 2001).

The *S*-nitrosylated product is a reversible modification that can be cleaved back off *in vitro* using a reducing agent, typically ascorbate. To specifically detect cysteine nitrosylation, the biotin switch assay typically is used, which is a series of reactions that results in the biotinylation of a protein only at the sites of nitrosylation. First all free cysteine thiols are blocked in a sample using an SH-specific modification agent (such as MMTS, iodoacetamide, or *N*-ethylmaleimide; Chapter 2, Section 5.2) in the presence of SDS (to ensure reagent access to buried thiol groups). After removal of excess blocking agent, ascorbate is added to reduce the nitrosothiol group, thus cleaving off the post-translational modification and reforming the thiol. The freed cysteine thiols are then reacted with biotin-HPDP (Chapter 11, Section 6.3) or another SH-reactive biotin compound to result in a biotinylation event occurring at every site of nitrosylation (note: a thiol-reactive, PEG-based biotin compound can also be used to provide hydrophilicity; see Chapter 18, Section 1.3). The biotinylated proteins or peptides that are formed can be detected in western blots using streptavidin detection reagents or purified from a sample using immobilized streptavidin (Figure 1.67).

A similar biotin switch methodology has been developed for use in the measurement of fatty acid *S*-acylation (Drisdel and Green, 2004). This post-translational modification involves proteins conjugated with fatty acid acyl groups that are linked to cysteine thiols, which creates thioester derivatives with hydrophobic lipid chains protruding off. These lipid modifications enable the proteins to strongly associate with cellular membrane structures. This process is also commonly termed *palmitoylation*, although other fatty acids in

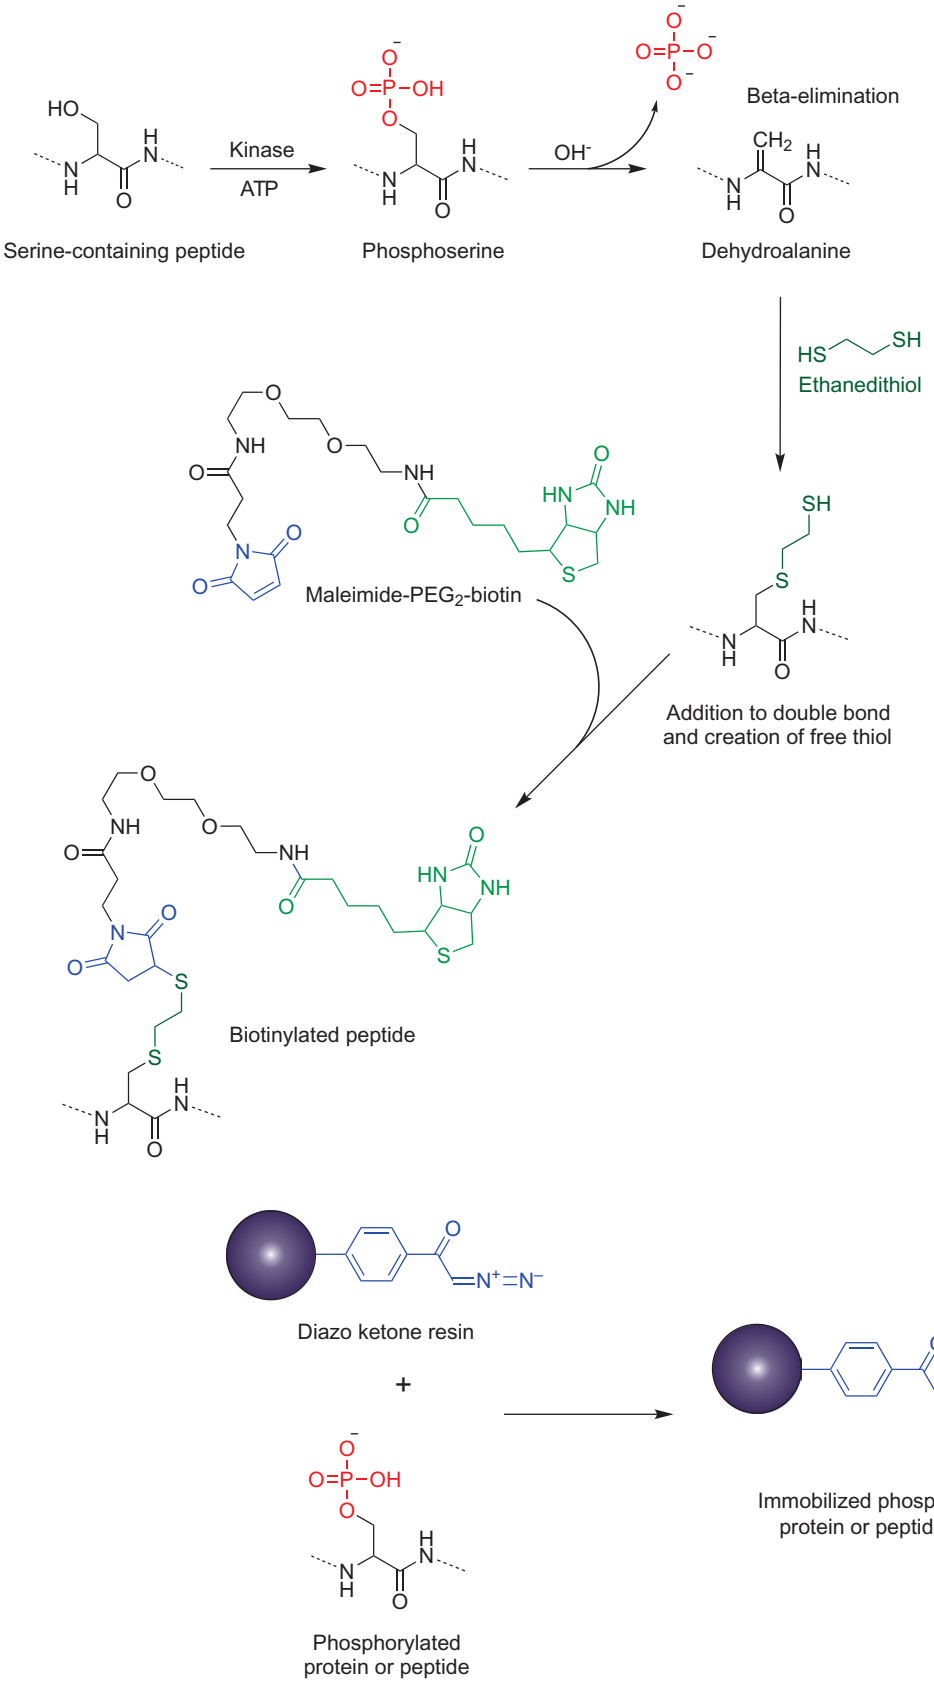

FIGURE 1.63 Phosphopeptides can be modified specifically at the site of phosphorylation using a three-step reaction that first involves a base-catalyzed beta-elimination reaction, which removes the phospho group and leaves a double bond. Modification of this carbon–carbon double bond with ethanedithiol by Michael addition provides a thiol group that can be reacted with a maleimide-PEG_2-biotin reagent to biotinylate the created thiol groups. This results in a biotin affinity group being attached at the site of every phosphorylation event on serine, which can be used to analyze the degree of phosphoserine production *in vivo*.

FIGURE 1.64 A diazo ketone containing-support can be used to react with phosphorylated peptides to covalently link to the phosphate groups through a phosphoester bond.

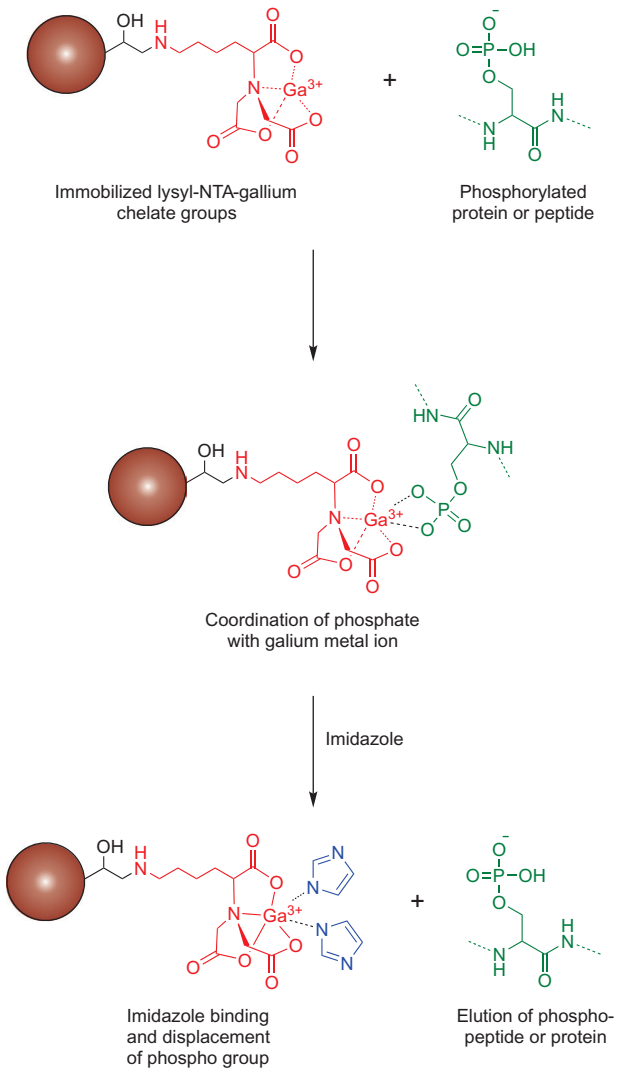

FIGURE 1.65 Immobilized metal chelate affinity chromatography (IMAC) can be used with an NTA-gallium ligand to reversibly bind a phosphorylated protein or peptide. This interaction can facilitate the enrichment of the phospho-proteome from a complex protein sample. Elution of the phosphopeptides can be carried out using a counter-ligand consisting of imidazole, which competes for the coordination sites on the chelated gallium salt.

addition to palmitic acid are involved with post-translational modification onto cysteine thiols. The thioester bond that is formed in *S*-acylation is reversible and can be cleaved using hydroxylamine, thus releasing the fatty acid and reforming the free SH group on the cysteines that were originally modified. If a protein sample containing palmitoylated or *S*-acylated proteins is first treated to block all free cysteines, using for instance *N*-ethylmaleimide and then hydroxylamine is added to cleave the thioester bonds, then all the revealed thiols will derive only from the post-translationally modified sites. Subsequent modification of the released thiols with a thiol-reactive biotinylation agent (Chapter 11, Section 6.3; Chapter 18, Section 1.3) will result in tagging all these sites with a biotin group. The biotin modified proteins can then be isolated on an immobilized streptavidin resin or detected using the appropriate streptavidin conjugates. For instance, fluorescently labeled streptavidin or HRP-labeled streptavidin conjugates can be used to probe western blots for palmitoylated proteins using this assay (Figure 1.68).

Another type of bioconjugate that can be used for affinity capture of phosphorylated target molecules is a biotinylated binding domain, which has the ability to specifically interact with another protein, typically binding to an activated form of the target. An example of such a system is the use of biotinylated SH2 domain fragments that can recognize certain phosphotyrosine residues in tyrosine kinases (Pawson and Nash, 2003; Hanke and Mann, 2009; Major *et al.*, 2009). In cells, a phosphorylation event at a particular site within a tyrosine kinase protein causes activation of the kinase with many downstream effects within signaling pathways. Protein–protein interactions typically occur subsequent to the phosphorylation event to cause certain SH2 domain-containing proteins to approach, interact with the tyrosine kinase, and then get phosphorylated and activated themselves. *In vitro*, a biotinylated SH2 domain molecule can be used to affinity target activated tyrosine kinases and bind to them in a cell lysate. The

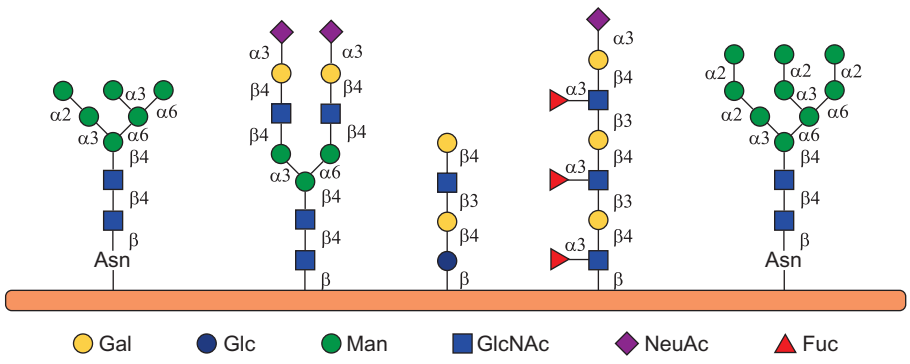

FIGURE 1.66 Immobilized glycan arrays can be created on surfaces that contain a variety of potential glycation forms, which can be used to study carbohydrate binding proteins in complex biological samples.

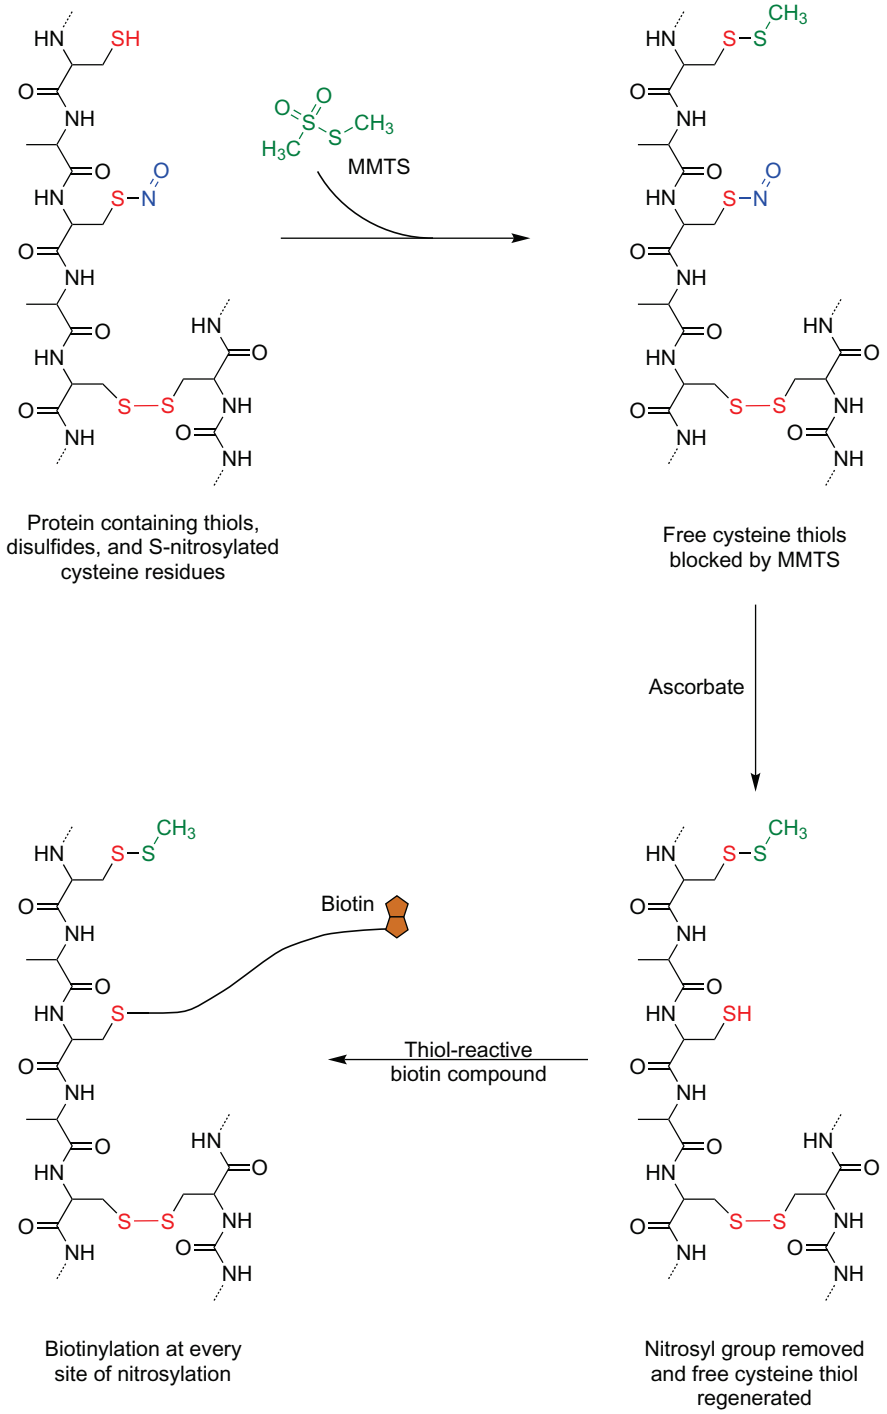

FIGURE 1.67 A post-translational modification event consisting of *S*-nitrosylation can be specifically targeted through modification with a biotin reagent. First, any free thiols in the sample are blocked with MMTS to eliminate interference from endogenous sulfhydryls. Next, the nitrosyl group is removed from the *S*-nitrosylation sites on cysteine using ascorbate treatment. Finally, a thiol-reactive biotinylation agent is added that couples with the freed thiols and provides a biotin affinity group at every site of original nitrosylation. The biotinylated peptides can be captured using an immobilized streptavidin affinity support for further characterization and study.

biotin tag on the SH2 domain can then be used to isolate these interacting complexes through its ability to bind to an immobilized streptavidin support. This "pull down" assay, as it is commonly called, can be used to study the activated tyrosine kinase population in a cell in response to disease or in response to a prospective treatment regime *versus* a normal cell. The enriched population of activated tyrosine kinases can be

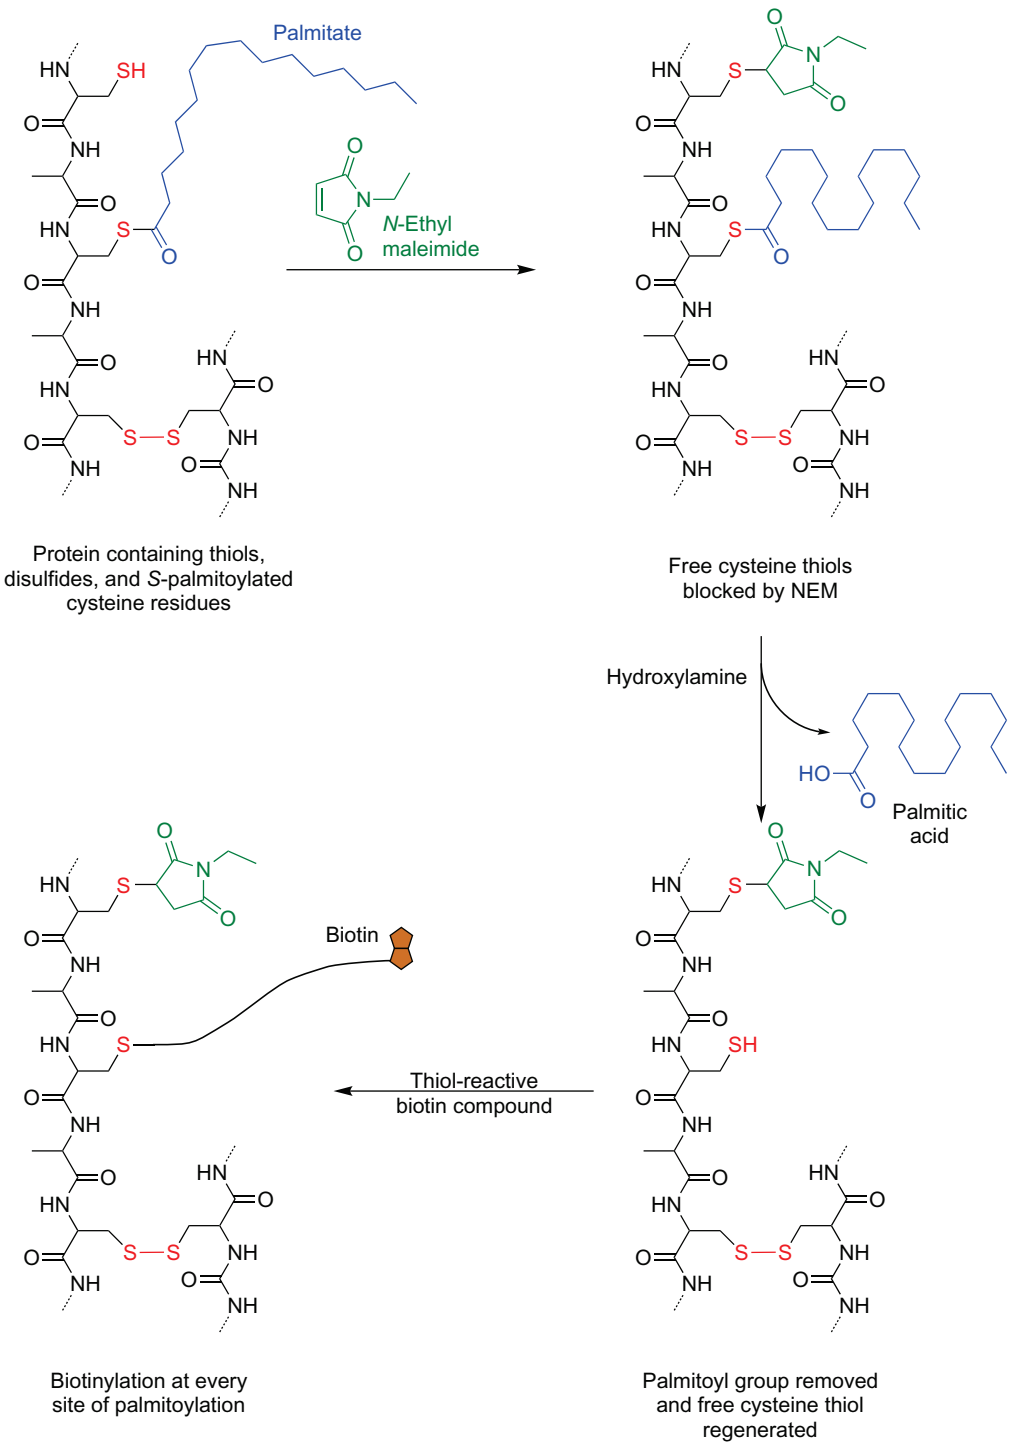

FIGURE 1.68 *S*-Palmitoylated proteins can be specifically biotinylated at each site of modification using a multi-step reaction sequence. First, *N*-ethyl maleimide is used to block all thiol groups in the sample so as not to interfere with subsequent reactions. Next, the palmitic acid groups are removed from cysteine residues using hydroxylamine. Finally, a thiol-reactive biotinylation reagent is used to add a biotin affinity group to each site that was initially palmitoylated. The biotinylated protein or peptide can then be isolated using immobilized streptavidin for further analysis.

analyzed by western blotting or mass spec to determine specific phosphotyrosine activation profiles. Figure 1.40 illustrates a pull-down assay to capture a phosphorylated tyrosine kinase through specific binding to an immobilized SH2 domain molecule, while Figure 1.69 shows the three-dimensional molecular model of an SH2 domain binding to a phosphotyrosine-containing peptide.

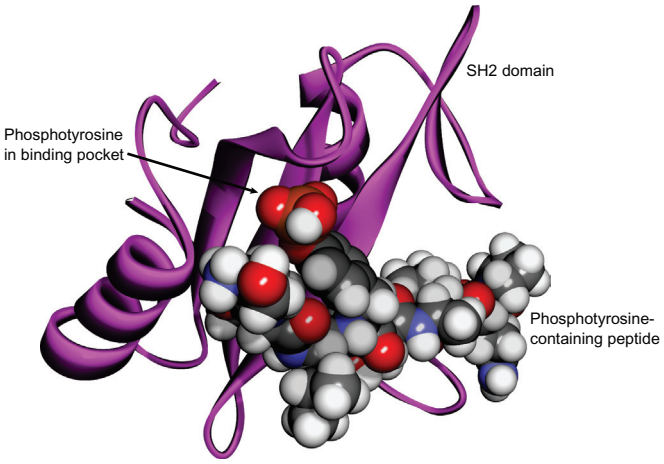

FIGURE 1.69 SH2 domains can be used as affinity molecules to specifically bind to phosphotyrosine-containing peptides. The SH2 domain is shown as the ribbon structure and the phosphorylated peptide as the space filling model.

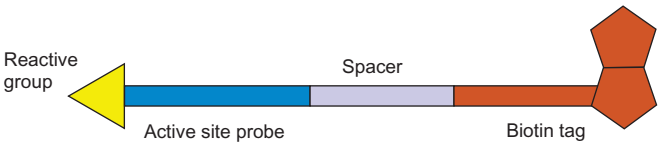

FIGURE 1.70 The general design of an active site warhead probe containing a biotin affinity group. The active site probe portion typically is a peptide binding sequence or an organic inhibitor of a specific enzyme active site. This facilitates the probe to initially interact with the enzyme, after which the reactive group covalently links to a functional group within or near the active center. The biotin handle can then be used to detect the modified enzyme or isolate the complex using streptavidin conjugates.

Affinity Capture using Active Site Binding Probes

Affinity probes containing active site binding components can be used to target and isolate specific enzymes, or enzyme classes, and other macromolecules within a biological sample. In this application, the bioconjugate probe may be an analog of a ligand that binds to a particular receptor or it may be a substrate analog that binds to the catalytic site of an enzyme. In either case, the probe can be designed to contain a detection component for assay or imaging, or an affinity component for purification using a complementary immobilized affinity support. The active site probe portion can consist of a binding molecule that interacts with high affinity but reversibly with the receptor or enzyme, or it can be a reactive probe which covalently couples in the region of the active site once bound. The second type of probe is often said to have a reactive warhead that spontaneously couples to a functional group within molecular reach of the active site.

Active site binding probes can be constructed to contain a terminal biotin group for detection or affinity isolation using streptavidin conjugates or immobilized streptavidin, respectively. Once the warhead end of the probe gets conjugated within or near an active site, the biotin tag can be used to enrich the population of active enzymes from a sample or detect the modified proteins on a western blot (Figure 1.70).

Probes can also be designed on their non-interacting end to contain a bioorthogonal or chemoselective reactive group that does not react with biomolecules, but can be used to subsequently label the probe with a detection molecule or affinity tag once the probe has bound to its target. Activity-based protein profiling (ABPP) has been used to globally assess enzyme activation and catalytic activity in samples (Kam *et al*., 1993; Abuelyaman *et al*., 1994; Speers *et al*., 2003). For instance, Singaravelu *et al*. (2010) used a phenyl sulfonate ester probe containing a terminal alkyne group for labeling a range of enzyme families associated with hepatitis C virus replication. The phenyl sulfonate ester end is able to covalently link to nucleophiles in the active site of many enzymes, while the alkyne group subsequently can be reacted in a click chemistry reaction (e.g., copper-catalyzed Huisgen's 1,3-dipolar cycloaddition; Chapter 17, Section 5) with an azide-containing compound to form a triazole ring linkage. The resultant bioconjugate can be used to capture and enrich the labeled enzymes or detect them in a western blot (Figure 1.71). Activated enzymes isolated from a cell lysate may be analyzed by mass spec to provide a global picture of enzyme status within a cell.

Specific kinase enzyme probes have been developed to permit similar targeting of the activated kinome. ATP analogs can be used that contain an electrophilic anhydride group (acyl phosphate) positioned at the gamma-phosphate of the nucleotide. Such derivatives made from a biotinylation compound containing a terminal carboxylate can be used to form the acyl phosphate group, which creates an ATP binding site warhead that can covalently link to a particular lysine amine immediately adjacent to the nucleotide binding site. This probe is able to label all kinases having their nucleotide binding site accessible and active (Patricelli *et al*., 2007). Similar nucleotide binding site probes can be constructed using photoreactive groups attached to an ATP derivative or using the reactive group 5′-p-fluorosulfonylbenzoyl adenosine. The fluorosulfonyl group can react with a nearby lysine amine residue similar to the acyl phosphate design. When using a photoreactive group, however, exposure to UV light is the driving force that facilitates the covalent attachment of the probe once it is bound to a nucleotide binding pocket (Karaman *et al*., 2008). In addition to ATP active site probes, reactive conjugates can be designed to contain ADP, GTP, GDP, or other nucleotides and are useful in probing enzymes that have binding

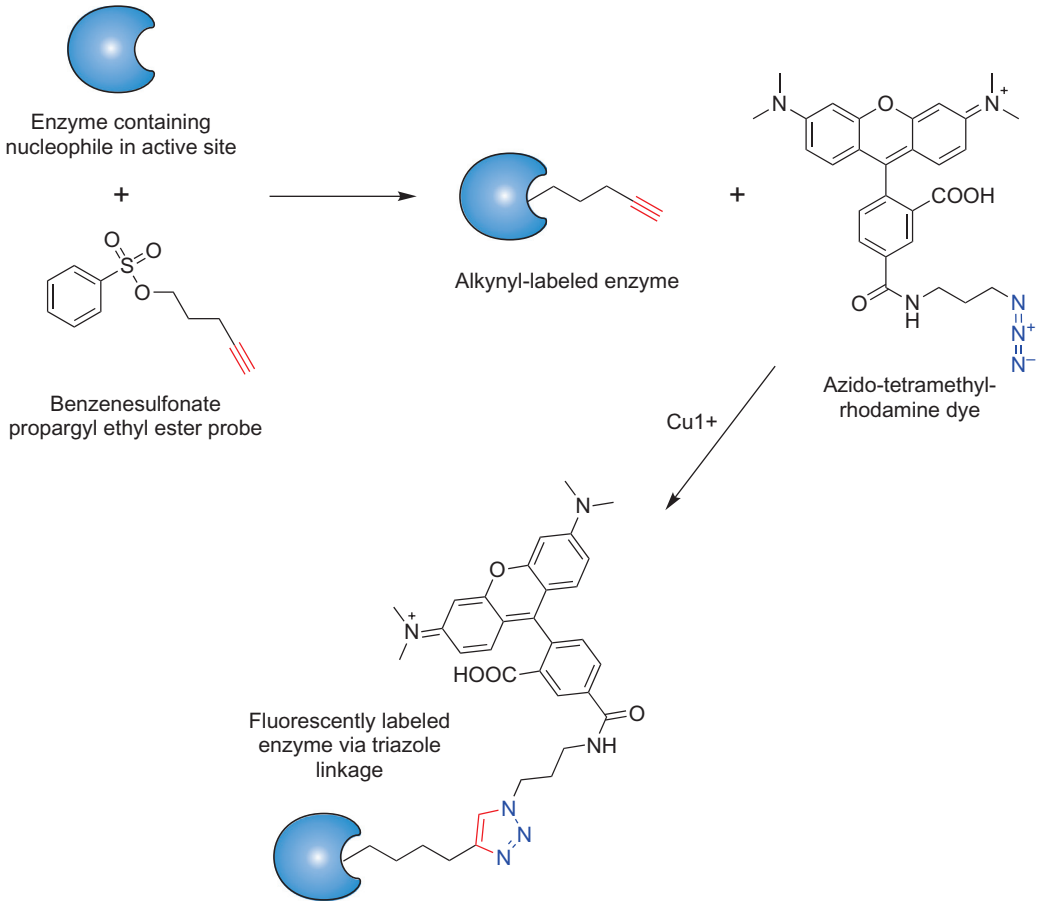

FIGURE 1.71 A benzene sulfonate ester reactive group probe can be used to covalently link to the active site within some enzymes and the alkyne group can be used for labeling with a fluorescent probe by a copper-catalyzed click reaction with an azido-rhodamine dye.

sites for particular nucleotide derivatives (Figure 1.72). Over half of all proteins produced in mammalian cells have a binding pocket for a nucleotide derivative; therefore, ABPP using nucleotide cofactors can be used effectively to analyze much of the proteome.

Other reactive probes can be created to target enzymes of a number of different substrate classes (Cravatt *et al.*, 2008). For instance small bioconjugate probes for serine hydrolases have been constructed using reactive warheads containing phosphonate reactive groups. Serine hydrolases are characterized by a highly conserved serine residue in the active site, which is crucial in forming an intermediate enzyme–substrate ester bond when hydrolyzing ester, thioester, or amide bonds. This serine group can be targeted for labeling by phosphonate derivatives prepared from native enzyme substrates. Examples are fluorophosphonate and aryl phosphonates, which position the phosphonate reactive group adjacent to the active site serine, causing a covalent bond to occur with the serine hydroxyl (Mahrus and Craik, 2005; Pan *et al.*, 2006) (Figure 1.73). Affinity tags or fluorescent labels can also be attached to the substrate–fluorophosphonate warhead for subsequent isolation on affinity supports or detection in western blots (Liu *et al.*, 1999; Kidd *et al.*, 2001; Patricelli *et al.*, 2001; Alexander and Cravatt, 2006). After enrichment of labeled enzymes from a cell sample, the global serine hydrolase activity profile may be analyzed by mass spectrometry.

Activity-based protein profiling using reactive bioconjugates can also be designed to target cysteine proteases, which contain a critical thiol in their active site. Cysteine proteases can be labeled by a bioconjugate warhead containing an epoxide reactive group, a vinyl sulfone, or various ketone derivatives, including diazomethyl ketones, acyloxymethyl ketones, or fluoromethyl ketones (Barrett *et al.*, 1982; Mason *et al.*, 1989; Bromme *et al.*, 1994; Ekert, 1999; Amstad, 2000; Bedner, 2000; Smolewski, 2001; Bogyo *et al.*, 2002; Blum *et al.*, 2005; Kato *et al.*, 2005; Fonovic and Bogyo, 2007). These electrophilic groups react and covalently couple with the active site SH group to form thioether linkages (Figure 1.74). Biotin or fluorescent tags conjugated to the active site probe/warhead combination

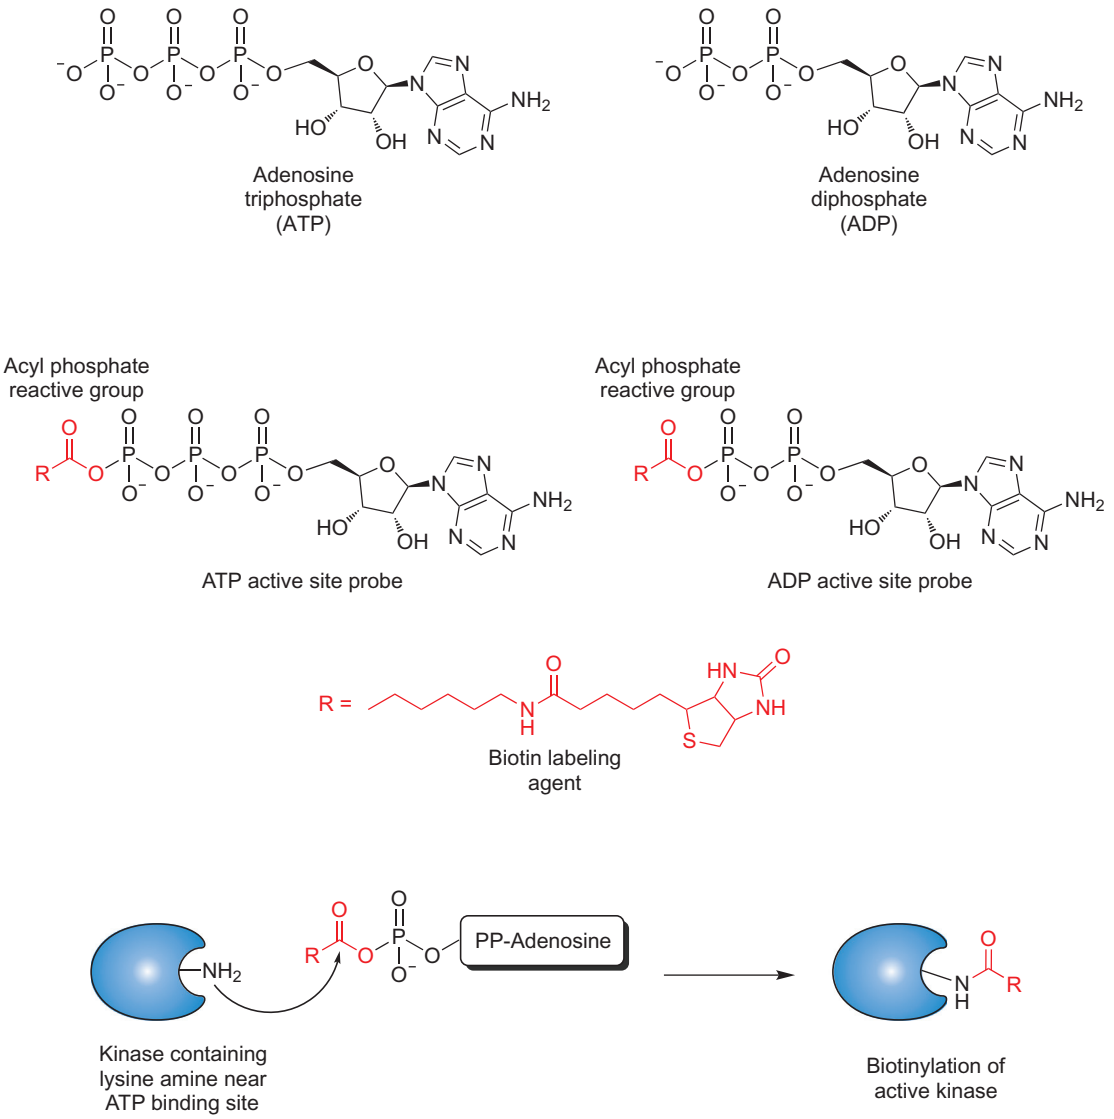

FIGURE 1.72 Active site probes for kinase enzymes consisting of an ATP or ADP analog and containing an amine-reactive acyl phosphate derivative on the terminal phosphate group. As the ATP or ADP probe binds to the nucleotide binding site on these enzymes, it positions the acyl phosphate reactive group near a lysine side-chain amino group. The amine reacts with the acyl phosphate to form a covalent amide bond with the acyl biotin arm while releasing the nucleotide portion, thus biotinylating every enzyme that can bind to the ATP or ADP probes.

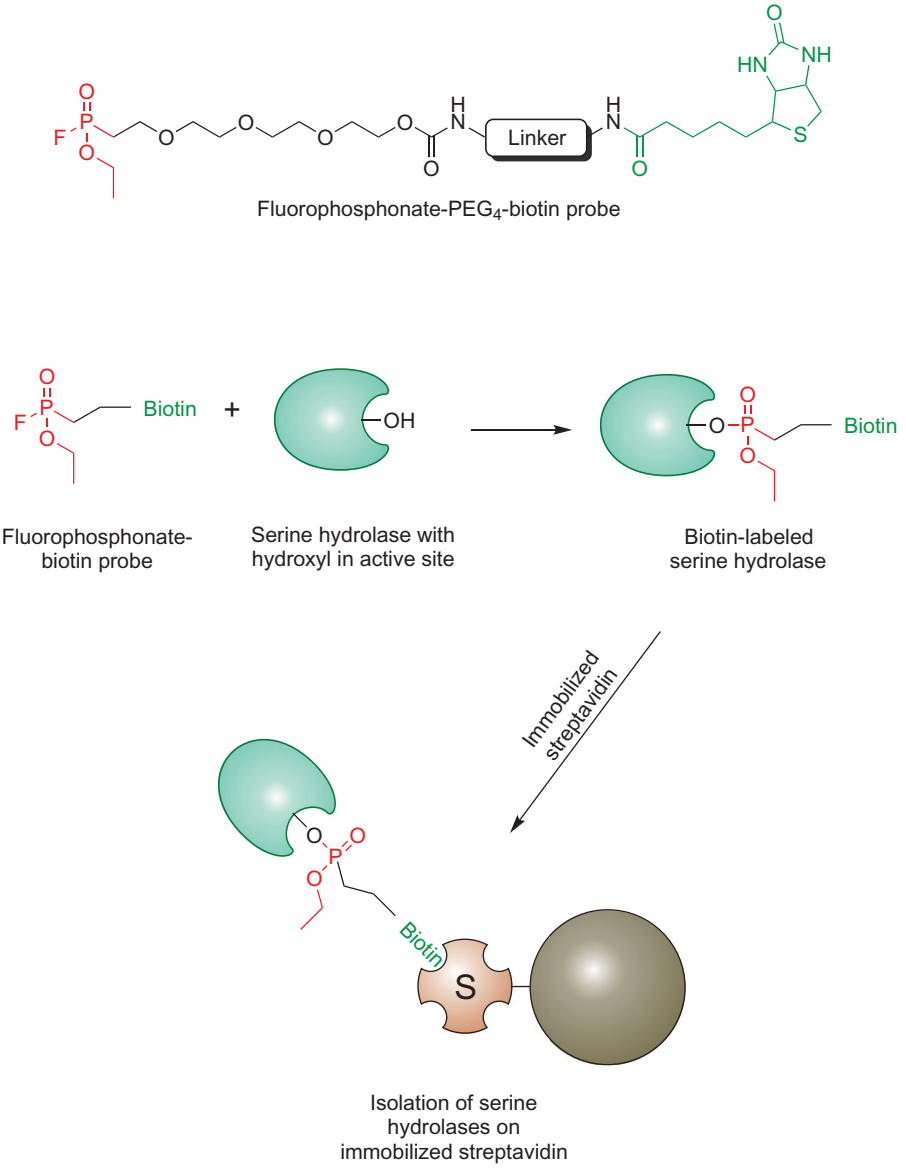
can facilitate affinity isolation on immobilized streptavidin or detection using the fluorescent signature. Biotinylated probes can also be detected through the subsequent application of streptavidin–enzyme or streptavidin–dye conjugates.

Unlike serine hydrolases or thiol proteases, metalloprotease enzymes cannot be targeted using an electrophilic reactive group, because there is not an accessible nucleophilic group within their active site. Typically, metalloproteases have a histidine-coordinated metal ion (zinc) in the active site that facilitates a proteolytic hydrolysis reaction through the activation of a water molecule. However, the chelated metal can be targeted using activity-based bioconjugates containing a tight binding peptide substrate with a hydroxamate group to chelate the metal in the active site and a photoreactive group to facilitate covalent coupling (Saghatelian *et al.*, 2004). The incorporation of a benzophenone photoreactive group, for instance, permits photo-crosslinking of the probe to the metalloprotease after exposure to UV light (Figure 1.75). If this type of probe is built with a fluorescent label or a biotin tag the labeled enzyme can be detected within cells or enriched on an immobilized streptavidin support.

Immobilized affinity ligands can also be designed to purify receptor proteins for analysis. Cell surface receptor activation through extracellular ligand binding causes many downstream effects within a cell, including



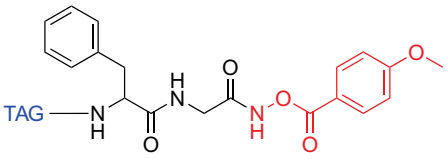


FIGURE 1.73 A serine hydrolase probe can be constructed from a fluorophosphonate-reactive warhead end and a biotin tag. The fluoro–phosphonate group covalently links to the active-site serine hydroxyl group and provides an affinity tag for detection of purification using streptavidin reagents.

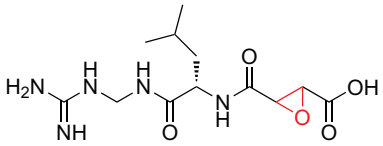
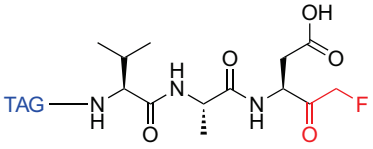


enzyme activation, protein translocation and translation, increases in energy production or glucose utilization, stress responses, transmission of action potentials, production of hormones, immune responses, secondary intracellular and extracellular signaling events, and sensing of environmental conditions (e.g., the sense of smell or taste). Many of these biochemical events are mediated through the specific interaction of a small organic ligand with a binding pocket on a receptor protein. Ligands may also be peptides or proteins, which interact specifically with the receptor binding site.

The immobilization of a specific ligand derivative onto an insoluble resin or support material can facilitate the targeting and isolation of corresponding receptors from cell lysates. In addition, the coupling of multiple ligands onto a scaffold can be used to present multivalent interactions that can in turn cause receptor aggregation and activation of signal transduction pathways within cells (Kiessling *et al.*, 2006). The appropriate affinity ligands may be coupled to chromatography supports (Chapter 15), microparticles (Chapter 14), carrier proteins (Chapter 19), dendrimers (Chapter 8), polymers (Chapter 18), or liposomes (Chapter 21) to facilitate receptor isolation or signal activation.



Immobilized affinity ligands and their analogs have been used for years to purify many diverse receptor

The targeting end of the molecule is shown in green, which contains a hydroxamate group that is able to bind through coordination with the chelated zinc ion in the enzyme active site. After binding, the benzophenone photoreactive group is photolyzed, which results in a covalent linkage with the enzyme near the catalytic site. The tag can be used to detect the enzyme or isolate it for further study.

types for analysis, including benzodiazepine receptors using an immobilized delorazepam derivative (Martini *et al.*, 1981); Fc receptors using an immobilized IgG support (Simister and Rees, 1985); human hepatic ferritin receptors using immobilized ferritin (Adams *et al.*, 1988); and estrogen receptors using immobilized 7β-estradiol, 4-hydroxy tamoxifen, or the synthetic active-site binding compound ICI-182,780 (Nalvarte *et al.*, 2010), to name only a few examples.

In addition, affinity chromatography using immobilized small molecule drugs or drug candidates can be used, followed by mass spec analysis for drug discovery to determine drug interaction targets (Saxena *et al.*, 2009). This technique, often called "capture compound mass spectrometry" (CCMS), can be used to determine pharmacokinetic properties of drugs, specific drug targets and off-target effects, and the toxicological indications of drug candidates (Kroll *et al.*, 2009). Trifunctional designs for CCMS probes have been developed that contain one arm having a drug derivative, a second arm

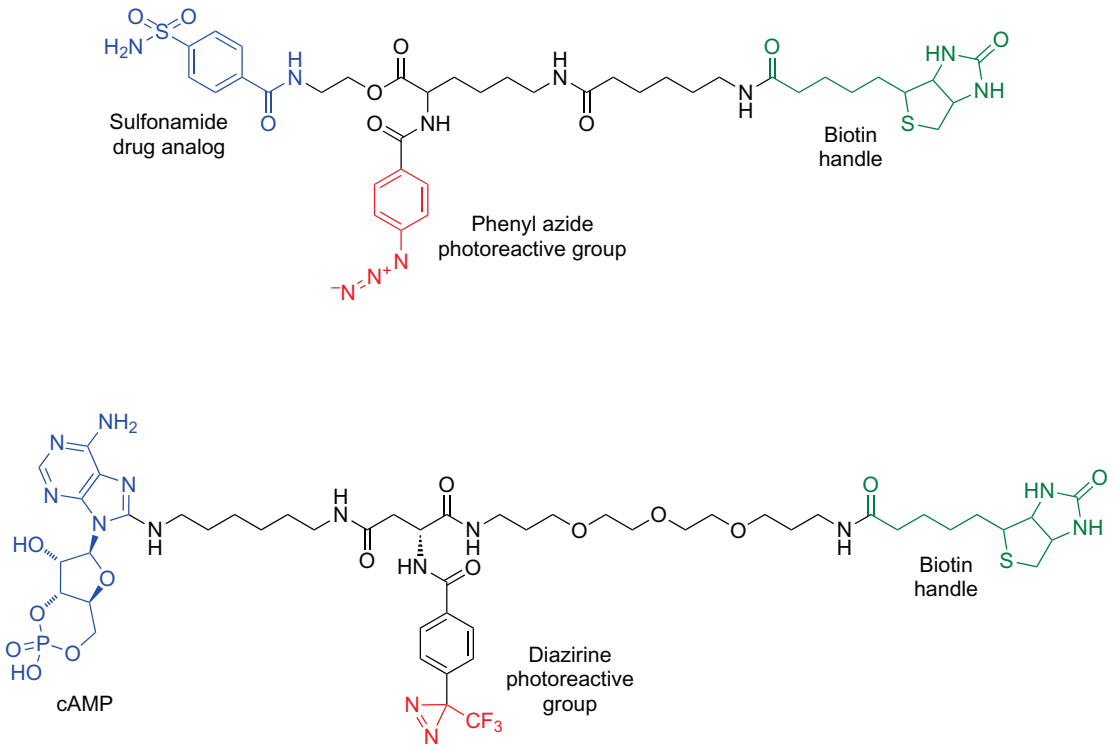

FIGURE 1.76 A CCMS probe containing a trifunctional design. The sulfonamide end binds to carbonic anhydrase and is an analog of a glaucoma drug, the phenyl azide photoreactive group facilitates covalent attachment to the enzyme target upon photolysis, and the biotin handle allows for purification on immobilized streptavidin. The captured molecules can be eluted and analyzed by mass spec.

with a photoreactive warhead, and a third arm with an affinity tag for capture on an affinity support. Köster *et al*. (2007) developed such probes containing a sulfonamide drug analog, a photoreactive phenyl azide group for covalent attachment, and a biotin derivative for affinity capture of the resultant complexes on a streptavidin resin (Figure 1.76). A similar CCMS compound was developed for affinity capture of *S*-adenosyl-L-methionine-dependent methyltransferases (Dalhoff *et al*., 2010). Its trifunctional probe design contained an *S*-adenosyl-L-homocysteine selectivity group (affinity ligand), a photoreactive phenyl azide, and a biotin tag for isolation on immobilized streptavidin. Other CCMS probes have been designed to contain a GDP selectivity group for capture of GTPases (Luo *et al*., 2009), a cAMP selectivity group for isolation of cAMP binding proteins (Luo *et al*., 2009b) (Figure 1.76), and a staurosporine selectivity group for broad binding of kinases (Fischer *et al*., 2010). The basic trifunctional design of CCMS probes can be used to create numerous affinity probes for study of small molecule binding to proteins, which is especially useful in drug discovery.

Affinity Capture of Recombinant Fusion Proteins

One of the most frequent applications of immobilized affinity ligands is in the capture or isolation of recombinant proteins containing fusion tags. Fusion protein technology has advanced in conjunction with recombinant protein production to allow easy purification of a wide range of expressed proteins by targeting a common peptide tag. In other words, if the recombinantly produced protein also contains another peptide chain attached to its C- or N-terminal end that has known binding characteristics to certain affinity ligands, then the fusion tag can facilitate immobilization, capture, or purification of the expressed protein. The fusion partner thus functions as a universal affinity handle that can be targeted by the proper immobilized ligands regardless of what recombinant protein is being produced.

Fusion protein affinity tags can consist of relatively short peptide segments (i.e., 5 to 8 amino acids) or intermediate length or longer polypeptides consisting of fragments, domains, subunits, or entire proteins having particular active-site binding properties. The shorter tags are often targeted through the use of an immobilized antibody to specifically interact with the fusion tag sequence or through the use of an immobilized metal chelating group (IMAC) (see Table 1.2). Fusion tags such as the FLAG tag, which contains an eight amino acid sequence, and the c-myc tag, which contains 11 amino acids, typically are targeted using monoclonal antibodies specific for their respective sequences. Immobilized immunoaffinity

TABLE 1.2 Common Fusion Protein Affinity Tags and Their Properties

Fusion Tag	Residues	Sequence	Molecular Weight (kDa)	Affinity Support
Poly-His	6–8 (usually 6)	HHHHHH	0.84	Metal chelate (Ni^{2+}-NTA, Co^{2+}-CMA)
HAT (natural His affinity tag)	19 (6 His)	KDHLIHNVHKEFH-AHAHNK	2.31	Metal chelate (Ni^{2+}-NTA, Co^{2+}-CMA)
Glutathione-*S*-transferase (GST)	211	Protein tag	26	Glutathione (GSH)
FLAG tag	8	DYKDDDDK	1.01	Anti-FLAG monoclonal antibody
FLAG repeat	22	DYKDHDGDYKDH-DIDYKDDDDK	2.73	Anti-FLAG monoclonal antibody
c-Myc	11	EQKLISEEDL	1.2	Anti-c-Myc monoclonal antibody
Poly-Arg	5–6	RRRRRR	0.96	Cation exchange resin
S tag	15	KETAAAKFERQHMDS	1.75	*S*-fragment of RNaseA
Calmodulin-binding peptide	26	KRRWKKNFIAVSA-ANRFKKISSSGAL	2.96	Calmodulin
Cellulose-binding domain	27–189	Domains of cellulose binding protein	3–20	Cellulose
Chitin-binding domain	51	TNPGVSAWQVNTAYT-AGQLVTYNGKTYKC-LQPHTSLAGWEPSN- VPALWQLQ	5.59	Chitin
Maltose-binding protein	396	Protein tag	40	Amylose
Streptavidin-binding peptide (SBP)	38	MDEKTTGWRGGHVV-EGLAGELEQLRAR- RLEHHPQGQREP	4.03	Streptavidin
Strep-tag II	8	WSHPQFEK	1.06	Mutant streptavidin (Strep-Tactin)
AviTag	15	GLNDIFEAQKIEWHE (facilitates biotinylation at lysine residue)	1.83	Streptavidin
HA tag (influenza hemagglutinin)	9	YPYDVPDYA (amino acids 98–106)	1.1	Anti-HA monoclonal antibody
DHFR (dihydrofolate reductase)	187	Protein tag (sometimes used as fragment containing 6xHis sequence)	23.8	Anti-DHFR monoclonal antibody

supports thus can be used to isolate any recombinant proteins containing the FLAG or c-myc fusion tags.

Another common fusion tag is a short eight-amino-acid sequence, called Strept-tag II, which binds to the biotin-binding pocket of streptavidin (Schmidt and Skerra, 2007). Typically, a mutant streptavidin protein is used with the Strept-tag II to further enhance the binding affinity of the peptide to the biotin binding region. The Strep-tag II sequence has also been used in dual-tag approaches wherein a recombinant protein is purified through use of two different affinity tags on either of its C- and N-terminal ends (Clontech). This technique, called "tandem affinity purification" (TAP or TAP tag) has important application in the isolation of recombinant proteins (Rigaut *et al.*, 1999; Puig *et al.*, 2001). Purification of an expressed protein using a series of two different affinity chromatography separations directed at the different TAP tags results in increased purity of the desired protein (Figure 1.77). TAP tags have also been used to isolate interacting proteins or protein complexes and even enhance the identification of the interacting partners (Séraphin *et al.*, 2002).

A unique poly-DOPA (dihydroxy phenylalanine) fusion tag has been described that allows the immobilization of a recombinant protein through interactions of the dihydroxy groups with surfaces (Jennissen and Laub, 2007). The tag is expressed as a series of four tyrosine residues at the N-terminal with an intervening serine residue. The tyrosines can be chemically or enzymatically transformed into the DOPA derivatives. This technology mimics the native foot proteins found in mussels, which contain DOPA groups that allow tight noncovalent interactions with mineral, metallic, or organic surfaces in aqueous environments. DOPA

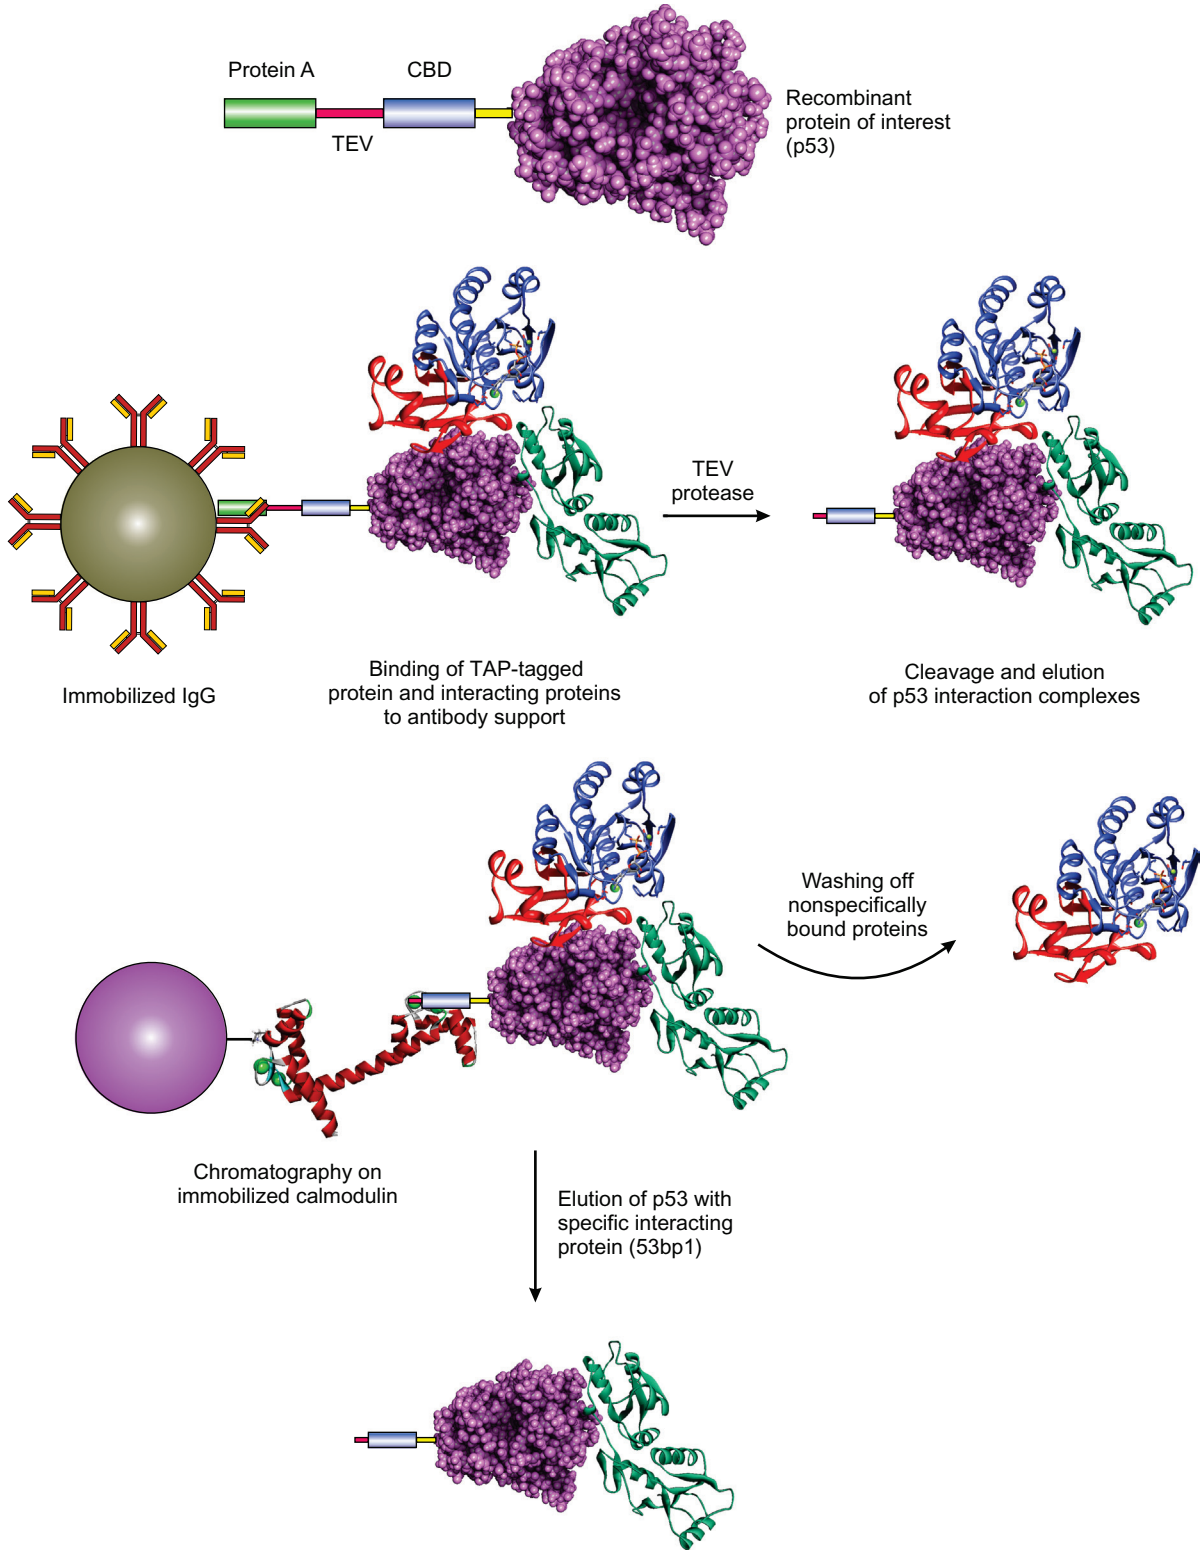

FIGURE 1.77 Tandem affinity purification (TAP) tags make use of a design consisting of two fusion proteins linked by a TEV protease sequence and followed by the protein of interest. This design permits the isolation of true interacting proteins in two chromatography steps by removing any other proteins that may be carried along through nonspecific binding. A common pair of fusion protein tags for this purpose includes the use of protein A to bind immunoglobulins as well as the calmodulin binding domain (CBD) to bind calmodulin. Upon expression of the recombinant protein of interest (in this case, p53) and incubation with a sample to allow binding of putative interacting partners, the fusion tags are used in a series of two affinity steps to aid in the removal of nonspecifically bound proteins that may be interacting with the desired protein interaction complex. Thus, the expressed protein complex is first subjected to affinity purification on immobilized IgG, which binds to the protein A tag and facilitates washing away of the bulk of non-bound proteins. Next TEV protease is added to the affinity resin to cleave the linker between the protein A and CBD fusion partners, thus releasing the recombinant protein complex of interest, which still has the CBD fusion tag attached to it. In a second affinity chromatography step, immobilized calmodulin is used to capture the CBD fusion tag and a second wash step is carried out to remove any contaminating proteins. Elution of the remaining interacting proteins then results in a higher certainty that any bound proteins still remaining are true interacting partners to the protein of interest and not just nonspecific binders.

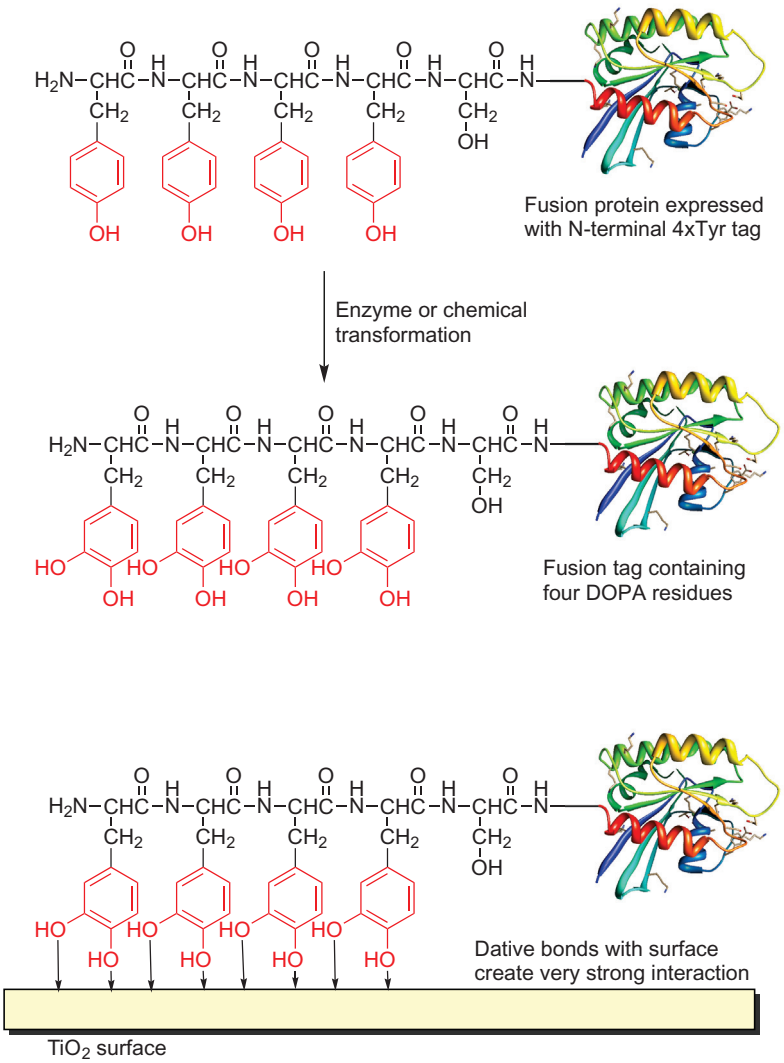

FIGURE 1.78 A fusion protein tag consisting of four tyrosine residues can be transformed into a poly-DOPA tag either enzymatically or chemically. The high density of the hydroxyl groups within this short sequence can provide strong binding potential to metallic surfaces through dative bonds.

groups have been shown to present high-affinity binding with TiO_2 surfaces, which reflect dual coordination of the hydroxy groups providing incredibly high dissociation energies (Lee *et al.*, 2006). A single DOPA residue was found to require in the range of 750 to 800 pN to break its interaction with a TiO_2 surface, thus placing its dissociation energy midway between one of the strongest noncovalent interactions (streptavidin–biotin at ~160 pN) and true covalent bonds, which are on the order of 1,600 pN (note that a single hydrogen bond only requires about 4 pN to dissociate the interaction). Thus, a poly-DOPA-labeled fusion protein can be immobilized onto surfaces with high efficiency and with an effective strength of binding that places it even above the realm of covalent coupling, due to multiple DOPAs interacting simultaneously (Figure 1.78).

Perhaps the most popular fusion tags, however, are the 6xHis or the glutathione *S*-transferase (GST) tags. A 6xHis tag contains a sequence of six histidine residues in a row at one end of the recombinant protein. Occasionally, additional histidine residues are used and sometimes spaced by other non-chelating amino acids (such as in the HAT tag; see Table 1.2). Neighboring histidines are very adept at coordinating transition metals through the unshared pairs of electrons on their side-chain imidazole nitrogens. An immobilized metal chelate containing nickel, cobalt, or gallium with unoccupied coordination sites (or occupied only by water molecules) is commonly used to purify His-tagged proteins or even immobilize them to a surface for analysis.

Recombinant proteins containing a GST fusion partner can be isolated through its native interaction with glutathione (GSH). GSH can be immobilized to an affinity matrix through its thiol group by using an epoxide- reactive group, which forms a thioether upon coupling (Chapter 15, Section 2.3). GSH presented in this manner has good capacity for interactions with GST fusion proteins and can

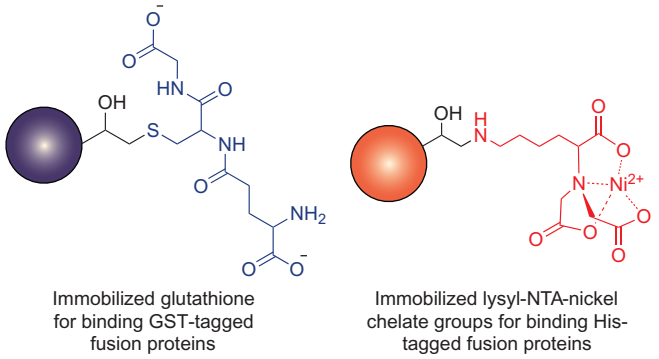

FIGURE 1.79 Two of the most common affinity ligand conjugates for capturing fusion proteins constructed with GST or 6xHis tags are immobilized glutathione and immobilized nickel chelate, respectively.

be used for either isolation or immobilization of the recombinant protein associated with it. Fusion proteins therefore can be used for purification of the desired recombinant protein or for oriented coupling of the protein to a surface or particle. Since the affinity ligand only interacts with the fusion tag, the recombinant protein ends up sticking off the surface with a predictable and reproducible orientation (Figure 1.79). This is an advantage for ensuring that the recombinant protein activity or binding site is available upon immobilization.

Covalent Fusion Tag Technology

A variation on standard fusion tag design is the development of mutant enzyme tags that can bind and covalently bond to a particular substrate molecule. Certain enzymes are designed to cleave substrates through the temporary covalent linkage of an intermediate of the substrate to a residue within their active sites followed by release of the temporary link to free the active site for another substrate. Esterases, such as cutinase for example, are one class of enzyme that undergo such reactions and if they are mutated or used with a special substrate analog, a substrate derivative can be designed to permanently link within the active site through covalent bond formation. Alternatively, some enzymes are classified as suicide enzymes, because they react with a substrate and covalently transfer part of the substrate to a functional group within their active sites, while the remainder of the substrate is cleaved and released. Mutagenesis has been used to mutate amino acid residues around the active site of such enzymes and create a new enzyme with altered activity, which functions to covalently link the substrate to its active site without the subsequent cleavage event taking place. The results of these approaches are enzyme–substrate pairs that are able to covalently couple to the appropriate substrate ligand with high selectivity and efficiency.

Using enzymes and substrates that are able to form a selective covalent bond between one enzyme molecule and one substrate molecule is useful for making reactive fusion proteins, which can then be used to label or immobilize the recombinant protein at a specific site on the fusion partner (Figure 1.80). Examples of this technology include the use of the serine esterase cutinase along with a chlorophosphonate ester substrate (or fluorophosphonate or *p*-nitrophenyl phosphonate) derivative to form a covalent link with the serine in its active site (Hodneland *et al*., 2002; Nickel *et al*., 2012); a mutant haloalkane dehalogenase enzyme that covalently links a terminal chloroalkyl substrate derivative to an aspartate carboxylate in its active site to form a stable ester bond (Hata and Nakayam, 2007; Shinohara and Matsubayashi, 2007; Schröder *et al*., 2009) (HaloTag, Promega); a mutant human O^6-alkylguanine-DNA-alkyltransferase (hAGT) that is able to covalently link a substrate analog containing a terminal benzylguanine group to a cysteine thiol in its active site (Jongsma and Litjens, 2006; Iversen *et al*., 2008; Engin *et al*., 2010) (SNAP-tag, NEB); and a second mutant of hAGT that specifically reacts with substrate derivatives containing a benzylcytosine group to the cysteine thiol in the active site (Gautier *et al*., 2008; Schulz and Köhn, 2008) (CLIP-tag, NEB). The combined use of both the SNAP-tag and CLIP-tag fusion proteins can facilitate multi-protein labeling with different fluorescent substrate derivatives for *in vivo* cellular imaging (Gautier *et al*., 2008).

Covalent fusion tags allow highly discrete labeling of recombinant proteins at a single site per fusion pair. The mutant enzymes have been engineered to have high-affinity binding constants to their substrate derivatives combined with a high yield of covalent attachment. The result permits selective labeling of expressed fusion proteins in complex solutions containing many other proteins, similar to bioorthogonal chemical labeling techniques. It also allows such fusion proteins to be immobilized onto array surfaces or particles without purification from an expression lysate. Cells expressing a protein containing a covalent fusion tag partner can be grown in microplates and the cells lysed. If the appropriate substrate derivative is immobilized on the plate surface, the expressed protein in the lysate is quickly coupled to the surface through the fusion tag active site, thus immobilizing it for subsequent assay or analysis.

Scavenging of Contaminants or Unwanted Components

Another major application area for immobilized bioconjugate affinity ligands is the removal of contaminants or unwanted components in a biological sample. Often, certain components in a sample extract can interfere with subsequent analysis or inhibit activity of

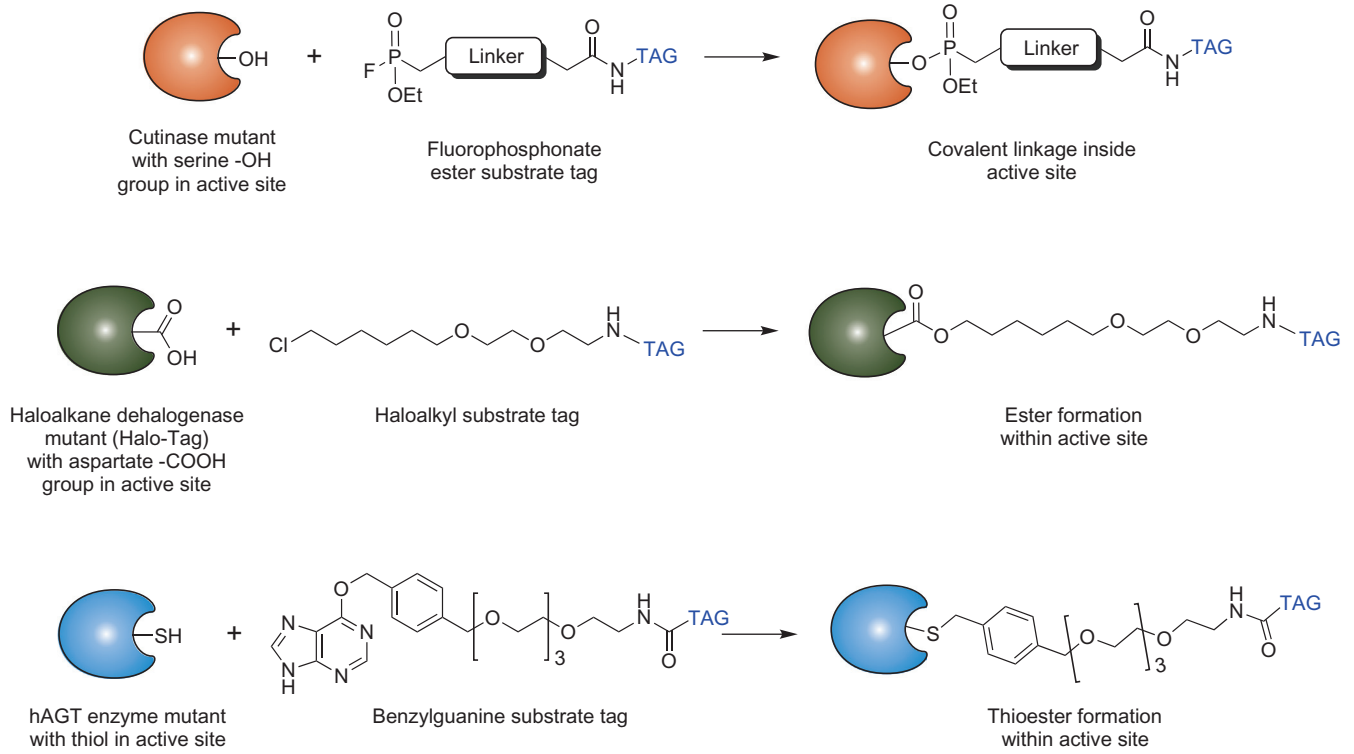

FIGURE 1.80 Three examples of covalent fusion tags consist of mutant versions of the enzymes cutinase, haloalkane dehalogenase, and human O^6-alkylguanine-DNA-alkyltransferase (hAGT). These mutant enzymes react with certain substrates to result in covalent linkages with the key functional groups within their active sites. Substrate derivatives containing detection tags, affinity handles (e.g., biotin), or even immobilized substrates may be used to specifically link to these tags, which can be associated with expressed proteins.

a protein to be studied. Specific removal of such components can be done through affinity chromatography using an appropriate immobilized affinity ligand that interacts selectively with the unwanted molecules. An example of such a scavenging affinity support includes the removal of detergents from protein solutions, especially from cell lysates prepared by detergent-mediated lysis. Detergents are difficult to remove from aqueous solutions, because micelle formation typically restricts their diffusion through dialysis membranes. This also makes it difficult to remove them from proteins by size-exclusion chromatography, because their effective micellular molecular weight is on the same order as proteins or greater.

Affinity supports designed to remove detergents from biological solutions have been developed using hydrophobic interaction chromatography. In this case, the affinity ligand typically is a small hydrophobic molecule or a hydrophobic polymer attached to a resin, which allows the hydrophobic tail of the detergent molecules to bind while proteins pass through (Figure 1.81). In other cases, the entire beaded matrix can be made from a hydrophobic polymer, which can bind to detergents. However, to eliminate the potential for proteins to bind nonspecifically through hydrophobic interactions to these particles, many detergent-removing supports use porous chromatography beads with a rather small molecular exclusion limit (<10 kDa), thus restricting access of the average-sized proteins to interact with the interior of the particles. This design allows proteins to pass around the beads while detergent molecules are able to diffuse within the porous structure and get bound by the hydrophobic ligands.

Variations on this concept have been commercialized by Pierce (Thermo Fisher Scientific) (Extracti-Gel D) as well as Pall Corporation (SDR HyperD resin). Both of these affinity resins contain proprietary hydrophobic molecules immobilized onto the interior spaces of the particles. Another matrix is available made from a polystyrene/divinylbenzene copolymer particle (BioBeads SM-2 from Bio-Rad), but this support can also bind considerable protein molecules nonspecifically due to the hydrophobic surface character of the beads and the fact that the particles are not porous to better exclude proteins from interacting with the hydrophobic surfaces.

Scavenging affinity supports can also be prepared to remove hazardous components from solution, such as in the removal of endotoxins from biological preparations. Lipopolysaccharide (LPS) molecules (also called lipid A) consist of a hydrophilic head group containing

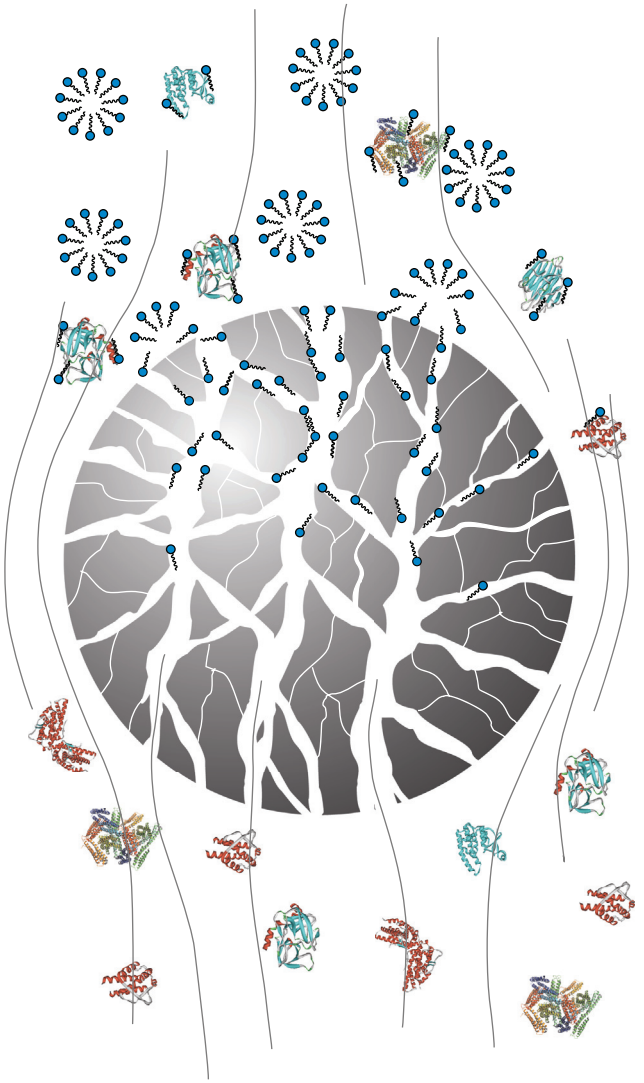

FIGURE 1.81 The principle of detergent removal using hydrophobic interaction chromatography. Porous particles containing hydrophobic ligands coupled to the surface can be used to bind the hydrophobic tails of detergent molecules. If the pore structure is small enough to prevent most proteins from entering the pores and being bound, then the detergents will be removed as the proteins pass around the particles and elute from the column.

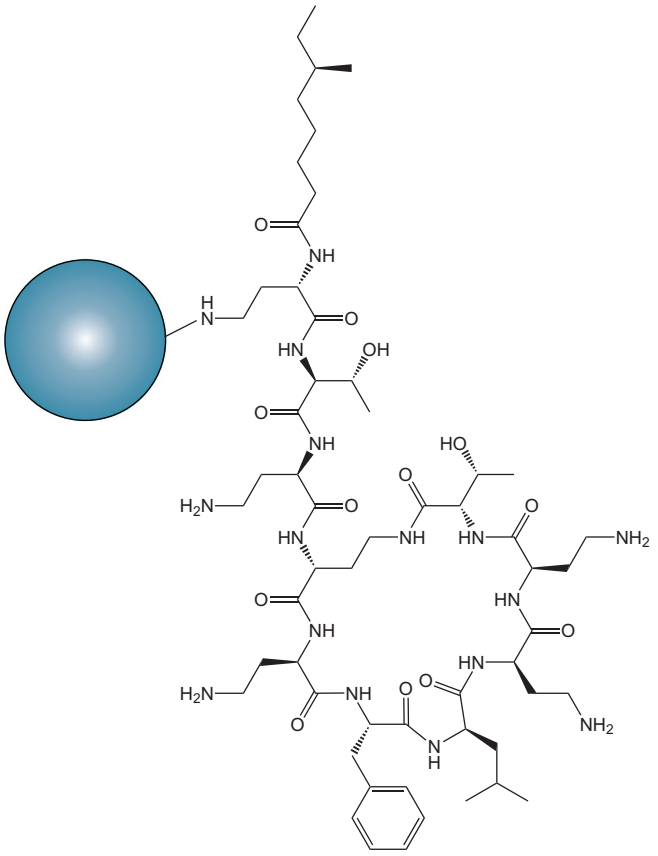

FIGURE 1.82 Immobilized polymyxin B can be used for the removal of endotoxins from solution.

carbohydrate along with two negatively charged phosphate groups as well as seven hydrophobic fatty acid tails attached to the sugar groups. LPS molecules are often components of bacterial membranes with their lipid chains embedded in the bilayer membrane structure. Bacterial contamination of biological materials can cause endotoxins to be present in protein solutions. Endotoxins are pyrogens that cause fever in animals in small doses or even death in larger amounts. Biological solutions containing endotoxins can also cause unwanted cellular effects if they are inadvertently added to cells grown in culture.

Removal of endotoxin can be accomplished through conjugation of polymyxin B to a chromatography resin (Magalhães *et al.*, 2007). Polymyxin contains a large cyclic peptide derivative with a hydrophobic tail that has antibiotic properties and which is able to interact rather specifically with lipid A molecules (Figure 1.82). Protein solutions containing unacceptable amounts of endotoxin can be cleansed from this contaminant by affinity chromatography on an immobilized polymyxin B support. Another specific endotoxin-binding matrix was prepared using an immobilized version of the drug pentamidine, which was found to have similar binding capacity to polymyxin B supports, but is much less expensive (McAllister *et al.*, 2007). In addition, immobilized amino acids have also been found to be effective at removing endotoxins from biological preparations (Wei *et al.*, 2007).

Another type of scavenging affinity support that has found extensive use is an immunoaffinity matrix containing immobilized antibodies that target the most abundant proteins in plasma. Abundant protein removal using immobilized antibodies is often important to uncover and analyze the less abundant protein population in plasma by 2D electrophoresis or mass

spectrometry. Blood contains soluble proteins ranging in concentration from albumin at about 80 mg/ml and immunoglobulins at about 20 mg/ml to several other abundant proteins in the mg/ml range to many proteins in the μg/ml range and many thousands more at lower concentrations (down to the low pg/ml levels and below). The range of protein concentrations in blood spans over 10 orders of magnitude. However, the bottom 10% of proteins in plasma in terms of concentration represents over 90% of proteins actually in plasma (in terms of the number of different proteins present). The problem with analyzing the vast majority of proteins in blood is that they are obscured by the ones at high concentration. Removal of the dozen or so most abundant proteins from plasma is beneficial for separating and analyzing proteins at lower concentration without interference.

The preparation of scavenging immunoaffinity supports containing a mixed bed of different immobilized antibodies with specificity toward the most abundant plasma proteins is typically used to remove these high concentration proteins from samples prior to analysis. Each immobilized antibody is prepared individually and then the affinity resins are mixed in proportion to the amount of protein they must remove from a sample. Such affinity supports are available commercially with anywhere from a few antibodies to remove albumin and the major immunoglobulins up to about 12 to 20 different antibodies to eliminate all the most abundant proteins in a single chromatographic step (BAC, Agilent, Pall, Sigma Aldrich, Beckman Coulter). The protein passing through such affinity resins is cleaned of the indicated abundant proteins, but contains all the remaining proteins within the sample (Figure 1.83).

Affinity resins also have been designed to remove viruses from solutions. Immobilization of a Tamiflu analog, for instance, was used to chromatographically isolate influenza A viruses through specific binding to the H1N1 neuraminidase coat proteins (Kimura *et al*., 2009). Although this was used in a purification mode, the affinity support could also function to remove influenza viral contamination from biological solutions. In addition, Tsao *et al*. (1988) used immobilized cells on polymer membranes as the affinity ligands to capture viruses able to bind to specific cell surface receptors. The support was simple to prepare and highly selective for removing any viruses able to interact with the cells. Immunoaffinity chromatography can also be used to remove contaminating viruses. Detmers *et al*. (2010) developed a specific virus-binding support using camelid antibodies to adenoassociated virus, which is difficult to purify using other techniques.

Another type of scavenging support is one that contains a ligand able to interact and bind to a small contaminant in solution. For instance, immobilized metal chelators can be used to remove metal contamination from aqueous solution, as in remediation processes. This application is different from the use of immobilized metal chelate affinity chromatography (IMAC) for the purification of target molecules (Section 2.3, this chapter). In this case, an uncharged chelating support is used to capture and remove metal ions from solution, whereas in IMAC a pre-charged, metal chelate support is used to affinity capture certain targets having binding ability for the bound metal. To remove metals from various solutions, Duru *et al*. (2001) prepared a composite microparticle containing covalently attached poly(ethylene imine) on a poly(methyl methacrylate) core microsphere. The resultant scavenging affinity support could remove cadmium, copper, and lead ions from aqueous solution with high capacity.

Inorganic solid phases often perform better as a base for producing a metal-scavenging affinity support than polymeric materials, because they are less susceptible to shrinking and swelling or mechanical damage under harsh conditions of use. Silica in particular can be modified with functional silanes to contain a number of metal chelating groups (Chapter 14), which can then be used for metal ion capture. Jal *et al*. (2004) reviewed a number of chelating groups and their immobilization chemistry on silica supports for the selective binding of many metallic ions from solution.

Biopolymer constructs have also been immobilized on solid phases to create a metal scavenging support. Kostal *et al*. (2005) described the use of certain peptide sequences that can be produced by recombinant means and used to effectively remove metal contamination from waste water. For example, a poly-histidine-containing peptide is known to have excellent affinity for chelating a number of metal ions from aqueous solution. A hexahistidine tag on recombinant proteins can be used to purify the protein on an IMAC support (Section 2.3, this chapter), but in this case the poly-histidine ligand itself becomes the chelator to sequester and remove metals. Other peptide sequences known to bind metal ions can also be used for this purpose and immobilized on solid phase supports for heavy metal removal.

3.4. Catalysis and Chemical Modification

One of the most widely used applications of immobilized ligands is to catalyze a reaction in solution. Typically this is done using enzymes, but it may also involve the use of immobilized reactive groups that create certain modifications on target molecules. These immobilized reactants may facilitate specific cleavage of peptide bonds in proteins, hydrolysis of glycosidic bonds in carbohydrates, or the facilitation of chemical reactions to alter the structure of target molecules or synthesize particular substances. Conjugation of such

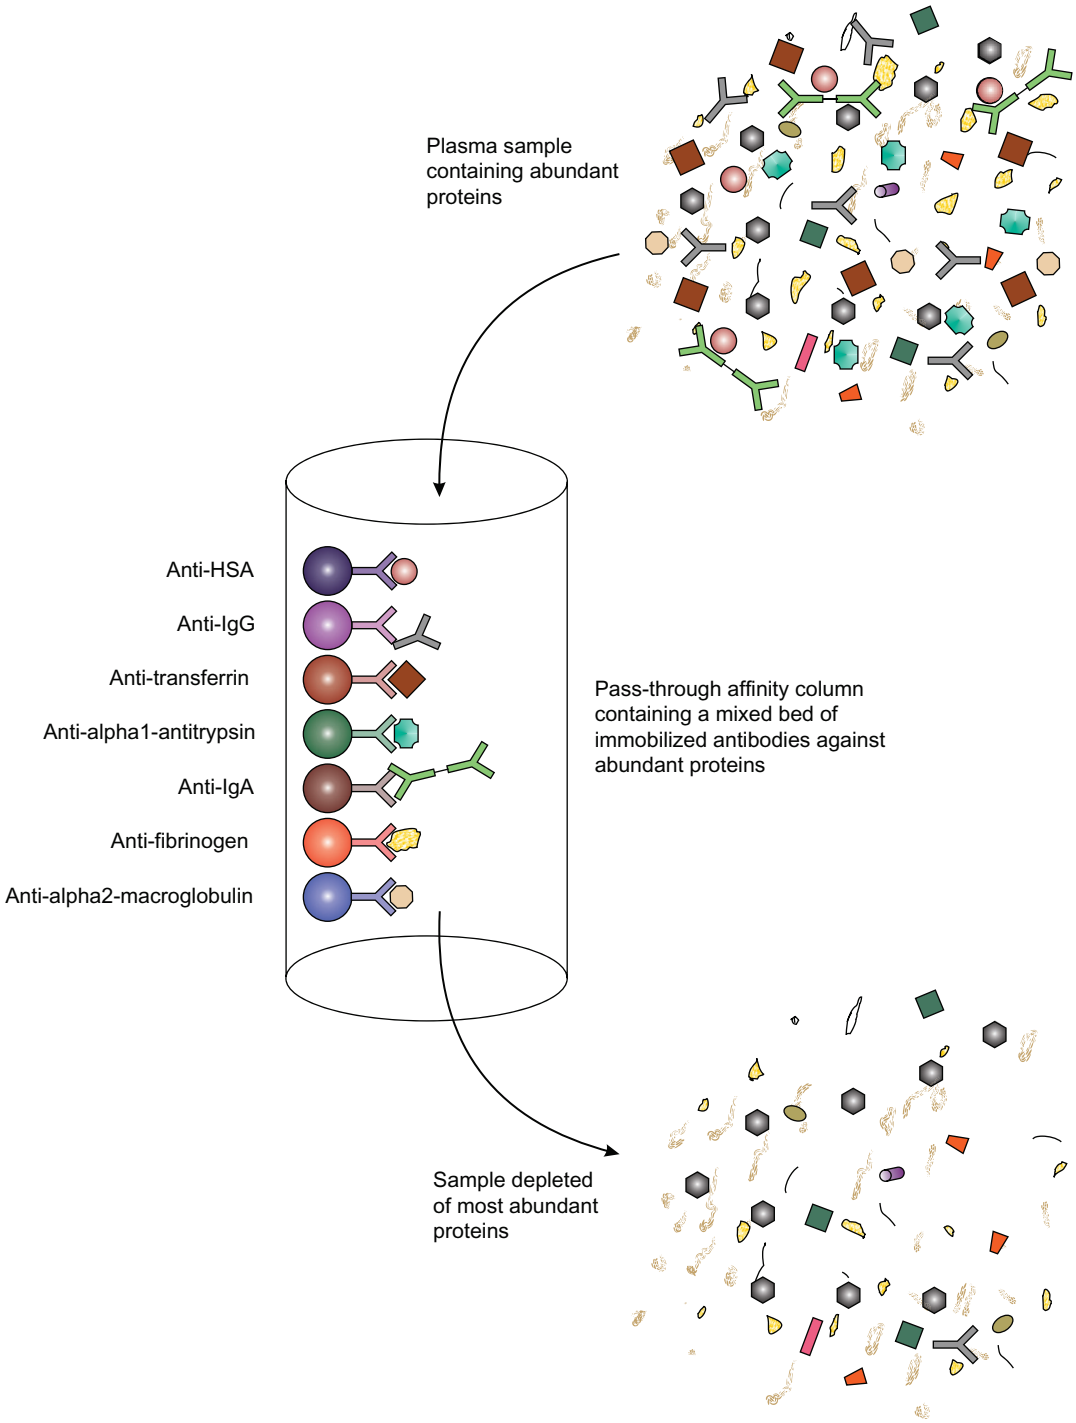

FIGURE 1.83 The principle of abundant protein removal from plasma samples is illustrated. A mixed-bed column is packed with immobilized antibodies against the major proteins in plasma. As a sample is passed through the column, the antibodies remove these predominant proteins from the solution and the remaining plasma proteins pass through essentially depleted of these high-concentration proteins.

reactive agents to solid phases creates a system that permits modification of target molecules without contamination of the solution with the reactive agent. After the reaction, separation of the immobilized catalyst or reactive compound is accomplished simply by filtration and washing of the solid phase to recover the sample solution. Many agents that can catalyze a reaction or react with a target molecule can be covalently attached to resins or surfaces to form an immobilized analog, which has convenient properties for numerous applications.

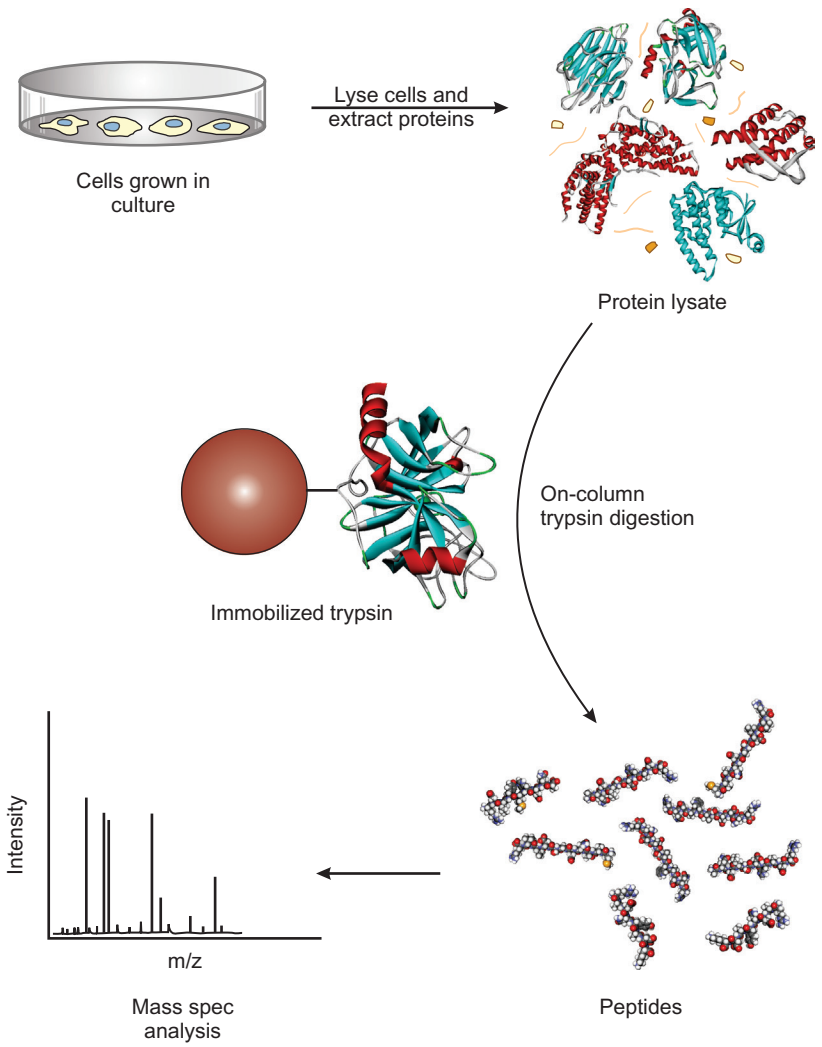

FIGURE 1.84 Immobilized proteases such as trypsin can be used to digest protein samples prior to mass spec analysis of the peptides produced. The use of an immobilized protease prevents contamination of the sample with free protease and its autolysis products.

These reagents are often called "immobilized reactors," and they have found extensive use in the fields of proteomics and biotechnology (Krenkova and Svec, 2009; Ma *et al*., 2009), in cellulosic ethanol production (Brethauer and Wyman, 2010), in the production of biodiesel fuels (Jegannathan *et al*., 2008), in the synthesis of organic compounds (Miyazaki and Maeda, 2006; Zhang *et al*., 2010), and in the remediation and treatment of pollutants (Husain *et al*., 2009).

Immobilized Proteases for Proteomic Analysis

One of the most common immobilized catalysts used for biological research applications is a protease. Protein hydrolases are enzymes that can cleave peptide bonds at certain sequence-specific locations to form peptides of various lengths from protein samples. If the protease has a high specificity toward cleavage only at precise amino acid sites within a protein, then the peptides formed from the digestion will be of known size and sequence relative to the protein from which they originated. These peptide fragments can be analyzed by mass spec and their masses and sequences compared to established databases, which can then be used to determine the corresponding parent proteins (Figure 1.84). This workflow is the basis for most methods of mass spec proteomics analysis and specific proteases make it possible (Malmström *et al*., 2007).

Trypsin is a serine protease that cleaves on the C-terminal side of lysine and arginine, and it has become a popular choice for protein digestion prior to mass spectrometry. If trypsin is immobilized through its amine groups to a particle or membrane, a protein sample can be treated for digestion without ultimately contaminating the sample with the enzyme or its autodigestion fragments. Immobilized trypsin on particles

has often been exploited in mass spec applications, using it in formats such as spin columns or pipette tips to rapidly digest proteins and subsequently separate the peptide sample from the trypsin reagent (Ota *et al*., 2007). Additional information on the immobilization of trypsin and other enzymes is provided in Chapter 15.

Immobilized proteases are also used for the cleavage of fusion tags from recombinantly expressed proteins. Many fusion tags are co-expressed with a desired protein to enable solubilization, folding, and/or purification of the target protein (see Table 1.2). However, it may be desirable to remove the fusion tag and thus obtain an expressed native protein structure for study without the tag being present. If a peptide sequence is incorporated between the expressed protein and the fusion tag that can be recognized and cleaved by a highly specific protease, then the tag can be selectively removed. Solution-phase protease treatment as well as the use of immobilized proteases have been employed to cleave fusion tags and recover desired proteins (Kubitzki *et al*., 2008). The immobilized protease form of these reagents allows recovery of the desired protein to occur without further contaminating the solution with the enzyme, thus providing a more convenient work flow for purification.

Another strategy in the use of enzymes to cleave fusion protein tags is to initially add a soluble enzyme containing an affinity tag to the fusion protein solution. After cleavage of the target fusion protein the enzyme can subsequently be removed using an immobilized affinity column directed at the tag on the enzyme (Pedersen *et al*., 1999; Jenny *et al*., 2003; Abdullah *et al*., 2005; Arnau *et al*., 2006). This method is more convenient in cases where the amount of protease is limiting and the preparation of an immobilized enzyme support is impractical (Figure 1.85). A simple route to creating this type of workflow is to use a biotinylated protease, which can be removed from the cleaved fusion protein through binding to an immobilized streptavidin support.

Immobilized Reactors in Bioengineering

Immobilized reactors are bioconjugate supports containing an enzyme or some other reactive component that can interact with and convert a target molecule into a desired product. Many of these insoluble reactors have been developed to serve large-scale process operations in fields such as biotechnology, the food industry, organic chemical production, bioremediation, and in the generation of biofuels. Immobilized enzymes in particular can display dramatically improved stability in an immobilized state compared to the corresponding soluble form of the enzyme in solution. Some enzymes such as α-chymotrypsin, chloroperoxidase, glucose oxidase, and lipase have shown stability improvements (including in one case over a thousand-fold gain in half-life of activity loss), increased stability toward organic solvents, and resistance to thermal degradation (Wang *et al*., 2001; Borole *et al*., 2004; Kim *et al*., 2006; Sheldon, 2007).

The coupling chemistry used to attach an enzyme reactor to an insoluble support involves similar reactions to those commonly used to create soluble bioconjugates, except in this case one of the components linked together typically is insoluble and particulate in nature. In most cases, the particle is considerably larger than the enzyme, and thus in the final complex the particle contains numerous copies of the coupled enzyme. For large process operations, the insoluble matrix could consist of a high-fidelity chromatography support, such as agarose or porous beaded polymers typically used in protein purification and having diameters of tens or hundreds of microns, but more often it is a support material that is much less expensive and abundant for scale up.

Some materials that have been used to immobilize reactors for industrial operations include particulate supports made from polymers (e.g., polystyrene), silica (particularly kieselgur or diatomaceous earth), porous and nonporous glass beads, activated carbon, chitosan or chitin, alginate gel, gelatin, polyurethane, agarose, agar, cellulose beads, polyacrylamide, polyvinyl alcohol, alumina, oxides of various transition metals, graphite, many different membrane compositions, and even sand or soil. For a review that contains a comprehensive list of immobilized bioreactor supports see Durán *et al*. (2002).

Both covalent and noncovalent methods have been used to immobilize enzymes on insoluble supports for use as reactors. Noncovalent methods include entrapment in polymer structures as they are formed, encapsulation of enzyme droplets into polymerizing membranes, and passive adsorption onto particle surfaces using one or a combination of hydrophobic interactions, hydrogen bonding, dative bonding, or charge interactions. Covalent bond formation involves the use of a reactive group that can couple with a functional group on the enzyme, such as an amine or a thiol. The covalent coupling strategies useful for the preparation of immobilized reactors are discussed in Chapter 15, which covers general methods of protein and enzyme coupling to insoluble supports.

An example of an immobilized enzymatic reactor is one that is used in the production of ethanol from cellulosic materials. Although most ethanol is produced from corn or sugar cane, which contains large quantities of simple sugars that can feed directly into the fermentation process, the technology developed over recent decades also permits ethanol manufacture from nonedible cellulosic raw materials. Hydrolysis of cellulose

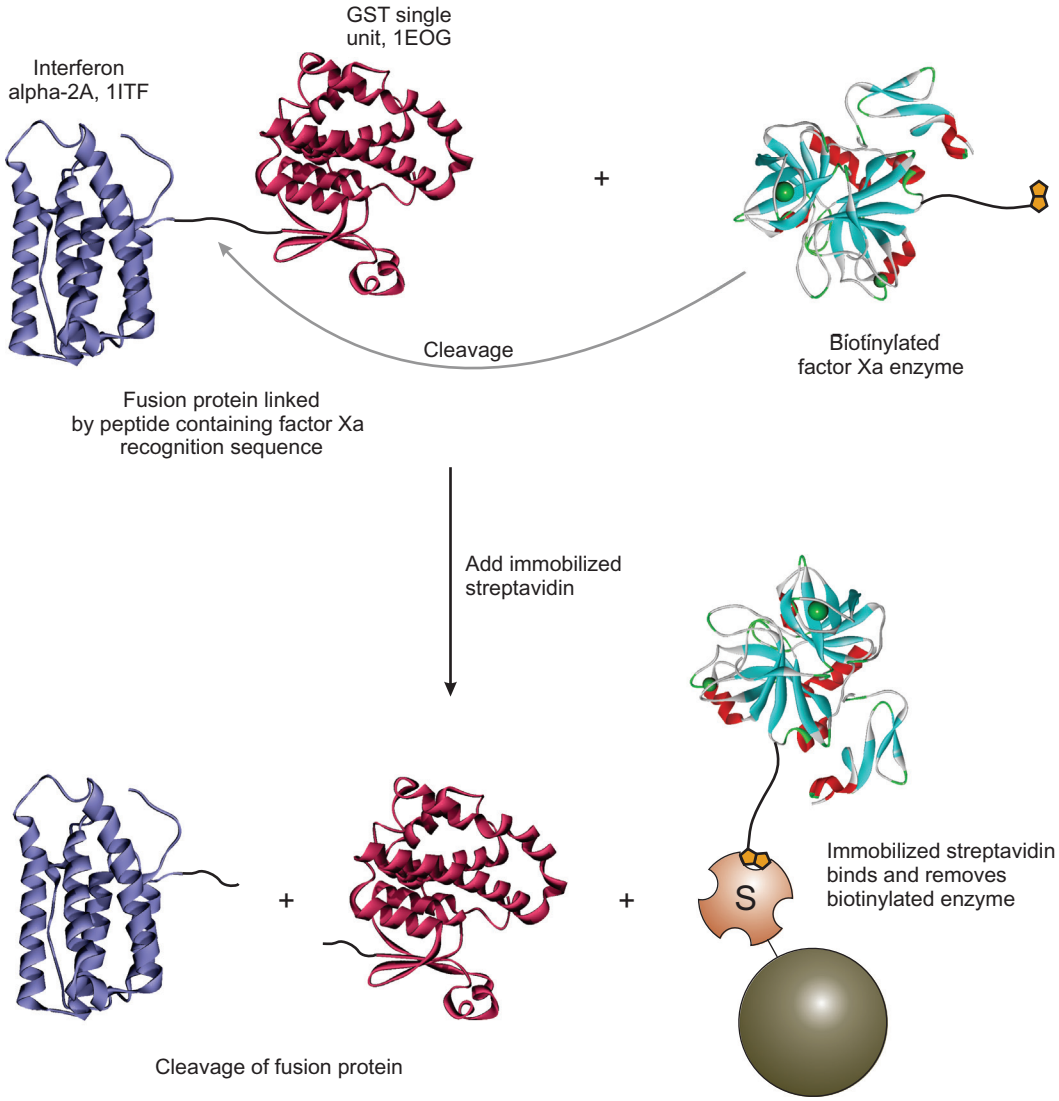

FIGURE 1.85 A biotinylated protease can be used to cleave a peptide sequence between a desired protein and an affinity fusion tag after purification of the complex on an immobilized affinity support. In this example, biotinylated factor Xa is used to cleave the recognition sequence present between interferon alpha-2A and the fusion tag GST after purification on immobilized glutathione. The biotinylated enzyme can then be removed from solution using an immobilized streptavidin support.

or hemicellulose can be carried out using chemical means, but the production can be improved through the use of enzyme reactors. Cellulase and hemicellulase enzymes are often used as alternatives to acid hydrolysis to convert cellulose or hemicellulose to glucose and other sugars in order to enter the fermentation process leading to ethanol (Taherzadeh and Karimi, 2007) (Figure 1.86). Although soluble enzyme can be used successfully in this process, the cost of the enzyme raw material may justify the use of an immobilized reactor for reusability purposes. The main issue in recycling an immobilized cellulase reactor is the difficulty in separating it from the insoluble materials that result from the processing of cellulose and lignin. One solution to this problem involves the use of paramagnetic particles that allow subsequent recovery of the immobilized reactor from the reaction byproducts through the use of a magnetic separation step (Qiu and Li, 2000, 2001; Feng *et al*., 2006; Liao *et al*., 2010).

The production of ethanol has also involved the use of immobilized cells as bioreactors, which can be used to convert the sugar raw materials into ethanol in the final step of the process (Anselme and Tedder, 1987; Gulnur *et al*., 1998; Wai *et al*., 2008; Menon *et al*., 2010; Mojović *et al*., 2010). The use of immobilized yeast cells in bioethanol production allows the saccharification and fermentation processes to go on simultaneously, thus streamlining its manufacture. The use of insoluble

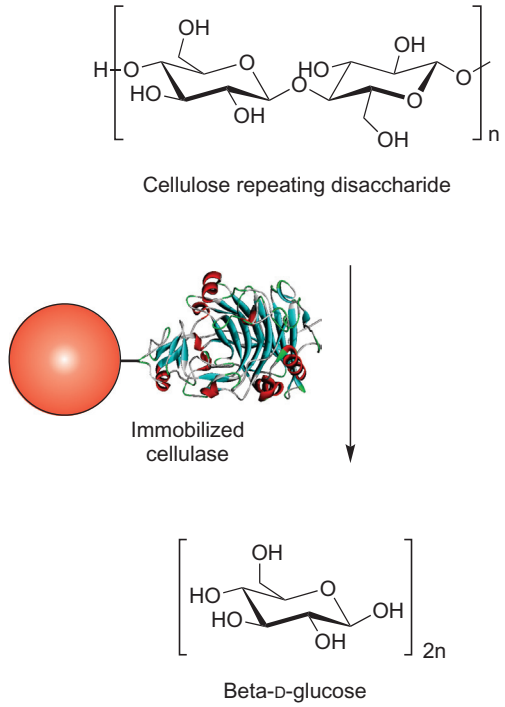

FIGURE 1.86 Cellulase can be used as an immobilized reactor to convert a cellulosic feedstock into beta-D-glucose. This type of reactor is being used in the development of biofuels.

enzymes or cells also eases the removal of these components from the final ethanol product at the completion of the process.

A second type of immobilized bioconjugate reactor involves the use of laccases or tyrosinases (two groups of phenoloxidases) in various process applications, including bioremediation, waste water treatment, wine stabilization, as well as other synthetic or analytical procedures (Durán *et al*., 2002). These enzymes can be used to catalyze the modification of many phenolic and some non-phenolic aromatic compounds. A phenol oxidation reaction involves the formation of an intermediate aryloxy radical that is subsequently derivatized to a quinone. The quinone can then polymerize through nonenzymatic means (Higuchi, 1989) (Figure 1.87). If one of the sites *para* to the phenolic OH group is occupied, then only a dimer will form from the reaction (Crestini *et al*., 2010). The products of the polymerization reaction can then be removed from the treated solution by adsorption onto inert polymers (such as Polyclar, which is a commercial polyvinylpolypyrrolidone) or the polymerized products that result can be considered unreactive or nontoxic compared to the initial aromatic substrates (such as in remediation processes). The removal of phenolic compounds from wine can be an important step in reducing a bitter taste, preventing discoloration of white wine, and stabilizing it for long-term shelf life. Immobilized laccases can be used as a reusable reactor in the process of polymerizing the phenolic compounds and removing them to limit the bitterness associated with increased phenol concentration due to the incubation time the must spent in contact with the grape skins (Brenna and Bianchi, 1994; Lante *et al*., 2000; Minussi *et al*., 2007).

An immobilized bioreactor conjugate that has found important use in bioprocess operations consists of lipase enzymes coupled to insoluble supports. Lipases are catalysts in the hydrolysis of fatty acid ester bonds, especially those in triglycerides, which can be used to produce oleochemicals in large scale. The preparation of fatty acids from triglycerides can be carried out using traditional chemical processing methods involving high temperatures and pressures. The use of an enzyme catalyst, however, can generate fatty acids at normal temperatures and pressures merely in the presence of excess water for hydrolysis (Malcata *et al*., 1990; Hermansyah *et al*., 2007) (Figure 1.88). In addition, under the right conditions, immobilized lipases can be used to effect the reverse reaction and form ester derivatives from fatty acid raw materials. The conversion of fatty acids into their methyl ester or ethyl ester derivatives has been used to produce biodiesel fuel under continuous operations (Shimada *et al*., 1999; Iso *et al*., 2001; Noureddini *et al*., 2005). Transesterification reactions of this type can be performed directly from the triglyceride raw materials in organic solvent with complete retention of enzymatic activity and while avoiding the unwanted production of sulfur oxides and soot common in chemical production processes. Immobilized lipase has also been used to initiate caprolactam polymerization in organic solution (Mei *et al*., 2003). Novozym 435 is a common commercial lipase (immobilized *Candida antarctica* lipase B) for the preparation of short-chain fats and other esters, including polyesters (Novozymes A/S, Denmark). This immobilized reactor is used extensively in the cosmetics industry and to produce specific fatty acid glycerol esters at relatively low temperatures (60–70°C) compared to standard organic synthesis.

Immobilized enzymes have been used extensively in organic synthesis procedures, especially to effect the creation of complex stereochemical derivatives without resulting in racemic mixtures (Brask, 2009). The use of immobilized enzymes as biocatalytic reactors is growing in popularity due to the realization that many immobilized enzymes can be used in organic environments without denaturing or affecting their catalytic activity. The ability of enzymes to recognize and act on substrates in an exquisitely enantioselective manner creates powerful tools for use in synthesizing drugs for biopharmaceutical applications. Immobilized reactors are currently used in dozens of biocatalytic processes in industry and their use is growing rapidly, especially

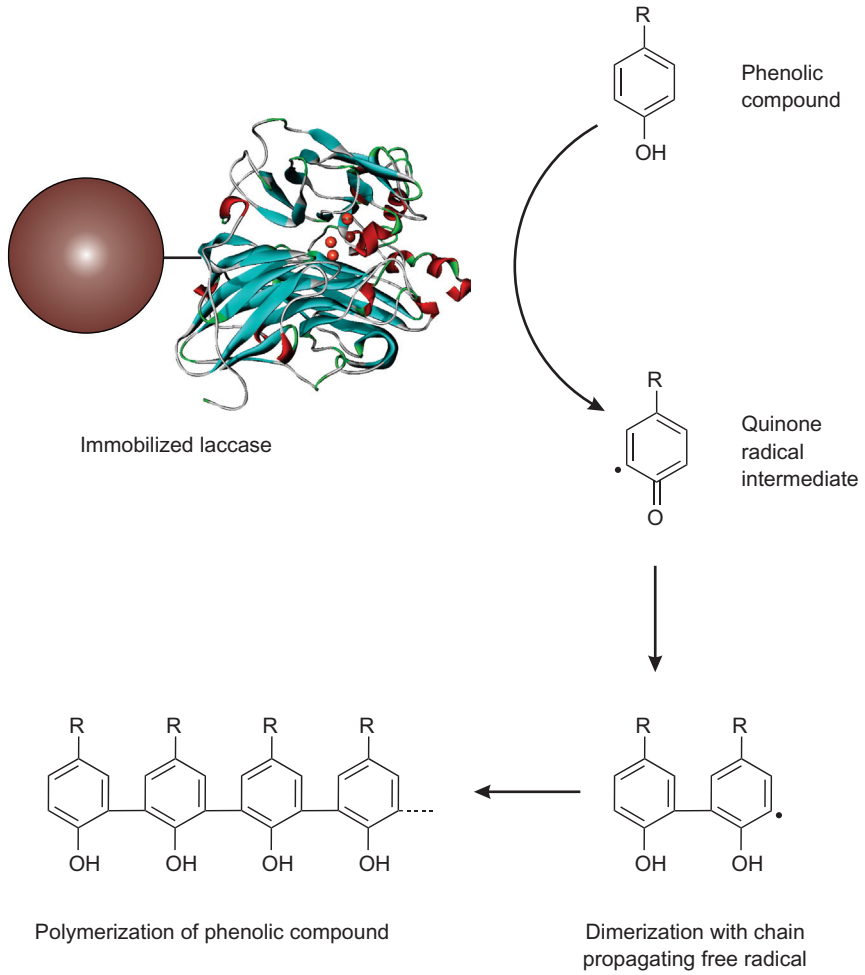

FIGURE 1.87 Immobilized laccase can be used as a reactor to produce a phenolic resin from a phenolic precursor through radical quinone formation, which initiates polymerization.

in situations where classical organic synthesis would prove much more difficult (Wohlgemuth, 2004). Some examples of large-scale biocatalytic processes include the production of high-fructose corn syrup using immobilized glucose isomerase, the transesterification of triglycerides using immobilized lipase, and the production of acrylamide using immobilized nitrile hydratase (Figure 1.89).

In addition to the immobilization of enzyme reactors onto solid phases such as particles, the enzymes themselves have been crosslinked to form insoluble particles without the need to attach them to a secondary support. One common method used for this procedure involves the formation of crosslinked enzyme crystals (CLECs) (St. Clair and Navia, 1992; Govardhan, 1999) or crosslinked enzyme aggregates (CLEAs) (Cao *et al*., 2000). The method for crosslinking enzyme aggregates is the simplest route, because it does not necessitate the prior formation of micro-crystals. Both CLEC and CLEA formation are typically facilitated by the addition of glutaraldehyde as the crosslinking agent to form the final immobilized reactor. Cao *et al*. (2000) used CLEA formation to prepare insolubilized penicillin G acylase for the synthesis of ampicillin from phenylglycine amide and 6-aminopenicillanic acid (6-APA) (Figure 1.90). The synthesis could occur in a wide range of organic solvents or in aqueous environments with highly selective stereochemical control. The reverse reaction can also be carried out using a CLEA consisting of insolubilized penicillin amidase to form 6-APA in industrial synthesis processes (Brask, 2009).

Immobilized enzyme reactors are also used extensively for analytical determinations. HPLC separations of small molecules can employ post-column detection of substrates using an immobilized enzyme reactor that can act on a substrate and create a fluorescent or chromogenic product, which then can be monitored using standard spectral means. In this application, the enzyme reactor is specific for only one component in the separated sample, and it can provide highly

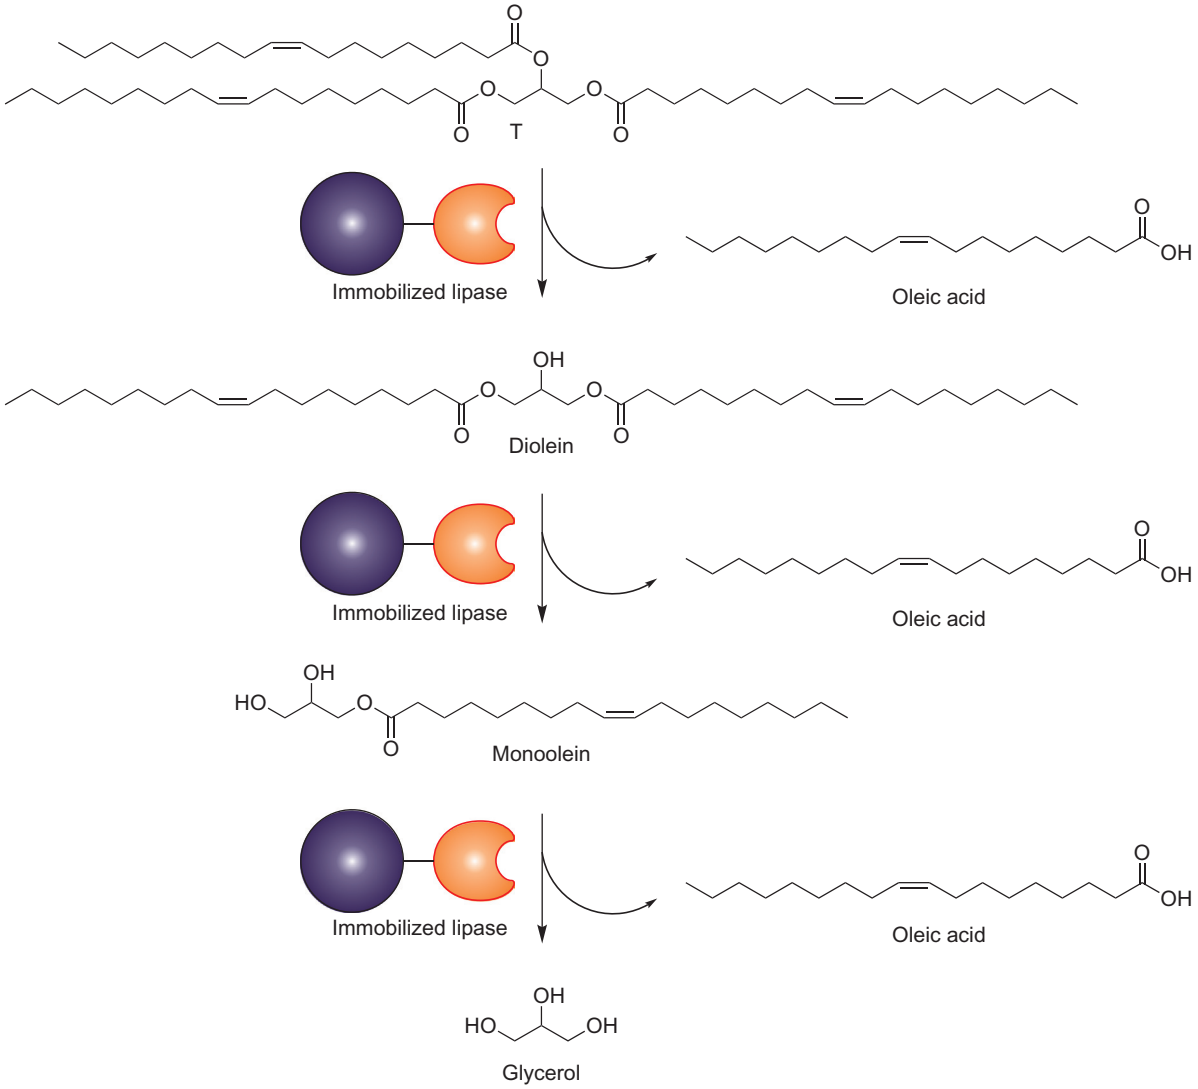

FIGURE 1.88 Immobilized lipase can be used as a reactor in the production of glycerol from a triglyceride feedstock, involving sequences of several reactions to remove the fatty acid acyl chains.

sensitive detection of biological or organic molecules otherwise difficult to analyze (Nagels and Maes, 1995).

In HPLC applications, the enzyme reactor is often immobilized on a silica or controlled pore glass support using an aminopropyl silane derivative (Chapter 13), which is activated with glutaraldehyde for attaching the enzyme through its amines (Girelli *et al*., 2007). For instance, the use of multiple enzyme reactors in an HPLC system has been successfully developed for the proteomic analysis of phosphopeptides in biological cell extracts (Yamaguchi *et al*., 2010). An immobilized protease such as trypsin was first used to digest the protein samples passing through the column, and next the peptides produced flowed through an immobilized alkaline phosphatase microreactor to analyze the phosphopeptide fraction. The HPLC enzyme reactor system was fed into a mass spec for final determination of the separated and processed peptides.

HPLC-based microreactors have also been developed for the analysis of a number of small molecules, including sugars or carbohydrates, such as glucose and fructose (Rahman *et al*., 2008), monosaccharides in cellulose (Olsson *et al*., 1990), galactose, lactate, ethanol, and L-amino acids (Vojinović *et al*., 2006), as well as for sulfite analysis in foods (Theisen *et al*., 2010), and in the determination of drug metabolites (Nicoli *et al*., 2008). Most of these applications would be difficult to perform if it were not for an immobilized reactor used in line with an HPLC separation column.

Another type of immobilized reactor is a non-enzymatic, single-use support that reacts with a target molecule and transforms it into a desired product. In

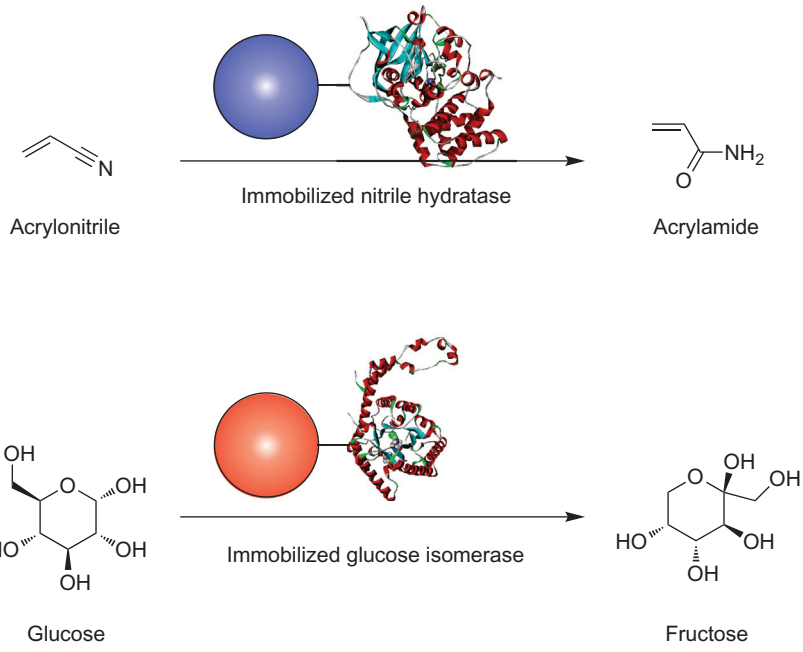

FIGURE 1.89 Two common bioreactor conjugates using enzymes include immobilized nitrile hydratase that can convert acrylonitrile into acrylamide and immobilized glucose isomerase, which can convert glucose into fructose.

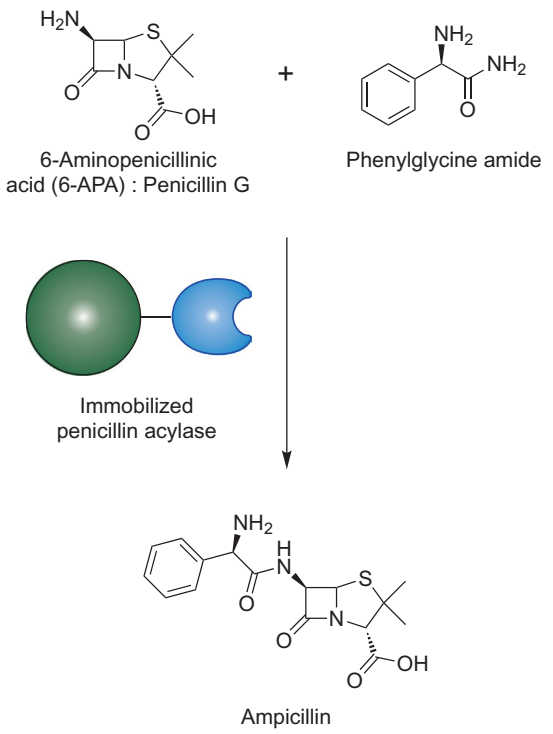

FIGURE 1.90 The antibiotic ampicillin can be synthesized using immobilized penicillin acylase, which acts on the precursors penicillin G and phenylglycine amide to link them together into the final product.

this case, the reactor is not catalytic in nature, but it is capable of spontaneously reacting with a target molecule in solution, and once used it cannot be reused without some sort of regeneration step. An example of this type of support is an immobilized reductant, which can reduce a target molecule to cause disulfide reduction or some other hydrogenation step. Disulfide reducing agents are often used in solution to reduce cysteine disulfides within proteins or peptides (Chapter 2, Section 4.1). Occasionally, it is beneficial to use an immobilized disulfide reducing agent, because it makes it easier to isolate the products of the reaction. For instance, a disulfide-containing short peptide may be reduced with immobilized TCEP (Thermo Fisher): (Chapter 2, Section 4.1) and the thiol-containing peptide is subsequently purified simply by filtering off the solution from the insoluble support. If a soluble disulfide reductant is used, such as DTT, then the purification step would be more difficult, because the molecules may be too close in molecular weight to facilitate simple mass-based separations, such as size exclusion chromatography or dialysis.

Other immobilized reactors have been created to perform certain organic chemical transformations in synthetic procedures, which eliminate the difficulty of subsequent purification steps to purify the product of a reaction. Polymer bound reagents can be designed to react with an organic molecule to produce a certain chemical reaction, while allowing the end product to be separated simply by washing it away from the resin. In

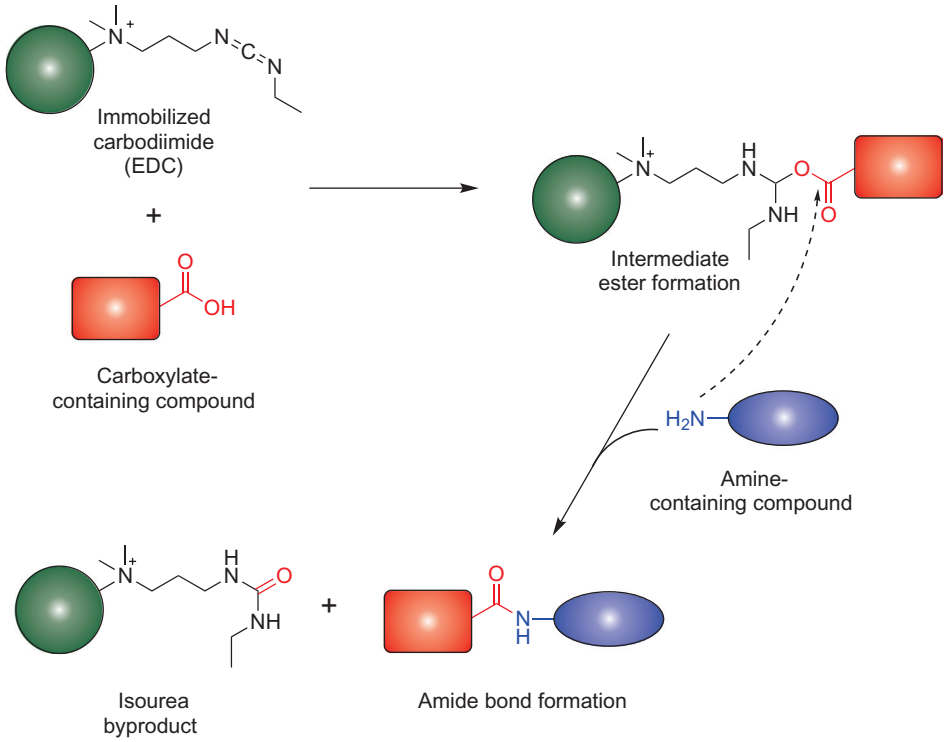

FIGURE 1.91 An immobilized chemical reactant can be used to facilitate a particular synthetic reaction without contaminating the reaction solution with a soluble byproduct. In this case, immobilized EDC is used to form an amide bond between two molecules containing a carboxylate and an amine. Removal of the spent carbodiimide is achieved by simply filtering off the reaction solution from the immobilized reactor.

some circumstances, the immobilized reactor is able to bind to a small molecule to purify it from other contaminants and then release it using a subsequent reaction. This second class of immobilized reactor is also a scavenger, which can be used to isolate a desired molecule or remove a contaminating substance from solution.

Biotage commercializes immobilized reactants for organic synthesis, including solid-phase versions of borohydride and cyanoborohydride for performing reduction of carbonyl compounds, azides, or oximes as well as for reductive amination conjugation of an aldehyde or ketone to hydrazines, hydrazides, and aminoxy groups. The immobilized reductants allow for reactions to be carried out on small molecules without the need for difficult purification schemes to remove the reducing agent. Borohydride or cyanoborohydride coupled to microparticles can simply be removed by centrifugation or filtration, while the product of the reaction is captured in the solution phase.

In addition, amide forming reagents are available in immobilized form to couple a carboxylate-containing molecule to an amine-containing molecule (Biotage). An immobilized carbodiimide creates a convenient reagent for facilitating the conjugation of two small molecules together to form an amide linkage. If an immobilized form of this reagent is not used for small molecule conjugation, a purification strategy would have to be developed to remove the byproducts of the reaction from the final conjugate. With an immobilized carbodiimide, simple removal and washing of the support facilitate removal of the carbodiimide and the isourea byproducts from the desired conjugate (Figure 1.91). The reaction typically is performed in organic solvent, such as dichloromethane and DMF. The reagent may also be used to create reactive esters from carboxylate-containing molecules. In this regard, NHS esters, PFP esters, or HOBt esters (Chapter 15) may be made from a carboxylate-containing compound to activate it to a reactive intermediate that may then be used to conjugate to amine-containing molecules in aqueous solution to form amide bonds.

Immobilized reactors in the form of enzyme catalysts or small reactive molecules can be used to effect many chemical transformations, including ones that would be extremely difficult from a stereochemical perspective if they were done using classical organic synthesis. These immobilized conjugate reagents are currently being used in diverse applications spanning the scale from small lab bench reactions to large industrial production processes. The application of such reagents is only now beginning to become routine across many disciplines and no doubt their use will continue to grow as their advantages become more apparent.

3.5. Therapeutics and *in vivo* Diagnostics

Among the largest and most important application areas for bioconjugate techniques is the field of human therapeutics and diagnostics. Bioconjugation reagents developed for these applications have contributed

significantly to the growth of the diagnostic, biotech, and pharmaceutical industries over the last few decades. The advent of targeted therapeutics has almost entirely been made possible by the ability to create designer bioconjugates that can specifically target a disease while limiting its effects on normal tissue. The ideal therapeutic bioconjugate might consist of a targeting component coupled to a drug or an effector molecule, which can deliver an active payload directly to tumor cells, attack invading pathogens, or target other sites within the body for therapy with little to no binding or toxicity toward untargeted cells and organs.

Targeted bioconjugates have also been used for *in vivo* diagnostic procedures to detect and image the sites of tumors and for *in vitro* assays to quantify disease markers or drug concentrations within patients' serum. The specificity and sensitivity of many diagnostic procedures depend on developing the optimal bioconjugate that can interact with specific targets and provide sensitive detection capability.

In addition, the use of designer bioconjugate drugs has had considerable advantages over traditional pharmaceuticals beyond just targeted delivery. The right bioconjugate design can provide increased chemical stability, protection from proteolysis or degradation *in vivo*, increased half-life of the drug within the body, a decrease in off-target effects, a reduction in undesired immunogenicity, increased water solubility, decreased removal by the kidneys or liver, increased specificity to interact with the desired target, and an increase in potential cellular penetration by endocytosis (Monfardini and Veronese, 1998; Veronese and Morpugo, 1999).

Applying the right bioconjugation methods can also result in enhanced properties of more traditional organic pharmaceutical drugs. Small drug compounds have been used for many decades in the treatment of diseases. The preparation of conjugate derivatives of these drugs to create second-generation pharmaceuticals with novel properties is a field that is being explored extensively (Kojima *et al*., 2000; Kim *et al*., 2008). For instance, a sparingly soluble organic compound may be rendered much more hydrophilic through selective covalent modification with a water soluble polymer, such as polyethylene glycol (PEG) (Chapter 18). Conjugates of this type can also increase biodistribution and drug availability *in vivo*, while increasing its overall half-life in blood. In addition, dendrimers and other polymers have been favorably investigated for their ability to carry multiple copies of organic drugs to targets *in vivo* better than the administration of the drug without the conjugate carrier (Chapter 8 and Chapter 18, Section 2). Thus, even traditional pharmaceuticals have realized benefits from the design of novel bioconjugate derivatives.

In the following sections some of the major designs and application areas will be discussed for the use of pharmaceutical and diagnostic bioconjugates. These conjugates include compositions made up of antibodies, enzymes, protein toxins, peptides, small molecule organics, radiolabels, metal chelates, inorganic nanoparticles, polymers, and bioaffinity ligands. Bioconjugation for the development of advanced therapeutics and diagnostics is entering into an exciting age of new development, which will no doubt affect the way drugs are designed and disease is detected from this point forward.

Bioconjugates for Cancer Therapy

The strategy in creating therapeutic bioconjugates for cancer is to design a final complex that has high specificity for the intended cells combined with high efficacy in killing the tumor being targeted, but with no off-target effects or toxicity. At first, this goal may seem easy to attain—just conjugate an affinity targeting agent with an anticancer drug component and the result should be an effective biotherapeutic. Unfortunately, even the most logical ideas for constructing anticancer bioconjugates typically run into problems far more complex than such a simple design concept would suggest. Bioconjugates can be rendered ineffective due to unexpected immune system responses including severe allergic reactions, a limited half-life *in vivo* that decreases the availability of the drug, lack of penetration into solid tumors, changes in the antigenic presentation on cancer cells rendering the targeting agent less capable of binding, sequestration of the drug in the liver or other organs, rapid clearance through the kidneys, nonspecific binding to off-target sites, unexpected toxicity or side effects, and a general lack of effectiveness in killing the tumor cells.

Such problems are the reason that the design and development of therapeutic bioconjugates are typically a billion-dollar investment taking seven to ten years to complete. To avoid these negative issues, a bioconjugate destined for use in humans must be developed with precise control over every conceivable aspect of its preparation. For instance, it has been found that relatively minor alterations in the ratio of the molecules making up a final conjugate can result in dramatic changes in specificity and effectiveness. Different bioconjugation methods can also have tremendous effects on the performance of a prospective drug. In some cases, it has been shown that relatively small changes to the cross-bridge formed between a targeting agent and the drug component in the conjugate can have significant effects *in vivo* (Doronina *et al*., 2006). In other instances, a polymer drug carrier of incorrect type or size can result in rapid kidney ultrafiltration and clearance or undesired polymer accumulation within tissues

resulting in toxicity (Seymour *et al*., 1990; Duncan *et al*., 2001; Thanou and Duncan, 2003; Jones, 2004).

The challenging aspect of developing anticancer bioconjugates has led to the study of many different conjugate types for their effectiveness in treating the disease. In general, though, the concept of combining a targeting agent with a therapeutic component remains a common theme throughout these bioconjugate designs.

Antibody Targeting for Biotherapeutics

Therapeutic conjugates for cancer often have used antibodies or antibody fragments as the targeting component. The binding specificity of an antibody for an antigen can be used to advantage to target only epitopes on tumor cells while limiting nonspecific interactions with normal cells or tissues. Since the early days of monoclonal antibody technology, the dream of targeted drug therapy has been met with the harsh reality of how difficult it is to effectively utilize even a highly specific antibody *in vivo*. For instance, typical mouse monoclonals can be made to virtually any human tumor epitope, but their effectiveness for human use can be very limited. This is due to the fact that most people quickly develop an antibody response to the monoclonal, which renders the continued use of the antibody futile. To overcome the potential immune response to a mouse monoclonal antibody, particularly the production of what is called human anti-murine antibodies (termed the HAMA response), humanized or chimeric human/mouse monoclonal antibodies and fragments have been developed (Shawler *et al*., 1985). Such recombinant antibodies can be conjugated to an anti-cancer drug or toxin, bind specifically to a tumor cell, and deliver their chemotherapeutic package directly to the cells at high concentration, thus maximizing the effectiveness of the drug. In addition, it has been shown that chimeric antibodies, or those that contain part human and part mouse sequences, also help to limit the immune response and aid in getting the targeted payload to its intended destination. However, the very best monoclonal antibodies for cancer are those that are completely human in nature, even with respect to their hypervariable reagions. The advent of transgenic mice that have fully human antibody genes has facilitated the development of true human antibodies with high specificity and low immunogenicity *in vivo* (Jakobovits, 1995; Kucherlapati *et al*., 2012). This development has revolutionalized the use of monoclonal antibodies as targeting agents for the treatment of human disease.

By the end of the first decade of this century, the therapeutic monoclonal antibody market had total worldwide revenues exceeding $35 billion (USD) (from *Therapeutic Monoclonal Antibodies: World Market 2010–2025*, Visiongain, London, 2010). At least 25 antibody-based therapeutic drugs are on the market today, that are approved for use in various regions of the world, with hundreds more in various stages of clinical trials (Carter, 2006; El Bakri *et al*., 2010). Such biologic drugs as Avastin, Cimzia. Erbitux, Herceptin, Humira, Lucentis, MabThera, Remicade, Synagis, Tysabri, and Xolair employ monoclonal antibodies to successfully treat diseases. Most of the approved antibodies on the market today are not conjugated; they are known as "naked" antibodies and are used to block receptors or neutralize molecules such as epidermal growth factor (EGF), which can prevent activation of its receptor (EGFR) on certain tumor cells (e.g., metastatic colorectal cancer).

The bioconjugate antibody-based therapeutics that have been approved for commercialization include a PEGylated, humanized Fab′ fragment to treat Crohn's disease (Cimzia, UCB Pharma), an anti-CD20 mouse monoclonal that is radiolabeled with I-131 for treatment of non-Hodgkin's lymphoma (GlaxoSmithKline), a mouse IgG1 monoclonal radiolabeled with Y-90 to treat low grade follicular transformed non-Hodgkin's lymphoma (IDEC Pharmaceuticals), a radiolabeled (I-131) chimeric IgG1 monoclonal for the treatment of lung cancer (Shanghai Medipharm Biotech), and a humanized IgG4 against CD33 as an immunotoxin conjugate to treat acute myeloid leukemia (AML) (Celltech/Wyeth).

Cimzia (certolizumab pegol) is a bioconjugate consisting of a humanized monoclonal Fab′ fragment targeting human tumor necrosis factor alpha (TNFα), which is modified with an approximately 40-kDa polyethylene glycol molecule (Connock *et al*., 2010). The conjugate is formed through the use of a maleimido-PEG derivative that is coupled to a single thiol group on the Fab′ fragment (Figure 1.92). This forms a highly defined complex of approximately 91 kDa, wherein the PEG group functions to increase the hydrodynamic volume of the biologic and maintain the drug in circulation for a longer period *in vivo*. The antibody is able to bind to TNFα and neutralize its activity, which is involved in inflammatory processes. The drug treatment is indicated for the treatment of Crohn's disease and severely active rheumatoid arthritis (Rosa *et al*., 2010).

Antibody–drug conjugates (ADCs) have also been developed to combine the targeting advantage of a specific antibody with the known anti-tumor chemotherapy of a small-molecule drug (Chari, 2008). These complexes are able to deliver a high dose of the chemotherapeutic agent directly to the site of the cancer cells. The first ADC approved by the U.S. Food and Drug Administration (FDA) was gemtuzumab ozogamicin, which consists of a complex of a monoclonal antibody against CD33 and the drug calicheamicin (Haeuw *et al*., 2009). The anti-CD33–immunotoxin conjugate was the first approved biologic for antibody-targeted

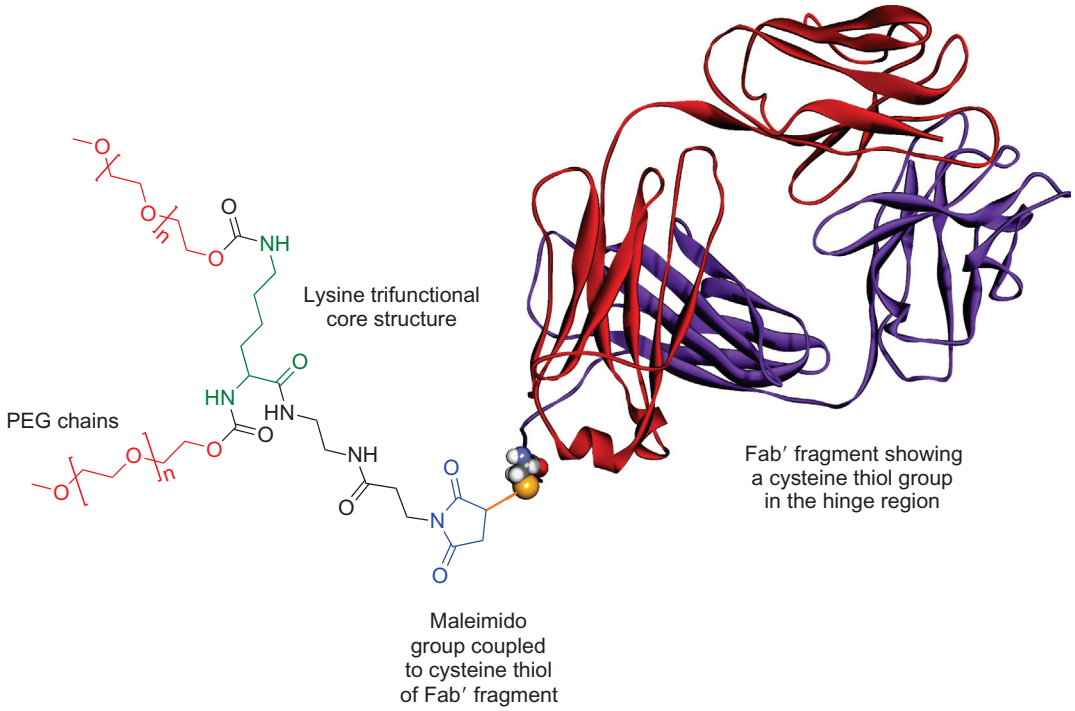

FIGURE 1.92 The structure of the bioconjugate drug Cimzia, which contains a humanized Fab′ fragment directed against TNFα and has been modified with two PEG chains by using a maleimide reactive group to couple with the available thiol in the hinge region.

chemotherapy in cancer, coming to market in the year 2000. The antibody is conjugated with a potent antibiotic that was originally isolated from bacteria in certain clay found in parts of Texas. The anti-tumor agent, calicheamicin, is linked to the humanized monoclonal antibody and commercialized under the name Mylotarg (Figure 1.93). The bioconjugate linkage chemistry proved to be very important for efficacy of this drug. Calicheamicin is a complex di-alkyne-containing molecule that is able to bind to the minor groove of DNA and subsequently cause widespread cleavage of genetic material, which then leads to tumor cell apoptosis. The key to getting the drug payload active at binding DNA was to ensure the release of the calicheamicin after conjugate entry into the cell. Surprisingly, the linkage of calicheamicin to the monoclonal antibody via a disulfide bond actually proved less effective at releasing the antibiotic within the cells than linking through a hydrazone bond using aldehyde and hydrazide reactive groups (Ducry and Stump, 2010). This is an important example of how a thorough exploration of bioconjugation designs can lead to a therapeutic conjugate with the highest possible activity.

Unfortunately, this first ADC to be approved eventually was removed from the market due to its lack of effectiveness. The conjugate proved to be highly heterogeneous, consisting of a broad distribution of calicheamicin substitution levels on the antibody (from 0–8 drugs per antibody) with up to 50% of the antibody present in unconjugated form (Bross *et al*., 2001). Since the launch and removal of Mylotarg from the market over a dozen other ADCs are in clinical development. Table 1.3 shows the list of current clinical trials involving ADCs in the United States. The future for ADC therapeutics may be much brighter than the initial failure of the first marketed drug would suggest.

The cytotoxic drug component of ADCs can be of many types. Some examples described in the literature include doxorubicin, methotrexate, calicheamicin, two maytansinoids (DM1 and DM4), duocarmycin, and two auristatins (MMAE and MMAF) (McCarron *et al*., 2005; Beck, 2010). In addition, the methods used to conjugate a drug to an antibody involve many different strategies to build linker arms and covalent bonds that in combination may vitally contribute to the effectiveness of the final complex *in vivo*. Often a cleavable bond and a hydrophilic bridge between the antibody and the drug are present in the final conjugate, which lends flexibility and water solubility to an otherwise rather hydrophobic chemotherapeutic agent. Figure 1.94 illustrates some of these ADC structures along with the exact linker arms and covalent bonds used to couple with the antibody molecules.

The use of antibody bioconjugates has only just begun to realize its true potential for human therapeutics. It is expected that the continued development

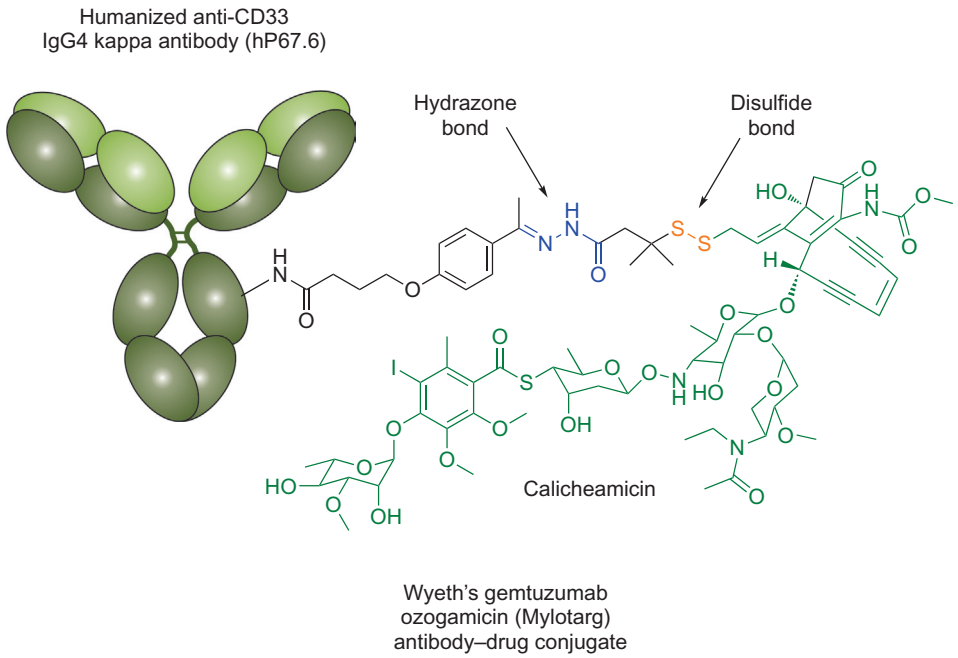

FIGURE 1.93 The antibody–drug conjugate (ADC) gemtuzumab consists of a humanized monoclonal antibody that has the anti-cancer drug calicheamicin attached to it using a linker arm that contains both a hydrazone bond and a disulfide group.

TABLE 1.3 **Antibody–Drug Conjugates for Cancer**

Name; Antibody Type	Company	Drug	Linker Type	Antibody Target	Disease Indication
Gemtuzumab ozogamicin; IgG4	Wyeth & Pfizer	Calicheamicin	Hydrazone and disulfide	CD33	Acute myeloid leukemia
Inotuzumab ozogamicin; IgG4	Wyeth & Pfizer	Calicheamicin	Hydrazone and disulfide	CD22	Non-Hodgkin lymphoma
SAR 3419	Sanofi-Aventis	DM4	Disulfide	CD19	Non-Hodgkin lymphoma
BT-062; IgG4	Biotest	DM4	Disulfide	CD138	Myeloma
IMGN-388	Centocor	DM4	Thioether	Alpha-V integrin	Solid tumors
BIIB015; IgG1	Biogen Idec	DM4	Unknown	Cripto	Breast cancer
Trastuzumab emtansine; IgG1	Genentech	DM1	Thioether	HER2	Breast cancer
Lorvotuzumab mertansine; IgG1	ImmunoGen	DM1	Thioether	CD56	Myeloma
Brentuximab vedotin; IgG1	Seattle Genetics	vcMMAE	Valine–citruline	CD30	Hodgkin lymphoma
Glembatumumab vedotin; IgG2	Celldex	vcMMAE	Valine–citruline	GPNMB	Breast cancer, melanoma
PSMA ADC	Progenics	vcMMAE	Valine–citruline	PSMA	Prostate cancer
ASG-5ME	Agensys	vcMMAE	Valine–citruline	SLC44A4	Pancreatic cancer
SGN-75	Seattle Genetics	mcMMAE	Maleimido–caproic acid	CD70	Non-Hodgkin lymphoma, renal cell carcinoma
MEDI-547; IgG1	MedImmune	mcMMAE	Maleimido–caproic acid	EphA2	Solid tumors
MN	BMS (Medarex)	Auristatin	Unknown	MN	Cancer
MDX-1203	BMS (Medarex)	Duocarmycin	Dipeptide linker	CD70	Non-Hodgkin lymphoma, renal cell carcinoma

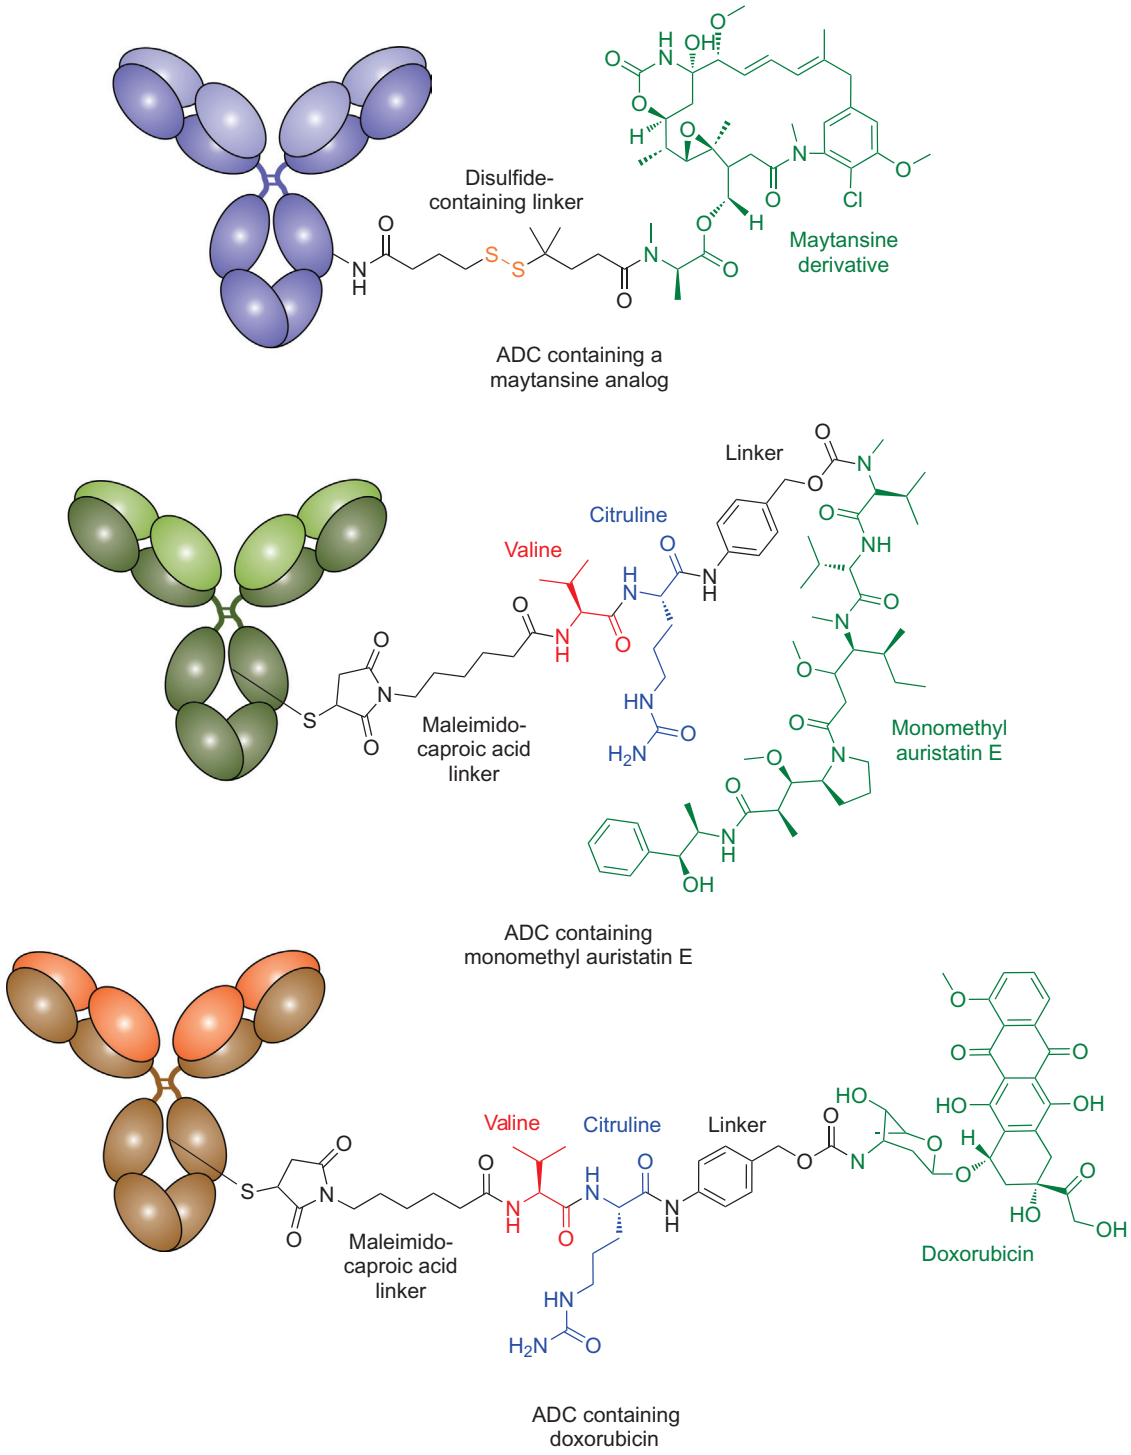

FIGURE 1.94 Examples of ADCs constructed with intact humanized monoclonal antibodies using the drugs maytansine, monomethyl auristatins E, and doxorubicin. Note the construction of the linker arms that may incorporate amino acid derivatives or cleavable groups such as a disulfide bond. Two of the ADC conjugates are linked through thiols on the antibody molecules, which were formed by mild and controlled reduction of disulfides within the IgG structure, while the other one is linked through amine groups on the antibody surface.

of antibodies and antibody conjugates for cancer and other indications will rapidly expand the biologic drug market in the first part of this century. With many hundreds of such bioconjugates currently in research and clinical trials worldwide, it is certain that the number of antibody conjugates on the market will dramatically increase over the next 20 years. We are truly entering the age of targeted therapeutics made possible through rational design using bioconjugate techniques.

Research into antibody bioconjugates for therapeutic purposes has included the use of every conceivable antigen binding construct from intact IgG-type antibodies to many different types of fragments, including $F(ab')_2$, Fab, and single-chain Fv (scFv) (Chapter 20). More elaborate antibody constructs have included the formation of recombinant multivalent hybrid designs having multiple specificities, such as bispecific (diabodies), trispecific (triabodies), tetraspecific (tetrabodies), and even small minibodies, which are constructs containing two of the smallest possible antigen binding fragments (Morrison, 2007; Sharkey *et al*., 2010). Some of these complexes are formed entirely through recombinant fusion techniques, but others involve the conjugation of fragments having different specificities to form the final multivalent molecule. For instance, trimeric Fab conjugates have been developed using chemical crosslinking of three different Fab fragments onto a central trifunctional core structure to form a trispecific antibody (Hudson and Souriau, 2003).

One unique trispecific cancer therapeutic was made from an IgG fusion of one heavy-/light-chain pair originating from one antibody fused to another heavy-/light-chain pair from another antibody. The result was a fused antibody conjugate with dual antigen binding ability with specificity toward a tumor cell epitope on one Fab arm and a second specificity toward CD3 surface protein on T cells on its other Fab arm, and its Fc region was able to bind to Fc receptors on macrophages, NK cells, or dendritic cells. The purpose of this elaborate trispecific construct was to bring the most important cells of the immune system together at the site of the tumor cell, thus initiating destruction of the cancer cell in the process (Figure 1.95).

Other bispecific constructs have been made by fusing two scFv fragments together that contain two different target antigen specificities. For instance, one scFv end can be designed to bind to a tumor cell epitope, while another scFv end can bind to T-cell surface antigens. One of the most advanced forms of this type of therapeutic agent is called a bispecific T-cell engager (BiTE) (Baeuerle and Reinhardt, 2009). At least two BiTEs are in clinical trials at the time of writing: (1) blinatumomab, which is under development for non-Hodgkin lymphoma as well as B-precursor acute lymphoblastic leukemia (Bargou *et al*., 2008; Topp *et al*., 2008); and (2) MT110, which is being developed for lung cancer, squamous cell carcinoma, and gastrointestinal cancer (Maetzel *et al*., 2009).

In addition, affinity targeting peptides based upon antibody–antigen binding regions within immunoglobulins or even using peptide sequences not originating from antibodies have been designed for therapeutic bioconjugate use. Short peptide sequences that have affinity binding specificity for a target molecule of interest, and which are of low molecular weight, can provide alternatives to traditional antibodies. Small targeting molecules have advantages in that they can provide excellent cell and tissue penetration *in vivo* and are relatively simple to synthesize. Such peptides can be identified through knowledge of native binding site sequences on larger proteins or they can be chosen by screening libraries of potential peptide-binding molecules (Kolonin *et al*., 2006; Eichler, 2008; Jüse *et al*., 2010).

Non-antibody-based scaffolds for developing recombinant affinity targeting molecules have also been developed for bioconjugate use (Plückthun, 2009). An alternative scaffold may consist of a protein or protein fragment that can be used as a structural foundation to create a binding region, which can then be recombinantly randomized at particular amino acid sequences to make unique affinity libraries. Such libraries can be screened for their ability to specifically interact with targets, such as biomarkers on tumor cells. Positive hits can be further investigated for targeting suitability and subsequently produced on a large scale by recombinant means, if desired.

Proteins or peptides that have been used as antibody-like scaffolds to develop binding molecules have included the Z-domain of protein A, the Kunitz domain inhibitors (60-amino-acid, single-chain peptide), human pancreatic secretory trypsin inhibitor (55 amino acids), Alzheimer's amyloid β-protein precursor inhibitor, the ecotin bacterial serine protease inhibitor sequence (142 amino acids), the knottin protease inhibitor including the cellulose-binding domain (CBD) peptide sequence (25–35 amino acids), fibronectin III (94 amino acids), and thioredoxin (108 amino acids) (Nygrena and Skerra, 2004). Within these peptide sequences a single loop or multiple neighboring loops are randomly evolved to create libraries of potential affinity binding surfaces that can function in a manner similar to the antigen binding sites on antibodies. Many of these alternative binding scaffolds offer advantages over traditional IgG-type antibodies in that they are mainly single peptide sequences, they have more stable and compact β-sheet or α-helical structures, and they are typically smaller than full-sized immunoglobulins, which has the added advantage of aiding tissue and tumor penetration *in vivo*.

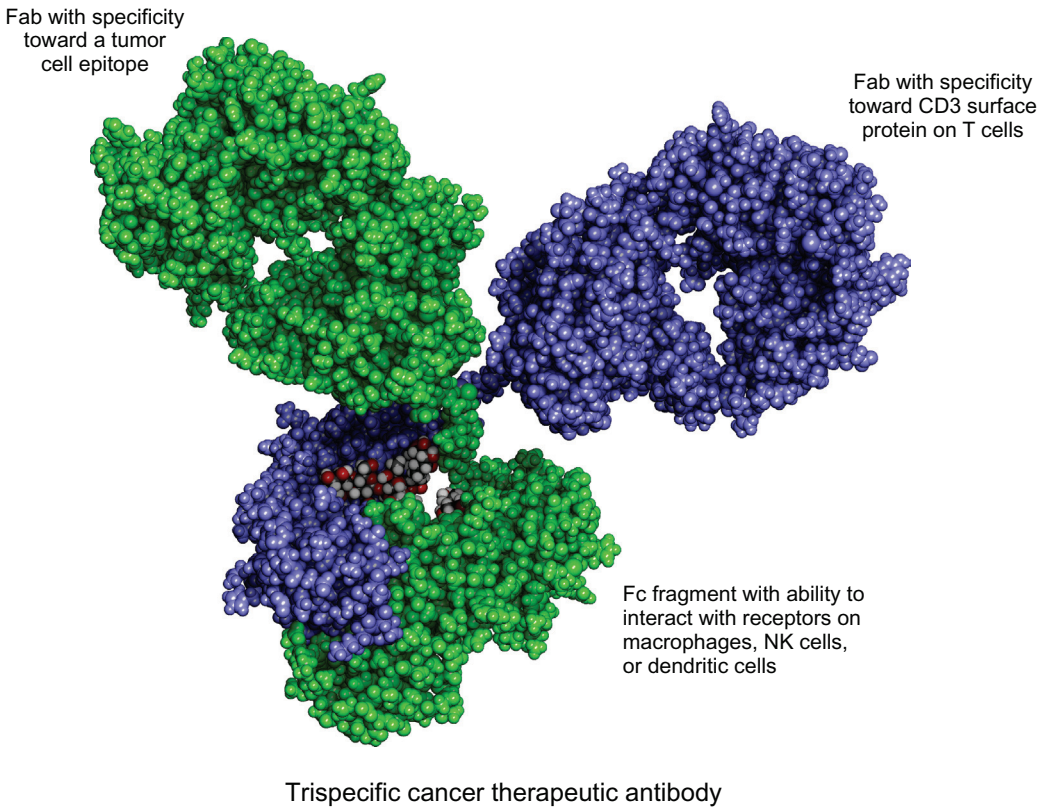

FIGURE 1.95 The design of a trispecific antibody involves the use of a heavy-/light-chain pair from one antibody combined with a heavy-/light-chain pair from another antibody (colored differently in this illustration). The specificities of the two heavy-/light-chain pairs are different to target a tumor cell epitope on one side and markers on T-cell surfaces on the other side. The third interaction potential for this construct occurs through the combined Fc region, which has the ability to interact with receptors on key immune cells. The effect of this conjugate is to bring the important components of the immune system together at the site of cancer cells to cause tumor cell death.

One commercial scaffold construct that has been used to develop diagnostic or therapeutic bioconjugate designs is the Affibody molecule consisting of 2 alpha-helices from the Z-domain of protein A (Tolmachev *et al*., 2007; Zielinski *et al*., 2009). This small 6-kDa protein is highly robust, as it resists high temperatures and extremes of pH. Libraries have been produced by randomization of a 13-amino-acid loop within the molecule and screening can be done against over 10 billion Affibody molecules to find specificity toward a desired target.

In addition to domain-based protein scaffolds, short peptide sequences have also been used to develop affinity binding molecules for bioconjugate targeting. One of the first peptide affinity agents to be created was a simple set of linear amino acid sequences that was engineered onto proteins normally present on bacteriophage particles—a technique called "phage display"—which could then be randomized to form a library of potential targeting peptides. First developed by Smith (1985), the method provides a powerful way of creating custom binding peptides with affinity toward desired targets. Screening of this combinatorial peptide library for its potential to bind an antigenic target can yield viable affinity sequences that can be used to conjugate with therapeutic drugs for targeted drug delivery (McCafferty *et al*., 1990). Libraries of this type can easily be created with selected modification of the minor (pIII gene) or major (pVIII gene) coat proteins located on the ends of phage particles. Using this technique, affinity binding libraries can be made that contain anywhere from 10^9 to 10^{12} potential peptide binders, depending on the length of the peptide sequences (Bratkovic *et al*., 2005; Lunder *et al*., 2005). The disadvantage of this type of small peptide targeting molecule is the lack of a constrained structure, as would be present if a loop or multiple loops were used in a larger scaffold. Freedom of motion of small linear peptides in solution often changes the binding characteristics toward targets, the effect of which often depends on the medium in which the peptide is present. For this reason, linear peptide libraries typically are not used to create bioconjugate therapeutics to target epitopes *in vivo*.

Other non-antibody-based bioconjugates have also been designed to carry drugs to tumor cells *in vivo*. In some cases these targeting agents are biological

molecules that are preferentially taken up by tumor cells rather than normal cells. For instance, transferrin has been used to effectively target tumors through the cells' inherent property of ingesting high quantities of this protein due to the high growth and division rate of tumor cells (Zheng *et al*., 2010). In addition, small ligands such as folic acid have frequently been used as targeting agents, because of the dramatic increase in folate receptors on tumor cell surfaces. A folate-containing bioconjugate can be captured by tumor cells much more effectively than by normal cells, thus providing a mechanism for directed delivery of the drug to the desired site without using an antibody (Prabaharan *et al*., 2009).

Polymeric Scaffolds and Nanoparticles for Biotherapeutic Conjugates

Antibody multimers built on a polymer scaffold have also been made to produce greater binding avidity toward certain antigens and to carry additional chemotherapeutic agents beyond that possible using a single antibody conjugate. For instance, dextran conjugates or liposomal conjugates with antibodies that incorporate multiple copies of an anti-tumor drug or toxin have been developed to treat specific tumor types (Chapters 18 and 20). Many of these polymeric constructs are particulate in nature and have diameters in the low nanometer range, which makes them eminently suitable for *in vivo* delivery. In many instances, the chemotherapeutic properties of traditional drugs administered in a free form can be dramatically improved when incorporated into a polymeric drug delivery system (PDDS) (Kwon, 2005; Uchegbu and Schatzlein, 2006).

A wide variety of polymer carriers have been designed for use as drug transporters, and the type of polymer can be of natural or synthetic origin and self-assembled or synthetically crosslinked (for reviews, see Cho *et al*., 2008; Duncan, 2003). PDDS constructs have generally fallen into four different structural categories: (1) linear; (2) nanoparticle; (3) branched; and (4) dendritic. Some of them have been used to carry only a chemotherapeutic agent without an associated antibody or other targeting molecule, while others have incorporated affinity binding agents to gain specificity for the particular cell or tissue type being targeted. The chemical structures of some of the major polymers used in the design of drug bioconjugates are shown in Figure 1.96. These polymers have been used alone or in combination with other monomers to form copolymer constructs having a variety of functional groups for conjugation or imparting water solubility or biocompatibility. In some cases, the purpose of the polymer modification is to alter the properties of the attached drug *in vivo* to make it more soluble or extend its half-life in circulation. In other cases, it is to link multiple copies of the drug to one bioconjugate and thus gain additional therapeutic efficacy at the targeted tumor or tissue *in vivo*.

Nanoparticle polymer delivery systems are usually constructed through crosslinking of linear or smaller polymers or alternatively through the self-assembly of amphipathic polymers into micellular structures. Polymer encapsulation into nanoparticles has been used to deliver large numbers of anti-tumor drugs at concentration levels far beyond that normally feasible using drug delivery without a particle transporter. Natural polymer particle constructs can be formed from proteins, inactive viral particles, or even crosslinked carbohydrates. For instance, albumin nanoparticles have been used to carry taxol (Gradishar *et al*., 2005), a heat-shock protein caged architecture has been used to carry doxorubicin (Flenniken *et al*., 2006), micellular structures have been used to carry daunorubicin (Rosenthal *et al*., 2002), and virus nanoparticles were constructed to carry doxorubicin (Manchester and Singh, 2006).

Other polymer constructs for drug delivery have incorporated poly-L-glutamate and poly-L-aspartate, the copolymer HPMA (*N*-(2-hydroxypropyl)-methacrylamide), PLA (poly-L-lactide), dextran and cyclodextrin, chitosan, heparin, PEG (polyethylene glycol), and various advanced dendrimer designs (Khandare and Minko, 2006). In these cases, a targeting agent and the therapeutic drug are conjugated to the polymer through functional groups normally present on the polymer or through short spacer arms extending off from the polymer core, which link the active components to the base structure (Figure 1.97). Regardless of its structure and morphology, the multivalent nature of a polymer backbone creates abundant functional groups for designing selective properties into the final conjugate. Antibodies or other targeting molecules can thus be attached covalently to the PDDS along with therapeutic agents and even detection components to make a multi-functional conjugate for *in vivo* use. Such polymer conjugates can discretely target particular cell types through antibody–antigen interactions or other affinity binding events, such as ligand–receptor interactions. In addition, if a detection molecule is also attached, the resultant complex can be tracked *in vivo* through, for instance, the use of near-IR fluorescent labels. Finally, this type of bioconjugate can carry multiple chemotherapeutic agents to destroy the intended targeted cells.

Polymeric, dendrimer-based constructs have been made that contain multiple functionalities to target, detect, and destroy tumor cells. Singh *et al*. (2008) prepared a G4 polyamidoamine (PAMAM) dendrimer that was able to target tumor cells which have increased numbers of folate receptors by coupling folic acid to the

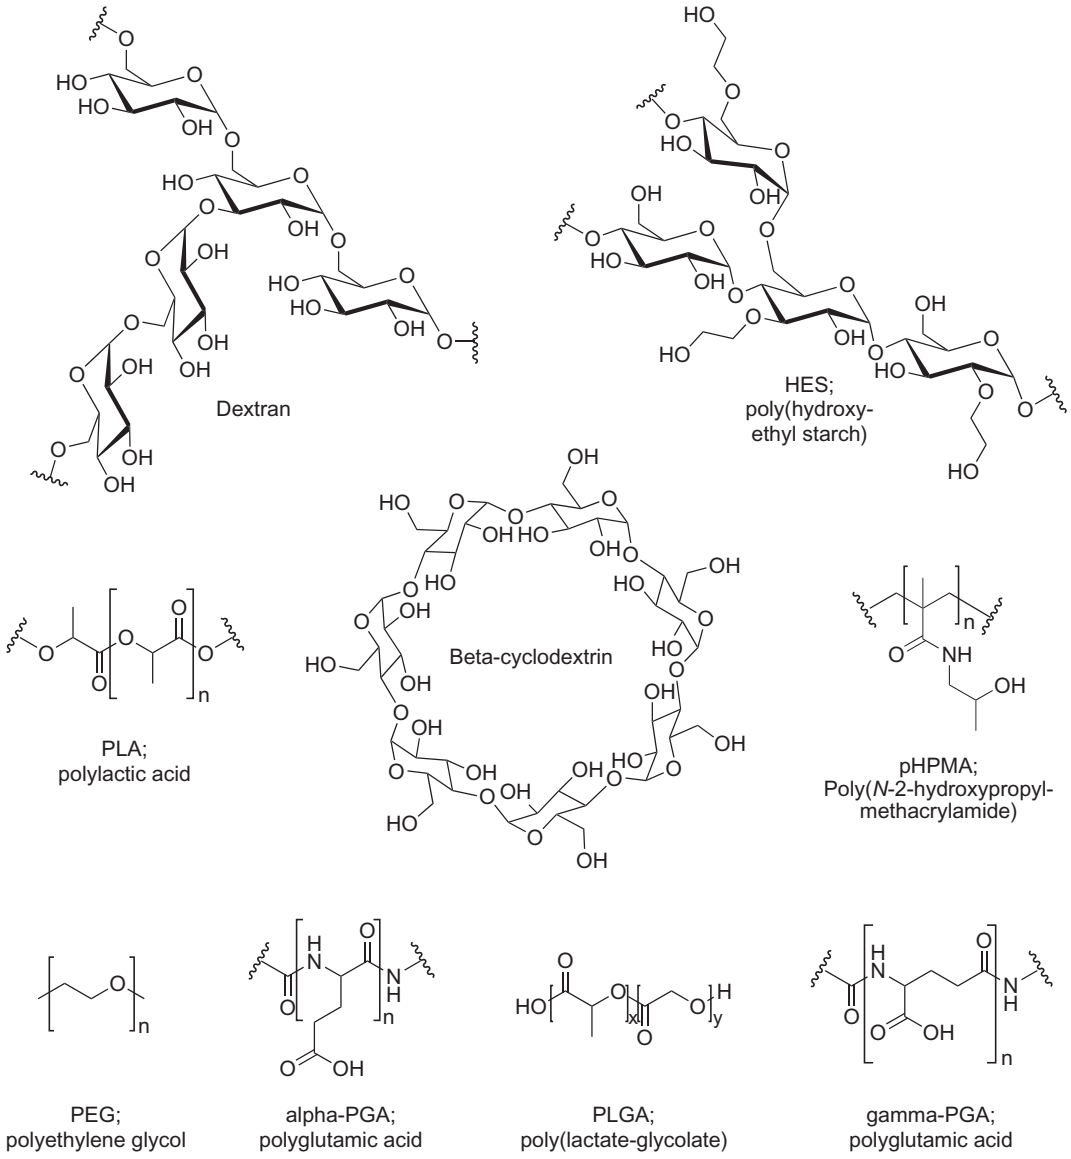

FIGURE 1.96 Some of the most common polymer types used in the design of therapeutic bioconjugates.

pendent amines or through PEG spacers. In addition, the central core of the dendrimer was used as a sequestration carrier to noncovalently encapsulate 5-fluorouracil, a well-known anti-cancer drug. The resultant multifunctional PDDS had the ability to specifically target human epidermoid carcinoma in mice without off-target effects or toxicity.

Liposomes have also been used to create drug delivery vehicles or imaging agents for *in vivo* targeting. A liposome is a synthetic micellular construct containing fatty acids, phospholipids, and other components self-assembled into a bilayer. They are designed to function as a multivalent conjugation scaffold or to sequester active molecules within its bilayer construction for delivery to targets *in vivo* (see Chapter 21). Liposomes can be constructed to contain multiple functional groups or reactive groups on their surface to facilitate conjugation with targeting molecules as well as for the attachment of drugs, enzymes, or imaging agents. Bioconjugates formed using liposome scaffolds can be used to create spherical micelle suspensions of nanometer-sized particles, which can also be filled on the inside of the bilayer with therapeutic agents or dyes for detection (Zhang *et al*., 2008).

Polymeric nanoparticle-based scaffolds used in biotherapeutic conjugate design have proliferated in recent years and include such constructs as polymeric lipid nanoparticles (PLNs), solid lipid nanoparticles (SLNs), magnetic nanoparticles (MNPs), nanocrystals and quantum dots, amphiphilic polymer vesicles, and phospholipid micelles (Koo *et al*., 2005; Kingsley *et al*.,

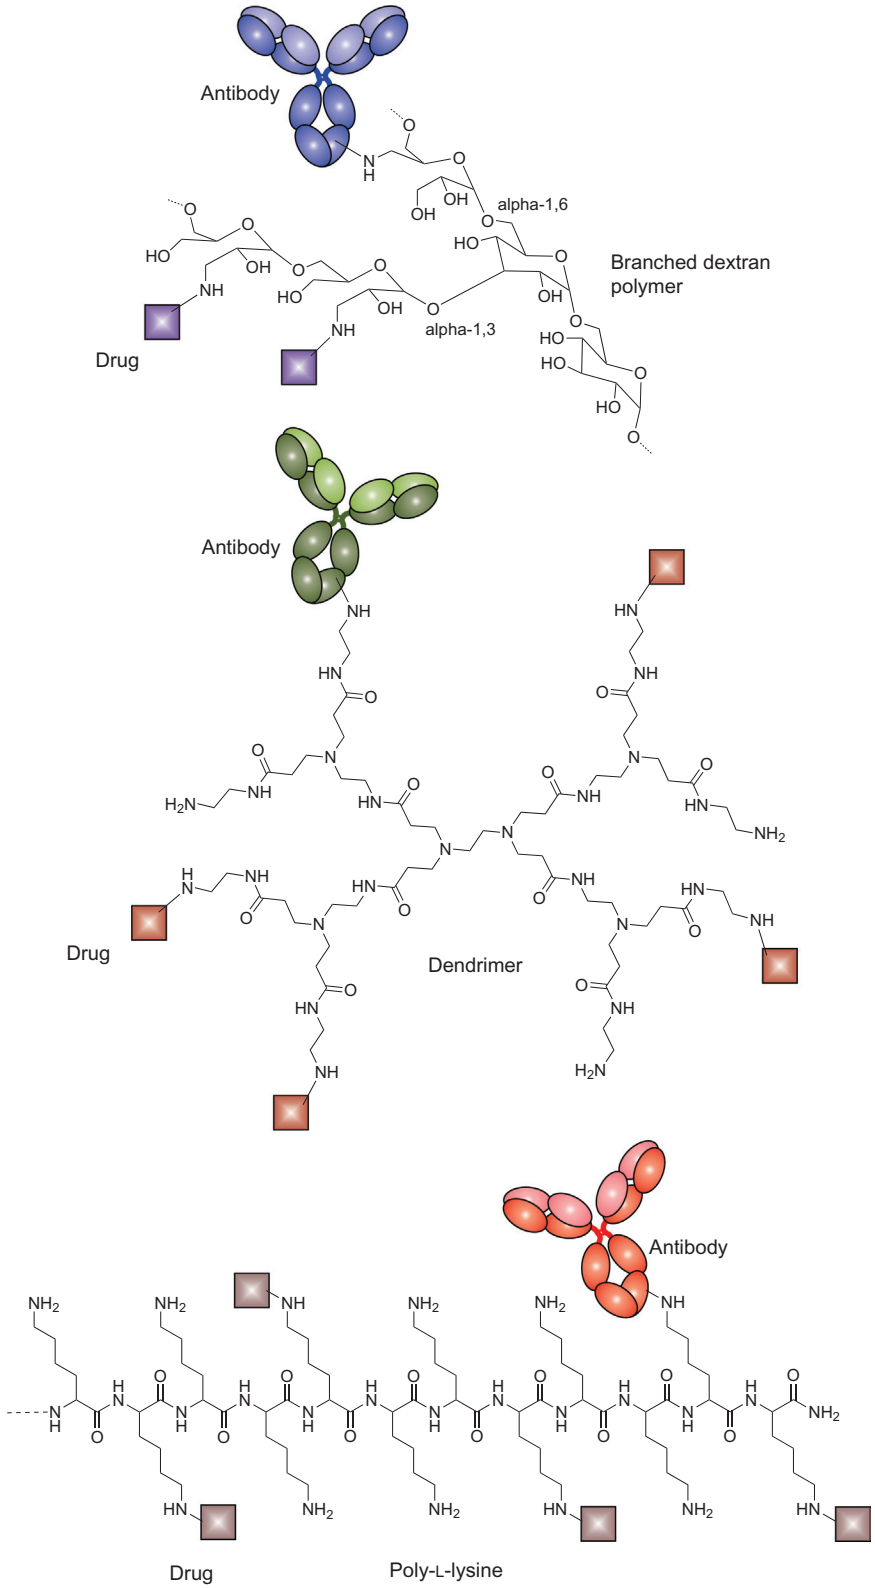

FIGURE 1.97 Polymer-based biotherapeutic conjugates combine the specificity of targeted antibodies with the ability to attach multiple drugs along the multivalent surface of the polymer. The result of this design is to provide a much higher concentration of chemotherapeutic agent at the site of tumor cells than would be possible by linking the drugs directly to the antibodies, as is done with most ADCs.

2006; Caruthers *et al*., 2007; Ganta *et al*., 2008; Keck *et al*., 2008). According to Mishra *et al*. (2010) there have been over 1000 patents or patent applications involving colloidal nanoparticles for use as therapeutic or *in vivo* diagnostic delivery agents.

Antibody-Directed Enzyme Prodrug Therapy

Another antibody-based therapeutic bioconjugate that has been used frequently as an anti-cancer agent is an antibody–enzyme conjugate, wherein the enzyme is chosen for its ability to act on a prodrug substrate and convert it into an active form. Called ADEPT, for "antibody-directed enzyme prodrug therapy," this strategy uses a conjugate that initially has little or no toxic effect on cells (Bagshawe *et al*., 1988; Neri *et al*., 1997; Rooseboom *et al*., 2004). The antibody component is able to interact specifically with the targeted tumor cells through a characteristic biomarker on the cell surface, but neither the enzyme nor the antibody has any immediate therapeutic activity against the tumor. During treatment, the antibody conjugate is administered to the patient, wherein the conjugate finds and binds to the tumor cells, and the excess conjugate is allowed to clear the system before the prodrug is given. The prodrug also has no initial therapeutic activity or cellular toxicity on its own, because of a chemical modification that renders it harmless. However, as the prodrug reaches the tumor cells containing the bound ADEPT conjugate, the enzyme acts on the compound, removing the chemical modification and initiating the drug's anti-tumor activity (Figure 1.98). The prodrug, therefore, has to be designed in anticipation of the enzyme being used in order to obtain successful catalytic removal of its modifying group with concomitant production of the active therapeutic.

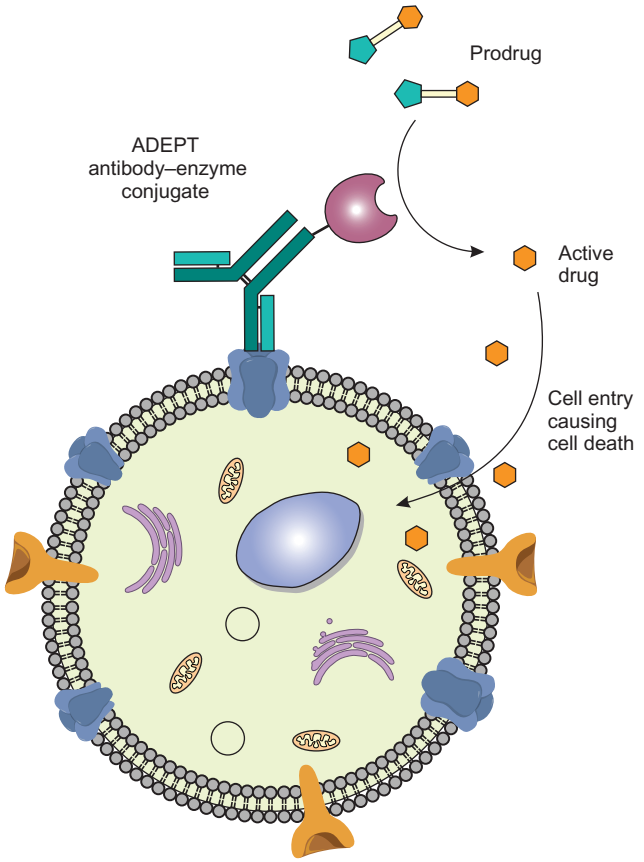

FIGURE 1.98 The principle of an ADEPT antibody–enzyme conjugate is to target the desired cancer cell with the conjugate and then provide an inactive prodrug in circulation, which gets activated only at the tumor cell surface by action of the enzyme. The result of this strategy is to limit the toxicity and off-target effects of the chemotherapeutic agent while maximizing its effect on the tumor cell.

This approach to tumor targeting has several advantages in that it does not use any immediately toxic compounds or conjugates, it involves targeted therapy wherein the antibody–enzyme conjugate only binds to the desired tumor tissue, and the active drug is formed only at the site of each tumor cell thus maximizing its nearby concentration and anti-tumor effectiveness. In addition, since a high concentration of the free drug is attained only around the site where it is needed most, the potential side effects to normal tissue are limited. In addition, the active drug is able to affect tumor cells in the immediate vicinity that may not be specifically labeled with the antibody–enzyme conjugate. This is particularly helpful when epitope changes occur on tumor cells that may eliminate the ability of the antibody to bind to all of the cells within the cancer tissue. Despite epitopic drift, the prodrug molecules will still get converted into the active drug within the tumor tissue and then penetrate throughout the mass to deliver an effective therapeutic dose. Finally, targeted production of a chemotherapeutic agent can avoid the system-wide toxicity of standard chemotherapy, which has numerous sickening side effects on patients.

Some enzymes that have been used in ADEPT bioconjugates include alkaline phosphatase, β-lactamase, carboxypeptidases A and G2, and cytosine deaminase (Senter *et al*., 1988; Senter, 1990; Senter *et al*., 1991; Wallace and Senter, 1991; Rodrigues *et al*., 1995; Vitols *et al*., 1995; Vrudhula *et al*., 1995, 1997; Wolfe *et al*., 1999; Napier *et al*., 2000; Francis *et al*., 2002; Harding *et al*., 2005).

The specific activity of the ADEPT enzyme component ultimately determines the successful design of the associated prodrug used in the therapy. For instance, alkaline phosphatase is particularly useful in removing an organophosphate group from a phenolic prodrug precursor to result in an active drug. One prodrug used for this purpose, etoposide phosphate, is the inactive form of the etoposide anti-cancer agent, which has potent tumor killing properties. The use of

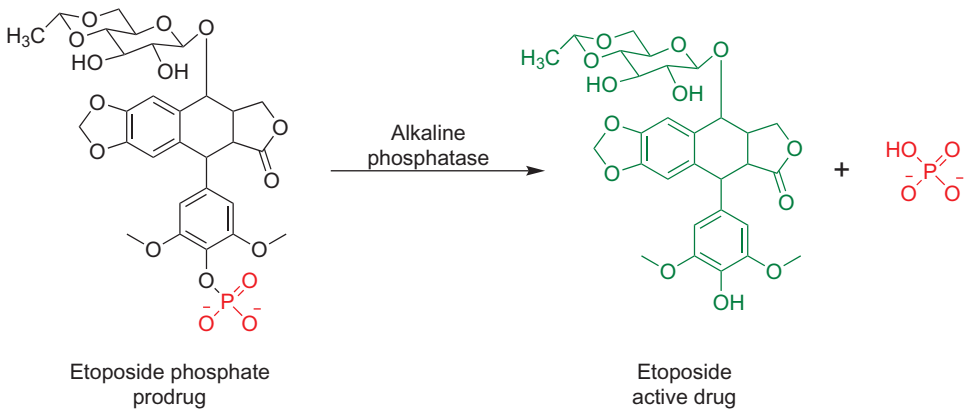

FIGURE 1.99 An example of a prodrug being converted into its active form using the enzyme alkaline phosphatase.

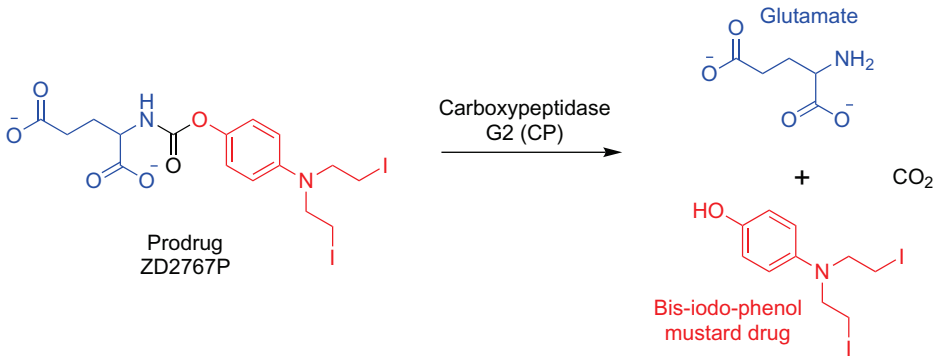

FIGURE 1.100 Carboxypeptidase G2 can be used in an ADEPT conjugate to convert the prodrug ZD2767P into the active chemotherapeutic agent, which is a toxic mustard compound.

the appropriate antibody–alkaline phosphatase ADEPT conjugate can be used to target an antigen on tumor cells, thus bringing the AP enzyme to the cancer tissue in high concentration. After clearance of excess conjugate and administration of etoposide phosphate, the antibody–AP bound to the tumor cells catalytically removes the phosphate groups from the prodrug, resulting in a very high concentration of the chemotherapeutic agent in the surrounding area of the targeted cells (Figure 1.99).

The reaction of an ADEPT biotherapeutic with a prodrug can also be illustrated by the use of an anti-CEA (carcinoembryonic antigen)–carboxypeptidase G2 conjugate and the prodrug ZD2767P as described by Mayer *et al*. (2004). The prodrug ZD2767P is a phenol mustard derivative containing an esterified glutamate residue on the phenolic OH group. Carboxypeptidase G2 can cleave the ester and release the active drug, which is the bifunctional alkylating agent, ZD2767D (4-[*N*,*N*-*bis*(2-iodoethyl)amino]phenol). The free drug is a nitrogen mustard compound that can rapidly induce cell death in the cells it enters. Figure 1.100 shows the reactions associated with the anti-CEA–G2 conjugate after binding to the targeted tumor cells and administration of the prodrug agent.

ADEPT conjugates using β-lactamase can be used to cleave many types of prodrugs containing β-lactam linkages. β-Lactamases are known to be involved in the metabolic breakdown of certain antibiotics, such as penicillins, carbapenems, monobactams, and cephalosporin, which all contain a lactam ring structure. The enzyme cleaves the lactam ring through hydrolysis, which causes an electron flow toward the associated six-member ring, inducing breakage of any bond at the 3′ substituted position (Kuhn *et al*., 2004). Due to the enzyme's rapid turnover rate and its ability to act on a wide variety of substrate structures containing a lactam ring, it is now seeing increased use in ADEPT conjugates to convert prodrugs into chemotherapeutic agents. For instance, Wang *et al*. (2001) demonstrated its usefulness in acting upon a cephalosporin-CC-1065 prodrug to ultimately cleave the internal carbamate bond and release the active anti-tumor agent CC-1065 (Reynolds *et al*., 1986). Figure 1.101 shows the enzymatic conversion of this prodrug to its active form. In a similar strategy, Alderson *et al*. (2006) synthesized the

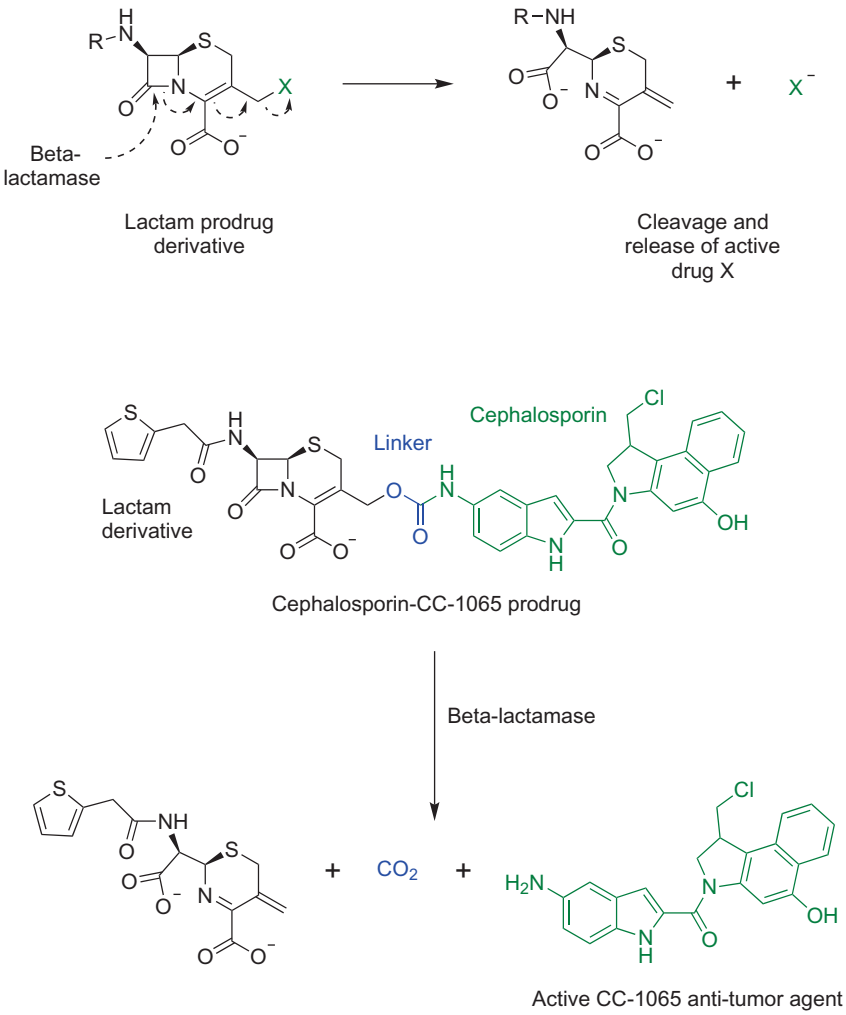

FIGURE 1.101 Beta-lactamase can be used in an ADEPT conjugate to act on lactam-containing prodrugs through a self-immolative process that removes the active drug as a leaving group. The upper reaction scheme illustrates this general concept and the lower reaction shows the specific release of the anti-tumor agent cephalosporin from the lactam precursor derivative.

prodrug GC-Mel, which upon cleavage by a scFv–β-lactamase bioconjugate produced as a fusion protein released the potent anticancer drug melphalan, another nitrogen mustard *bis*-alkylating agent.

Radiolabeled Bioconjugates for Cancer

Radiolabeled antibody conjugates have been prepared by modification with unstable isotopic emitters to create bioconjugates for tumor imaging or to target and destroy cancer cells *in vivo*. The preparation of bioconjugates for radioimmunotherapy involves the attachment of radioisotopes to antibodies or other targeting molecules, such as peptides or small ligands. It can be accomplished using several strategies: (1) direct modification of amino acid side chains in the protein, peptide, or ligand with one or more radioactive atoms; (2) indirect modification of the targeting molecule using a bifunctional chelating compound to coordinate and carry the radioactive isotope; or (3) through the use of a polymeric carrier or nanoparticle attached to the targeting molecule, in which the carrier is modified to contain the radiolabels (Chapter 12) (Figure 1.102). In each case, one or more radionuclides are attached to the targeting molecule to produce a therapeutic agent that can bring to tumor sites a highly concentrated dosage of radiation.

Radiolabeled conjugates for cancer have been used for *in vivo* imaging and for cancer cell destruction, which is called radioimmunotherapy. Some of the radionuclides used to modify peptides or antibodies for tumor imaging or therapy include I-131, Lu-177, In-111, Sm-153, Ho-166, Cu-64, Re-188, Tc-99m, and Y-90 (Weiner and Thakur, 2002). Iodine-131 can be conjugated to antibodies using oxidative techniques or through the use of an iodinatable modification reagent, as described in Chapter 12, Section 2. Modification with other radiolabels, however, typically involves the use of a bifunctional chelating agent, which is able to stably coordinate the isotope and also allow for covalent attachment to protein functional groups. These chelators provide a reactive group that can be used to couple with, for instance, amines on antibodies while the other

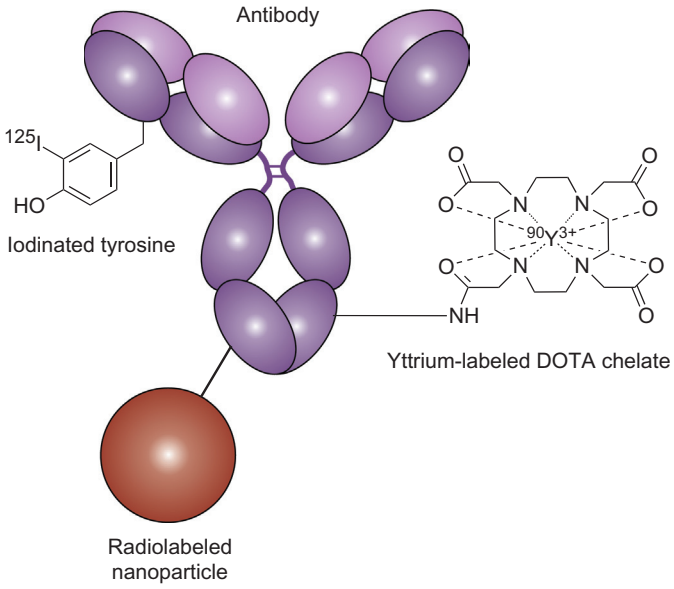

FIGURE 1.102 Several different types of radiolabeled antibodies have been used for therapeutic purposes, including a radioiodinated tyrosine, a radiolabeled nanoparticle conjugate, and a ^{90}yttrium-labeled DOTA chelate conjugate.

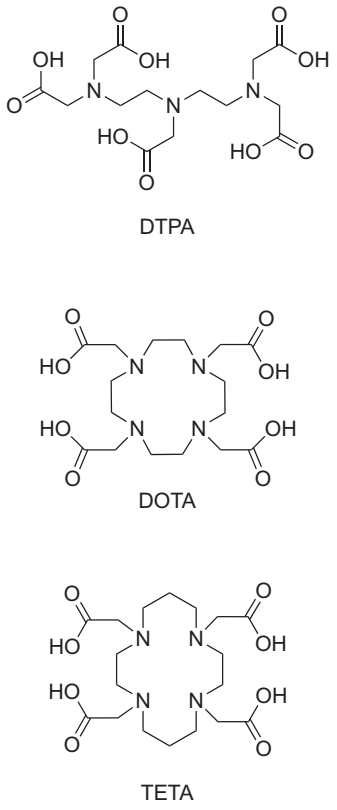

FIGURE 1.103 Three types of chelating groups are shown that are commonly used to make isotopically labeled bioconjugates for radiotherapy or imaging applications.

end of the molecule is designed with a cyclic or wrap-around type of chelation group that can fully coordinate the radionuclide, thus preventing it from leaching from the complex. Some of these bioconjugation chelating agents are illustrated in Figure 1.103 and include the tetraaza-macrocycles DOTA and TETA as well as the multi-armed carboxylate chelator DTPA.

Bioconjugates used in radioimmunotherapy usually employ radionuclides that emit high-energy particles or electromagnetic gamma radiation and are capable of rapid cellular destruction when greatly concentrated at a tumor site. Bioconjugate designs for these agents typically involve the use of one or more chelated radiolabels attached to an antibody targeting molecule, which is directed at tumor cell epitopes. For this type of bioconjugate, one of the most preferred radioisotopes is Y-90, because it emits a high-energy β^- particle and it has a half-life of only 2.7 days. Yttrium-90 labeled antibodies bind to the tumor cells and create extremely high radiation doses right at the site of the cancer mass, thus maximizing its effectiveness for tumor cell destruction and minimizing the effects on other organs and tissues. The first commercial drug of this type was approved for non-Hodgkin lymphoma in 2002 and is marketed under the name Zevalin (Y-90 ibritumomab tiuxetan) (Witzig *et al*., 2002; Bethge *et al*., 2010). It consists of an anti-CD20 monoclonal antibody that is modified with a DTPA derivative (tiuxetan), which contains the chelator groups and coordinates the Y-90 radionuclide (Figure 1.104). The chelator is conjugated to the antibody via a thiourea bond formed from the reaction of an isothiocyanate-phenyl-DTPA derivative with amine groups on the antibody molecule. The antibody conjugate is then loaded with fresh Y-90 prior to *in vivo* administration to ensure maximum activity for radioimmunotherapy.

Many other yttrium-90-based radioimmunotherapy conjugates have been investigated in their efficacy in killing tumor cells. DeNardo *et al*. (1997) created a DOTA–peptide–chimeric monoclonal antibody conjugate with a peptide linker that would be cleaved by lysozymes intracellularly. The chimeric antibody was developed by Bristol-Myers Squibb Pharmaceutical Research Institute and consisted of a human Fc region joined to a mouse Fab region, which had antigen binding characteristics toward an integral membrane glycoprotein, which is expressed on breast, colon, ovary, and lung cancer cells. The study found a positive synergistic effect in the use of yttrium-90 conjugate with the anticancer drug taxol, indicating that bioconjugates may also be important adjuncts to standard chemotherapeutic approaches in treating cancer.

In addition, Zang *et al*. (2009) developed an anti-CD25 monoclonal antibody conjugate containing ^{90}Y

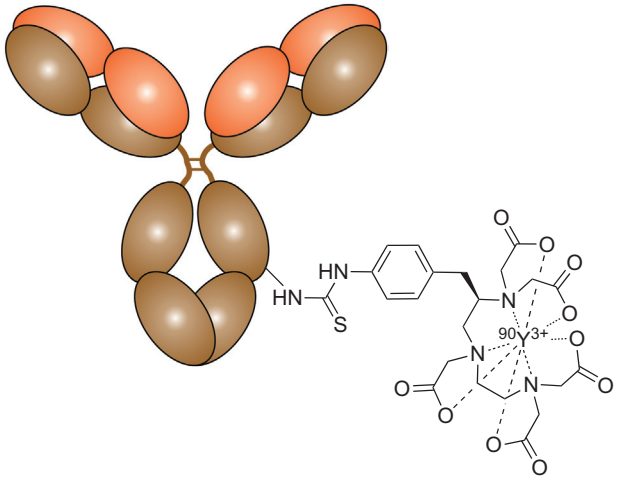

FIGURE 1.104 An antibody labeled with a yttrium-90 chelate can be used to target tumor cells for radioimmunotherapy purposes. This illustration depicts the design of the drug Zevalin, which is approved to treat non-Hodgkin lymphoma.

chelated with DTPA derivatives to investigate the treatment of CD25-expressing lymphomas in mice. This radioimmunoconjugate showed efficacy in the treatment of SUDHL-1 lymphoma in a preclinical animal study. Similarly, Shibata *et al*. (2009) used a ^{90}Y–DTPA–anti-CEA (carcinoembryonic antigen) conjugate in a phase I study on patients with advanced CEA-producing solid tumors. The chimeric antibody was labeled with isothiocyanatobenzyl-DTPA and loaded with Y-90 before administration. The major side effect seen in this study that limited the use of the bioconjugate drug was the formation of a human anti-chimeric antibody (HACA) response, which interfered with the targeted delivery of the complex to the tumor.

Boron Neutron Capture Therapy

Boron neutron capture therapy (BNCT) is another application area in which bioconjugates have found important use for the treatment of cancer. The ability of boron to capture neutrons was discovered by Taylor (1935) when he found that bombarding boron-10 with neutrons caused the release of He-4 alpha particles and converted the boron atoms into lithium-7 ions (Slatkin, 1990). Although simple inorganic boron-10-containing salts were found to be useful as neutron capture agents, the nonselective nature of these compounds proved impractical for *in vivo* targeting of tumor cells (Godwin *et al*., 1955). Second-generation boron compounds were developed and consisted of boron-modified amino acids, but these also suffered from lack of specificity in targeting most cancers, although some compounds do appear to accumulate preferentially in certain brain tumors (Snyder *et al*., 1958; Radioisotopes in Medicine, World Nuclear Association, 2010).

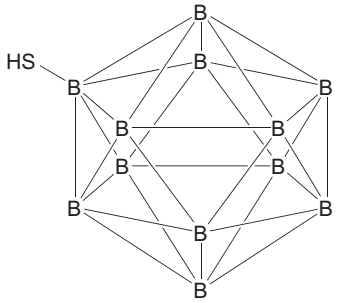

FIGURE 1.105 Borocaptate is a common label for use in boron neutron capture therapy. It consists of 12 boron atoms and a single thiol for convenient conjugation to targeting molecules.

Perhaps the most convenient form of boron that can be used for bioconjugation was discovered in the early years of boron compound development and consists of a polyhedral borane complex, mercapto-undecahydro-*closo*-dodecaborate (or sodium borocaptate, BSH), which contains 12 boron-10 atoms ($Na_2B_{12}H_{11}SH$). This compact polyhedral compound can be used as a label to provide a high concentration of boron atoms for *in vivo* therapy. Particularly, BSH has a convenient thiol group for conjugation with other molecules, making it ideal for labeling targeting molecules using crosslinkers having thiol-reactive groups (Figure 1.105). Borocaptate has also been modified to contain other functional groups or reactive groups suitable for bioconjugation to targeting molecules, thus establishing it as a powerful tool for BNCT of cancer (Hawthorne and Lee, 2003; Barth *et al*., 2005).

For BNCT to be effective at killing cancer cells at least 20 μg of B-10 per gram of tumor mass or approximately a billion atoms of B-10 per cell have to be delivered to the tumor site (Barth *et al*., 2005). This level of concentrated delivery can only be accomplished without side effects through the use of carefully designed bioconjugate drugs containing affinity-targeting agents specific to the tumor type requiring treatment. In some cases, low-molecular-weight targeting molecules have been found to be efficacious, such as a conjugate containing multiple BSH complexes linked to a porphyrin derivative (Evstigneeva *et al*., 2003; Vicente *et al*., 2003; Fronczek and Vicente, 2005). Porphyrin molecules are rapidly taken up by tumor cells due to their high metabolic rates, thus providing a mechanism for delivering the boron payload to the cells.

BSH may also be conjugated to monoclonal antibodies or other macromolecule targeting components for the delivery of B-10 to tumor sites (Novick *et al*., 2002; Wu *et al*., 2004). The production of these conjugates is rather straightforward, but their use in the treatment

of brain cancer may be somewhat restricted due to their limited ability to penetrate the blood–brain barrier and reach the tumor site. However, recent studies in rats have used the monoclonals cetuximab (against wild-type EGFR) or L8A4 (against mutant EGFRvIII), both conjugated with BSH and compared with that of a lower molecular weight conjugate consisting of EGF-BSH (Yang *et al*., 2009). Best results in that study were obtained using the monoclonal L8A4 as the targeting agent, because it had the greatest specificity for the mutant EGFR expressed on the gliomas.

Other bioconjugates with BSH have been created using various scaffolds to link the boron-10 complexes with antibodies or other targeting molecules. For instance, boronated polylysine was coupled to the carbohydrate groups on polyclonal antibodies to create a conjugate for neutron capture therapy (Novick *et al*., 2002). The final conjugate was estimated to contain about 6000 atoms of B-10 per antibody molecule, thus making a high-activity complex for targeted delivery directly to tumor cells at levels required to efficiently cause cell death in BNCT procedures.

Photodynamic Therapy

Photodynamic therapy (PDT) involves the use of an organo-metallic photosensitizing agent that combines irradiation by light with available dissolved oxygen within the surrounding media to catalytically produce reactive oxygen species (ROS). The rapid production of ROS at the site of the reaction can cause cell death in proximity to the photosensitizer (Usuda *et al*., 2006). Small-molecule photosensitizers have been used individually or in conjugated form with other targeting molecules to treat malignant or even certain benign diseases. Many of the photosensitizing agents that have been used for therapy or research involve porphyrin or phthalocyanine derivatives or porphyrin precursors such as 5-aminolevulinic acid (ALA), which is taken up by metabolizing cells (e.g., neoplastic tissue) to create an excess of porphyrin intracellularly. Upon exposure to light in the far-red to NIR region and in the presence of dissolved oxygen, a redox reaction is induced at the site of the coordinated metal ion, which ends up producing highly reactive singlet oxygen ($^1O_2$). The photosensitizer absorbs a photon of light and enters an excited state, which subsequently transitions into an excited triplet state. This intermediate can then undergo redox reactions with nearby molecules and create free radical intermediates, which subsequently can react with oxygen to produce ROS. Since the porphyrin photosensitizer acts as a redox cycle and gets regenerated during the course of the reaction, large amounts of singlet oxygen and other ROS can be produced in the immediate molecular vicinity. Thus, PDT can be very effective at producing a toxic reactive agent right at the site of a tumor or directly within cancer cells. See Chapter 2, Section 1.1, for additional information on the reactions associated with ROS on biomolecules.

At least eight photosensitizers have been approved and commercialized for PDT. Many of these compounds are porphyrin derivatives that are not conjugated with targeting molecules. They are administered and accumulate in membranes and organelles, especially within tumor tissue, because of their rapid growth characteristics. Some commercial photosensitizers consist of ALA derivatives, and these drugs typically are applied topically to skin lesions. Some studies have even found benefits to PDT in the treatment of port wine stain birthmarks (Yuan *et al*., 2009).

An example of a common drug derivative used for PDT is Photofrin, which consists of a short polymer of porphyrin derivatives linked together via ether bonds (Figure 1.106). Though it has been approved for use with a number of cancers, including non-small cell lung carcinoma, esophageal cancer, and bladder cancer, it and other PDTs suffer from a lack of affinity targeting agent to direct the drug specifically to the desired tumor cells. Side effects can include off-target tissue damage as well as eye and skin sensitivity to light due to the accumulation of porphyrin compounds throughout the body.

In use, the Photofrin compound is reconstituted from a freeze-dried product in 5% dextrose solution or 0.9% NaCl and injected intravenously. The drug is allowed to circulate for up to 40 to 50 hours before irradiating the tumor site with red laser light at a wavelength of 630 nm. The red light penetrates tissue to the tumor containing a high concentration of the Photofrin oligomer. Irradiation begins the ROS production that leads to tumor destruction. However, there are potentially serious side effects to this treatment partly due to the untargeted nature of the treatment. PDT done with advanced bioconjugates containing targeting molecules that limit off-target effects likely will alleviate some of the side effects observed with the use of Photofrin alone.

Another deficiency in the use of many porphyrin derivatives is that they often are best activated with light within the blue or green part of the spectrum. At these wavelengths, light cannot travel far through tissue without being absorbed by biological molecules, especially porphyrin-containing molecules like hemoglobin. This limits the use of some PDT compounds *in vivo* to skin or near-surface lesions. However a porphyrin-like compound called texaphyrin that was first synthesized at the University of Texas (Austin) includes a fifth coordinating nitrogen in its ring structure to chelate a lanthanide ion, such as lutetium or gadolinium (Sessler and Miller, 2000; Young *et al*., 1996; Sessler and Tomat, 2007). A common derivative of the texaphyrin core structure involves the addition of two short-chain

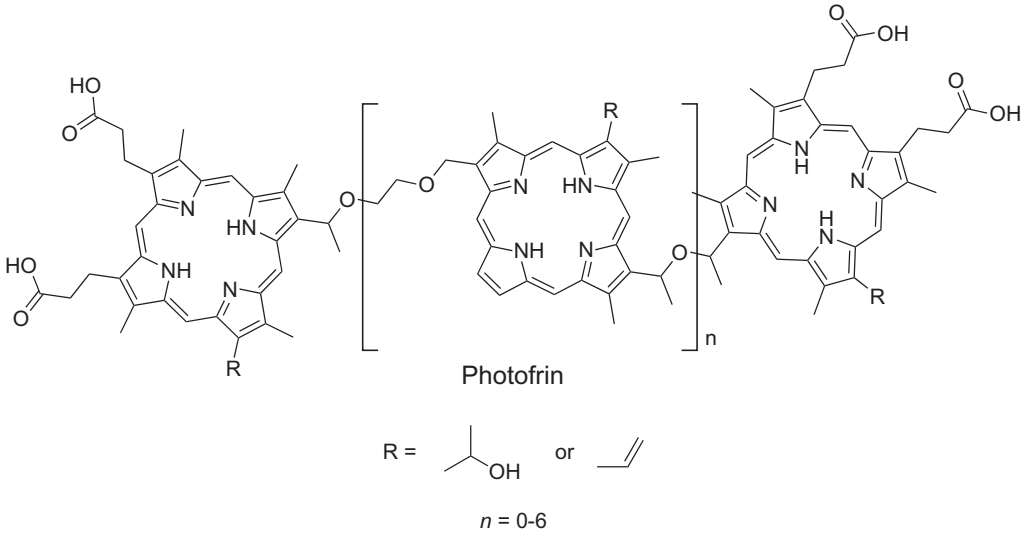

FIGURE 1.106 The structure of Photofrin, which contains multiple porphyrin units and can be used in photodynamic therapy to cause tumor cell death.

PEG arms to improve water solubility for i.v. administration while maintaining the lipophilic nature of the macrocyclic metal chelate (Figure 1.107).

Texaphyrin-based PDT compounds behave spectrally like phthalocyanine derivatives in that they display red-shifted absorbance properties relative to porphyrins. Texaphyrin derivatives can be activated by light in the far-red to NIR region of the spectrum (690–880 nm), thus allowing much deeper tissue penetration for therapy. These compounds also have enhanced relaxivity that makes them useful in nuclear magnetic resonance imaging (MRI) for dual-mode detection and therapy (Sessler *et al*., 1995). Considerable research is being done on Texaphyrin compounds due to their favorable absorbance properties for *in vivo* applications.

To overcome the nonspecific targeting of many standard PDT techniques, photosensitizer compounds can be conjugated to targeting molecules that have high affinity toward the diseased cells being treated. For instance, Staneloudi *et al*. (2007) designed a novel PDT bioconjugate using antibody scFv fragments directed against colorectal tumor cells and coupled with two different porphyrin photosensitizer derivatives, which contained amine-reactive isothiocyanate groups (Figure 1.108). It was found that a reaction ratio of 5:1 (porphyrin-NCS:scFv) was ideal for forming an active scFv–porphyrin conjugate while not affecting the ability of the small antibody fragment to bind antigen—an important factor to consider when working with low-molecular-weight targeting molecules.

A novel photodynamic conjugate was described by Cheng *et al*. (2008) using gold nanoparticles that were PEGylated with thiol-PEG tethers, which functioned as a biocompatible cage to transport a drug to a tumor site

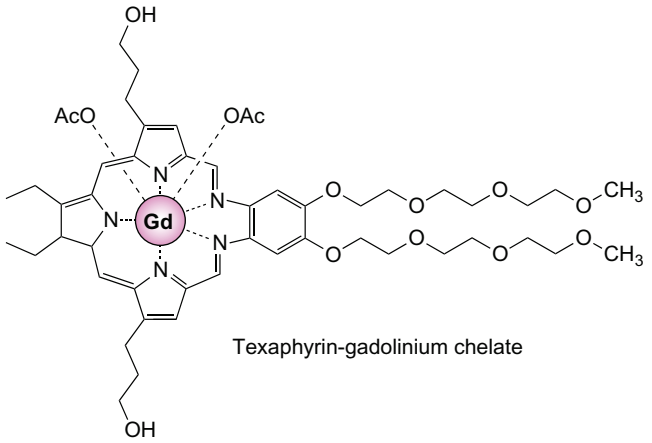

FIGURE 1.107 Texaphyrin is a phthalocyanine-like derivative containing a chelated gadolinium ion and two PEG chains to promote water solubility.

for PDT. The gold nanoparticles are known to have low toxicity and the addition of PEG tethers prevents nonspecific binding to proteins *in vivo*. After PEGylation, the gold was further derivatized with a phthalocyanine compound containing a side-chain tertiary amine (Figure 1.109). The unshared pair of electrons on the nitrogen can bind through dative bonds to the gold surface in areas that were not taken up by the PEG-SH tethers, thus forming a water soluble (or colloidal) nanoparticle containing photodynamic groups.

In another example, Liu *et al*. (2009a) developed a small molecule conjugate for targeted PDT consisting of an inhibitor of a biomarker for prostate cancer, the prostate-specific membrane antigen (PSMA), and a porphyrin-like derivative, pyropheophorbide-*a* (Ppa). The

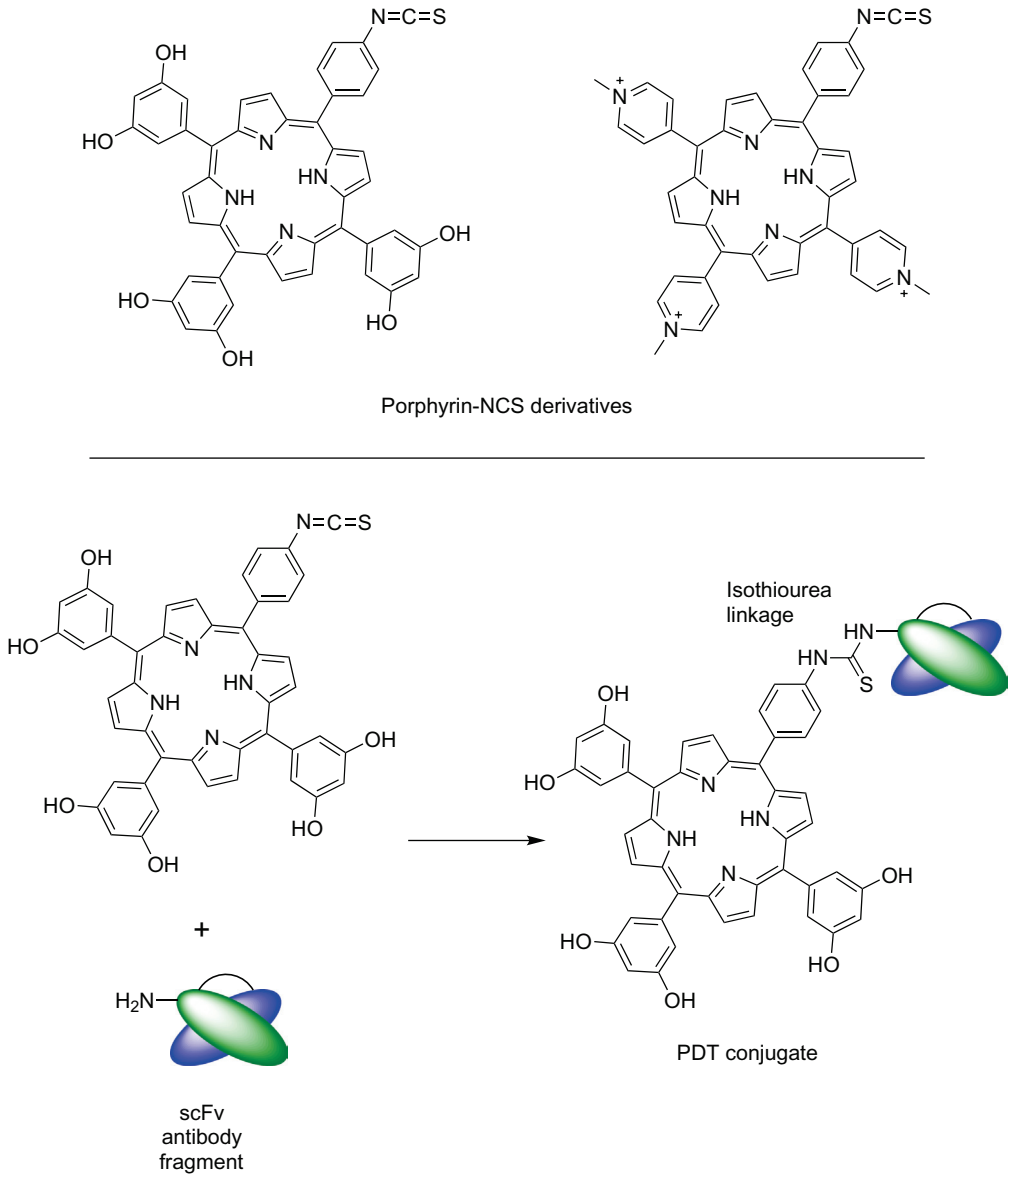

FIGURE 1.108 Reactive porphyrin-isothiocyanate derivatives have been created to provide reactive groups for conjugation of this photosensitizer to antibodies. The conjugate with a scFv monoclonal antibody fragment, made via an isothiourea linkage, was shown to be effective in targeting colorectal tumor cells.

PSMA inhibitor consisted of a peptidomimetic phosphoramidate derivative with a free alpha-amine at one end (termed PSMA inhibitor core 1). The conjugate was made through an amide bond that was formed using an NHS ester on the carboxylate end of Ppa and then reacting it with the amino end on the inhibitor (Figure 1.110). The conjugate was found to specifically target and bind to LNCaP cells in culture through the inhibitor's affinity toward PSMA. Cellular apoptosis was achieved after irradiation as a result of photodynamic destruction of the tumor cells by the generated ROS.

A targeted PDT bioconjugate was also designed by Lu *et al*. (2009) by modifying coagulation factor VII with verteporfin to provide a potential therapeutic for age-related macular degeneration (AMD). Factor VII is a serine protease involved with the initiation of the coagulation cascade. It forms a complex with tissue factor, a protein normally found on the outside endothelial cells of blood vessels and therefore inaccessible to agents in plasma. Upon vascular injury, however, tissue factor becomes available to interact with factor VII in the blood, which starts the enzymatic coagulation cascade process. In AMD involving choroidal neovascularization (CNV), tissue factor is aberrantly present on the inside of the blood vessels. Thus, a bioconjugate consisting of factor VII has affinity to bind only to the

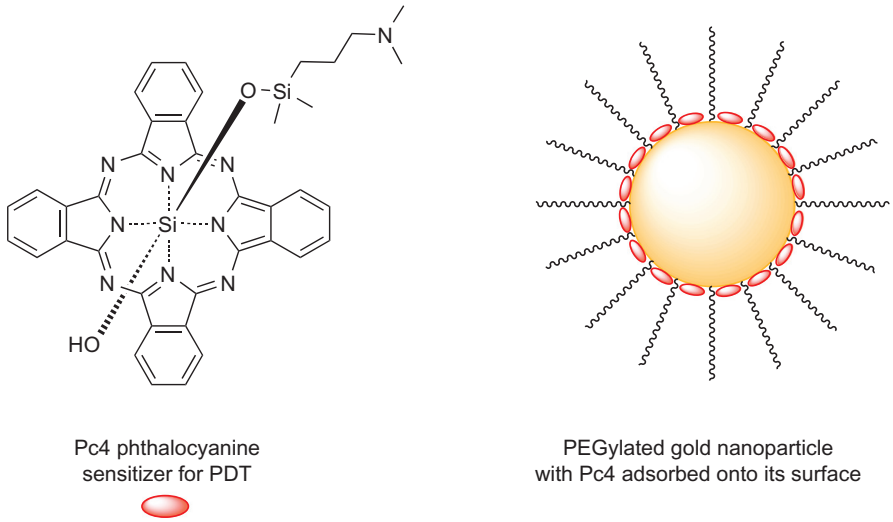

FIGURE 1.109 A nanoparticle sensitizer for photodynamic therapy was created by adsorbing a phthalocyanine compound onto a PEGylated gold particle. The conjugate provided intense singlet oxygen production through the high density of photosensitive groups on each particle surface. The PEG tethers provided water solubility and low nonspecific binding toward biomolecules *in vivo*.

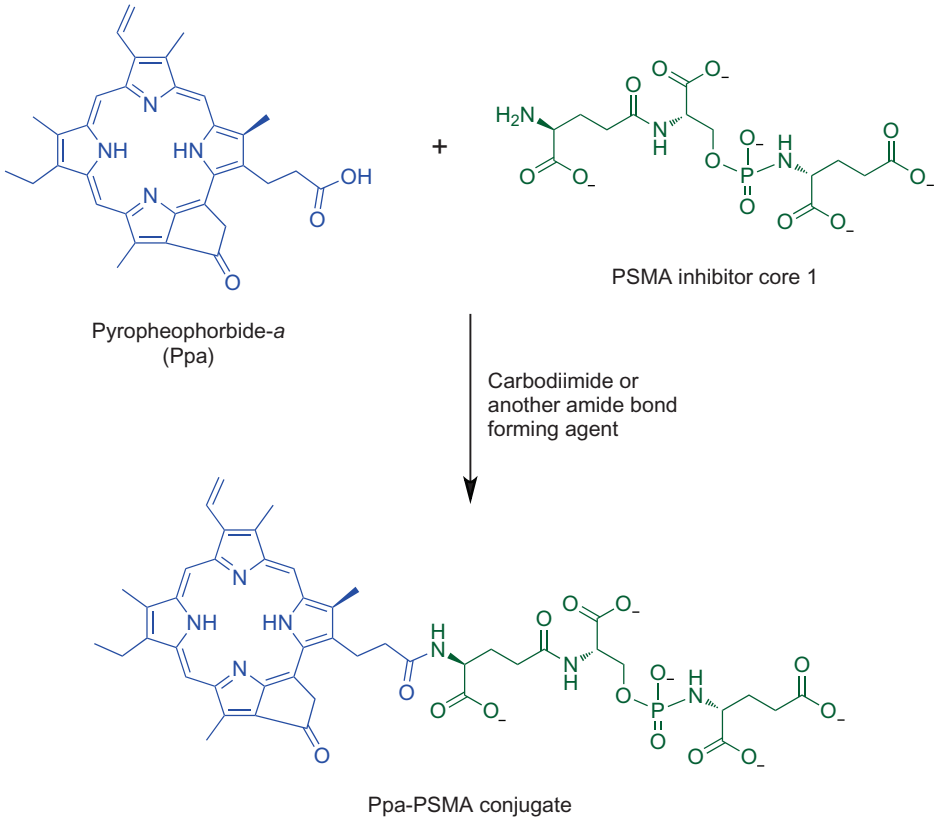

FIGURE 1.110 The conjugation of a porphyrin-like derivative, pyropheophorbide-*a* (Ppa), with the prostate-specific membrane antigen (PSMA) inhibitor core 1 provides targeted photodynamic therapy in the treatment of prostate cancer.

endothelium present in CNV lesions but nowhere else. The porphyrin derivative verteporfin, which contains a carboxylate group, was used in an EDC-mediated carbodiimide reaction (Chapter 4, Section 1) to conjugate with purified recombinant factor VII (Figure 1.111). The resultant PDT bioconjugate was found to be significantly more effective than untargeted reagents in treating AMD using photodynamic methods.

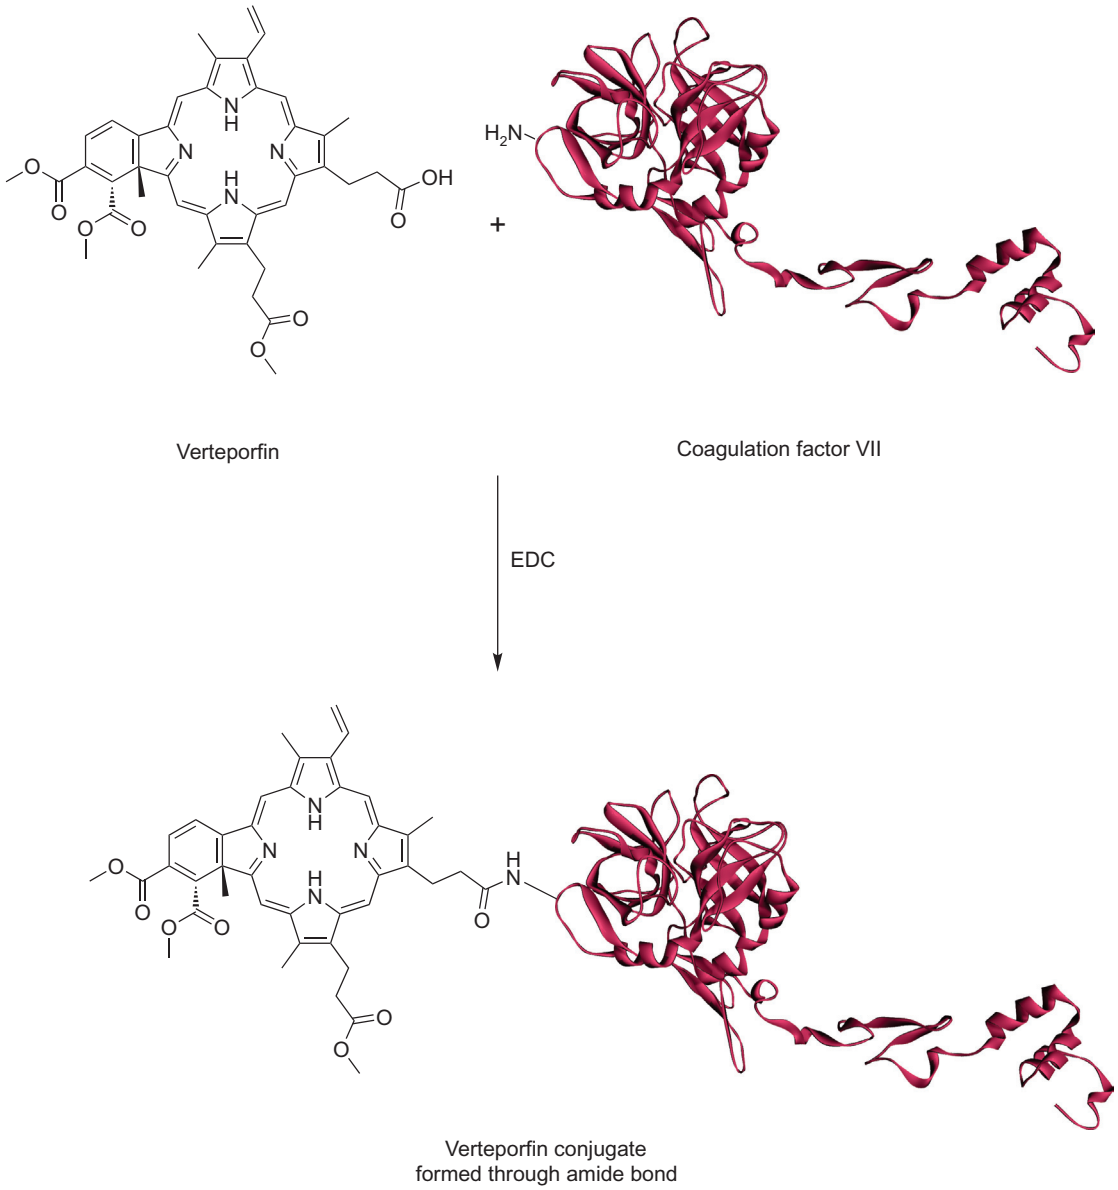

FIGURE 1.111 The conjugation of the photosensitizer verteporfin with protein coagulation factor VII provides a specific PDT agent to treat choroidal neovascularization (CNV) lesions.

In addition, bioconjugates have been designed using the red-shifted porphyrin derivative texaphyrin to provide targeted PDT while also being able to use NIR irradiation for activation *in vivo*. Wei *et al*. (2005) synthesized a conjugate of texaphyrin with the antitumor drug methotrexate (Figure 1.112). This unique conjugate used the tumor uptake capability of the texaphyrin component to better aid in getting methotrexate into tumor cells. This small molecule bioconjugate was designed to overcome the resistance of tumor cells to methotrexate, which can occur very rapidly after treatment. The complex creates the potential for dual-mode therapy using an anti-folate agent combined with PDT.

Diagnostic Bioconjugates for In Vivo Imaging

For decades diagnostic procedures to detect disease have been done *ex vivo* on samples extracted from patients consisting primarily of cells, tissues, or fluids. For example, classical immunohistochemical (IHC) staining methods in pathology have been widely used with antibody conjugates to assess disease states using patient tissue samples obtained through biopsies. These procedures are often unpleasant or painful and can yield differential results depending on how accurately the sampling process was performed. The bioconjugate reagents used for IHC typically are enzyme conjugates wherein an enzyme substrate reaction is used

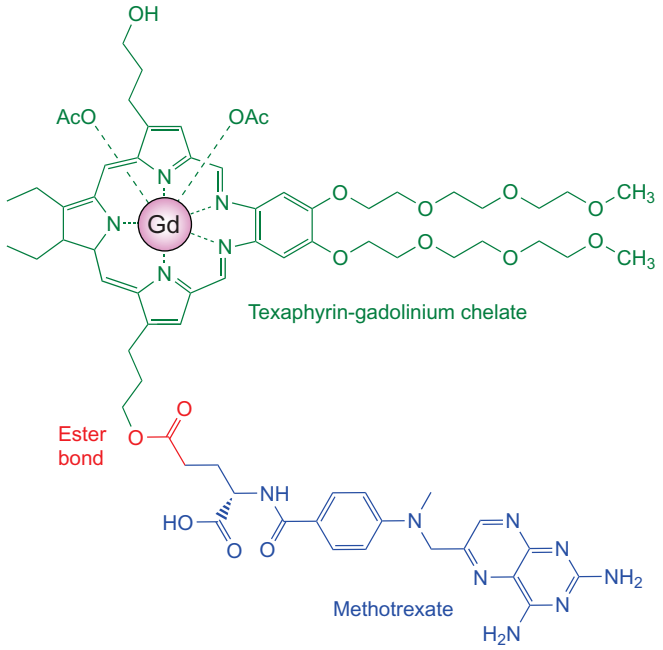

FIGURE 1.112 The conjugation of texaphyrin–gadolinium chelate for PDT and the anti-tumor agent methotrexate offer combined therapy for cancer.

to produce a precipitated chromogenic or fluorescent signal at targeted points within the extracted tissue section. Probing thin tissue sections or cells in this manner has also been done using fluorescently labeled antibodies to directly detect antigens present within the sample (see further discussion on IHC in Section 2.2 of this chapter). However, these procedures are all done *ex vivo* to target and detect diagnostically important pathology within samples extracted from patients in highly invasive procedures.

The current trend is to detect diseased tissues and cells directly within animals or human patients without taking a biopsy or using invasive methods to obtain the critical sample (for review, see Frangioni, 2008). Bioconjugates developed for *in vivo* diagnostic imaging have become a major research area that has grown rapidly over the last two decades. The use of targeted detection with affinity bioconjugates containing highly sensitive labels that can be imaged effectively through skin or tissue already generates billions of dollars annually in health care revenues. The major types of detection bioconjugates currently used for *in vivo* diagnostic procedures consist of chelated radionuclides, high-contrast agents, nanoparticles, and organic fluorescent labels. Many of these imaging bioconjugates also incorporate polymeric constructs (e.g., dendrimers) as scaffolds that can be used to couple multiple copies of detection molecules for enhanced sensitivity. Today, the majority of clinical *in vivo* imaging involves the use of contrast agents and radiopharmaceuticals along with instrumentation for magnetic resonance imaging (MRI) or positron emission tomography (PET); however, fluorescence detection is also predicted to increase dramatically over the next decade to become the third leading detection method for *in vivo* diagnostics (*Biologic Imaging Reagents: Technologies and Global Markets*, BCC Research, Wellesley, MA, 2009, pp. 124, 144). The following sections discuss the bioconjugates used in these three primary detection modes for *in vivo* imaging applications.

Bioconjugates for Radio Imaging

The overwhelming majority of radiopharmaceuticals prepared for *in vivo* imaging involve the use of Tc-99m-labeled compounds (Liu, 2004). This radiolabel is used in millions of diagnostic procedures every year. Tc-99m emits gamma radiation at approximately the same wavelength as X-rays used in diagnostic imaging; therefore, conventional medical instrumentation can often be used for detection. Many of the commercial Tc-99m complexes are not conjugates with antibodies or peptide targeting agents, but are chelator organo-metal complexes that are able to target certain sites within the body due to their small size, charge, or hydrophobicity. The design of Tc-99m chelators is highly diverse due to the complex redox chemistry of technetium (Liu *et al.*, 1997). A number of commercialized radiopharmaceuticals currently on the market are shown in Figure 1.113. One such compound is represented by the drug Cardiolyte (Bristol-Myers Squibb), which consists of a technetium complex of six molecules of 2-methoxy isobutyl isonitrile complexed with one Tc ion to form Tc99m[MIBI]$_6^+$ coordination complex (^{99m}Tc-Sestamibi, Figure 1.113). This diagnostic agent is indicated for detecting coronary artery disease and is used frequently in imaging procedures to noninvasively detect atherosclerosis.

Other popular small-isotope conjugates used for *in vivo* imaging consist of F-18-labeled reagents, which are used in positron emission tomography (PET). The F-18 radionuclide emits a positron, which is the antiparticle counterpart to an electron. As the positron is emitted within tissue, it soon encounters an electron at which point they both get annihilated, producing two high-energy photons (gamma emission). The emitted photons are detected in the PET scanning instrumentation, which frequently also incorporates a simultaneous X-ray CT scan or MRI that can produce 3D images of the body. Upon decay of F-18 the stable isotope O-18 is formed, which has no further radio-emission characteristics.

The most popular F-18-containing reagent is 2-deoxy-2-[^{18}F]fluoro-D-glucose (abbreviated ^{18}F-FDG) (Figure 1.114). This compound is preferentially taken up by cells undergoing rapid metabolism, such as is

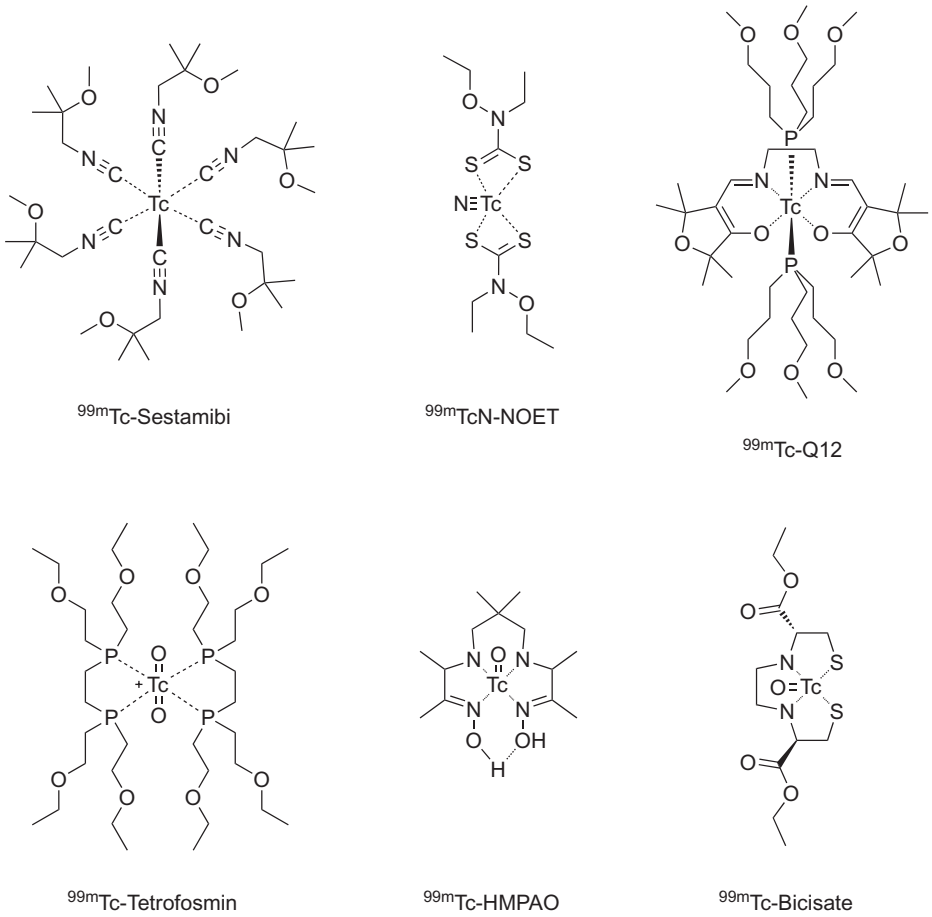

FIGURE 1.113 The major commercial Tc-99m complexes used for radioimaging.

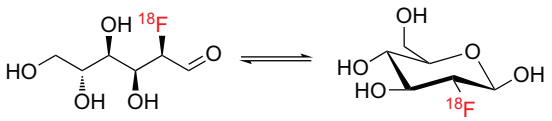

FIGURE 1.114 ^{18}F-labeled deoxy glucose is one of the major radiolabels used in PET imaging.

common in tumor cells. In ^{18}F-FDG, the 2-hydroxyl group normally present in glucose is missing; thus, once it enters a cell, it cannot enter the glycolysis pathway. Within the cell, however, it does get phosphorylated at its carbon-6 position, which prevents it from leaving the cell. Therefore, once it enters cells undergoing extensive glycolysis, it is trapped there and can be imaged until its positron emission capability decays. Upon decay, the 6-phospho-^{18}F-FDG becomes 6-phospho-^{18}O-FDG, which effectively transforms the molecule into glucose-6-phosphate containing the stable heavy isotope of oxygen, wherein it then gets metabolized normally within the cell without toxic effects.

Other conjugates of F-18 are being investigated for PET imaging purposes. Vandenberghe *et al*. (2010) reported on a phase two clinical trial involving an F-18 modified flutemetamol probe being developed by GE Healthcare. This compound is a thioflavin derivative of a previous C-11 isotopic probe of Aβ amyloidosis plaques (called ^{11}C-Pittsburgh compound B [PiB]), which is an important indicator of Alzheimer's disease (Rabinovici *et al*., 2007; Nelissen *et al*., 2009). The C-11 probe required more expensive processes for preparation of the unstable isotope, but the newer ^{18}F-flutemetamol is more widely available and can be used with any PET imaging instruments.

Another F-18 affinity probe has been developed to image tumors containing upregulated $\alpha_v\beta_3$ integrin receptors. This conjugate consists of an F-18 modified galactose group attached to the common integrin ligand recognition sequence Arg-Gly-Asp (RGD) (Haubner *et al*., 2004). The ^{18}F-galacto-RGD affinity probe binds to rapidly dividing cells, such as those involved in angiogenesis and metastasis (Beer *et al*., 2007) (Figure 1.115). Similar probes having enhanced *in vivo* characteristics were prepared using a dimeric RGD binding site

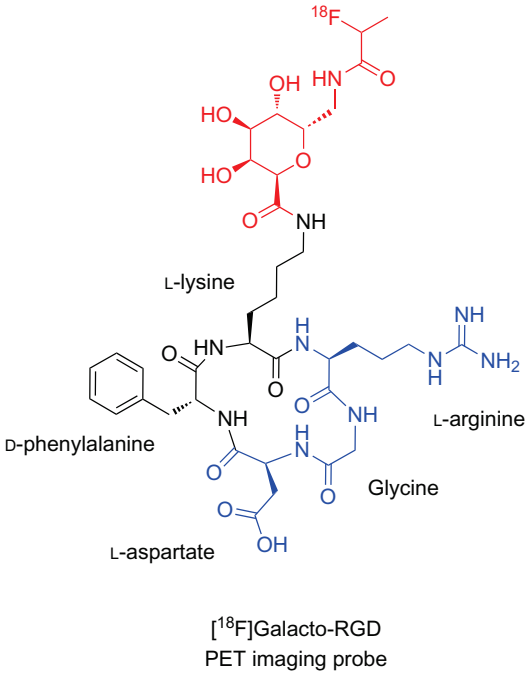

FIGURE 1.115 A targeted PET imaging probe has been constructed by conjugating ^{18}F-galactose (red) to a cyclic peptide containing the amino acid sequence RGD (blue), which binds specifically to integrin receptors.

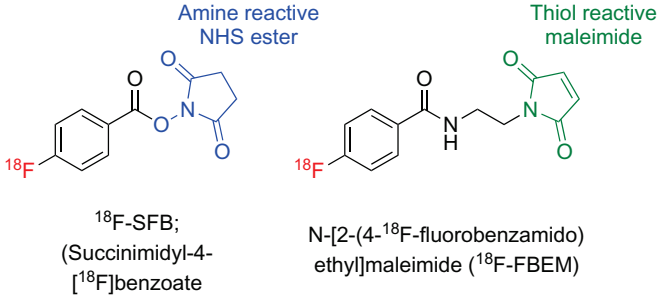

FIGURE 1.116 Labeling reagents have been made that allow the addition of ^{18}F groups to targeting molecules, such as antibodies, for *in vivo* PET imaging applications. The compounds react with amines using an NHS ester group (l) or with thiols using a maleimide group (r).

and a PEGylated arm leading to the ^{18}F modification (Cai *et al*., 2005).

Other probe conjugates containing the positron emission isotope F-18 may be constructed for PET imaging by coupling a compound containing the radionuclide to an affinity molecule that can bind *in vivo* to the desired diagnostic target. Cai *et al*. (2006) prepared two modification reagents to add an F-18 label to amine-containing molecules (using an NHS ester) or to thiol-containing molecules (using a maleimide group) (Figure 1.116). De Bruin *et al*. (2005) also reported a maleimide-containing F-18 compound for protein and peptide labeling. These reagents provide flexibility in the design of custom PET imaging probes for diagnostic use. In addition, an F-18 labeled antibody mimic (Affibody) was developed against the epidermal growth factor receptor 2 (HER2) to target cells over-expressing this protein, as is common in some breast and lung tumors. Affibody can be used in PET imaging and for imaging guided surgical techniques (Kramer-Marek *et al*., 2008). The bioconjugate probe was prepared by reacting the modification reagent N-[2-(4-[^{18}F]fluorobenzamido)ethyl]maleimide with a thiol-modified anti-HER2 Affibody.

Nanoparticles labeled with multiple F-18 isotopes have also been used in bioconjugates with a targeting agent for *in vivo* PET imaging (Devaraj *et al*., 2009). The particle was constructed from a superparamagnetic core that was coated with dextran and labeled with F-18 using short PEG spacer arms with terminal azido groups for a click chemistry-based reaction scheme. The probe could be used for PET imaging with 200 times greater sensitivity than MRI imaging with iron oxide nanoparticles alone.

There have also been reports on the development of F-18 labeling reagents for the modification of oligonucleotide probes for *in vivo* imaging. Kuhnast *et al*. (2003, 2004) reported the synthesis of a bromoacetamide reactive group on two types of ^{18}F-tagged small organic reagents for labeling DNA by alkylation. In addition, Mercier *et al*. (2011) used a click chemistry-based reaction with an azide and an alkyne (see Chapter 17) to couple an F-18 reagent with an siRNA probe for therapeutic *in vivo* inhibition of protein synthesis with simultaneous PET imaging capability (Figure 1.117).

It has been shown that bioconjugates incorporating any one of the three most popular radionuclides, Y-90, F-18, or I-131, can be imaged using rather inexpensive optical imaging devices (Liu *et al*., 2010), because their photon emission is intense enough to be detected using CCD cameras. The emission wavelengths of these isotopes actually encompass a broad region through the visible and NIR, which is the standard range used for most imaging instruments; therefore, most commercial imagers are suitable for rapid imaging, especially when working with animals for research purposes.

Bioconjugates for High-Contrast Imaging

High-contrast *in vivo* imaging using magnetic resonance imaging (MRI) techniques has become a common way to noninvasively detect pathophysiological abnormalities in individuals with disease or injury. MRI can provide high-definition 3D images of internal structures through the use of a combination of an intense magnetic field and radiofrequency radiation. Images are formed through detection of the energy released from hydrogen atom relaxation in tissue after application of the magnetic field followed by a pulse of radio waves

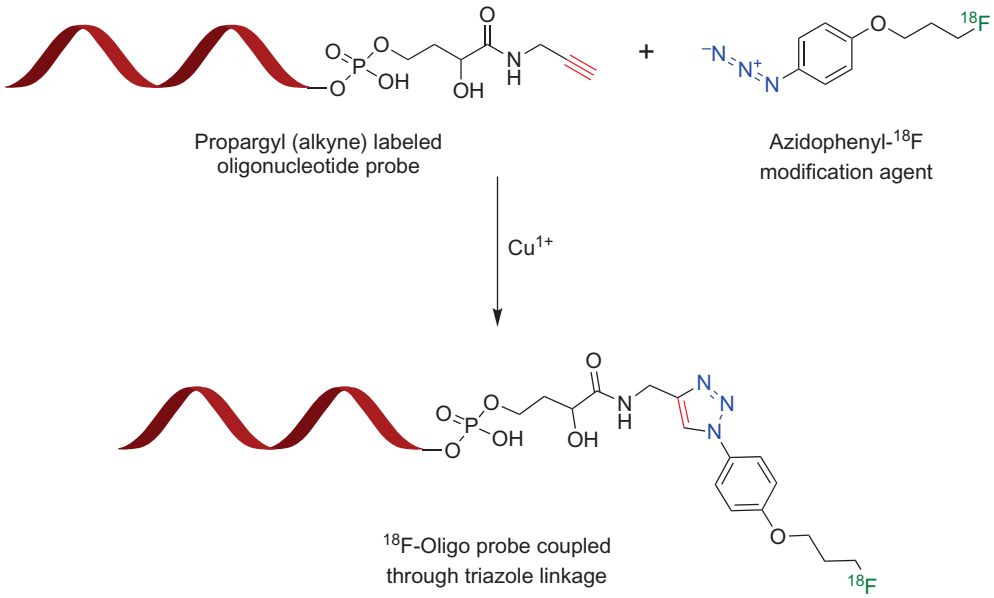

FIGURE 1.117 An azido ^{18}F labeling reagent can be used to modify alkyne-containing molecules using the copper-catalyzed click reaction, which forms a triazole linkage.

tuned to the proper frequency (Sands and Levitin, 2004; Strijkers *et al*., 2007).

Lanthanide contrast agents have been used in MRI procedures to increase the contrast between differences in tissue types and thus improve the images obtained through scans. In particular, chelates of the trivalent, paramagnetic gadolinium or dysprosium ions have been developed for use with or without conjugated targeting agents to aid in the production of high-resolution images (Rocklage and Watson, 1993). The chemistry of the lanthanide metals, including gadolinium, and their complexes with caged bifunctional chelating agents such as DOTA have recently been reviewed (Sherry *et al*., 2009).

At the time of writing, there are nine gadolinium-based contrast agents (GBCAs) approved for diagnostic use in the United States and Europe. All of these agents are low- molecular-weight constructs containing a single gadolinium ion coordinated in the core of an organic chelate. Products such as Magnevist and Omniscan consist of a linear chelating molecule built from a DTPA derivative (Chapter 12, Section 1.1), while the product ProHance is a DOTA derivative having a cyclic caged structure to coordinate the metal ion (Chapter 12, Section 1.2).

Bioconjugates of GBCAs with targeting molecules have also been developed to form enhanced delivery agents able to target disease *in vivo* with high specificity toward a particular tissue or cell or to have greater half-life in circulation. One simple conjugate consists of a GBCA–albumin complex that, once injected IV, functions to maintain greater circulating drug half-life to better image fine vasculature (Niemi *et al*., 1991). This conjugate provides a significant increase in half-life over the use of small organic chelating compounds in an unconjugated state. However, other bioconjugate designs have incorporated modified targeting molecules such as monoclonal antibodies to perform enhanced imaging of tumors or other structures *in vivo* (Göhr-Rosenthal *et al*., 1993; Ramakrishnan *et al*., 2008). Figure 1.118 shows the bioconjugation reactions involved in creating the Gd-DTPA-anti-VEGFR2 antibody as described by Jun *et al*. (2010). Chapter 12, Section 1, describes the bioconjugation of suitable reactive chelating compounds with targeting molecules of all types to form specific high-contrast imaging agents that can bind to targeted cells and tissues *in vivo*. Once charged with a lanthanide metal ion such as gadolinium, the resultant conjugate can be used as a MRI contrast agent, which can enhance the detection of diseased cells and other tissue structures.

To increase the sensitivity of MRI even further using contrast agents, polymeric scaffolds have been used to permit greater numbers of chelated gadolinium ions associated with each targeting agent. For instance, Swanson *et al*. (2008) used a G5 PAMAM dendrimer (see Chapter 8) to create a conjugate containing multiple Gd(III)-DOTA chelate groups (>50) in addition to folic acid groups (~4.5) for targeting folate receptors on tumor cells. The resultant bioconjugate was retained in tumor cells and functioned in MRI to give greater relaxivity (more than four times that of the commercial agent Omniscan) and higher contrast sensitivity compared to other Gd chelates that lack the dendritic core.

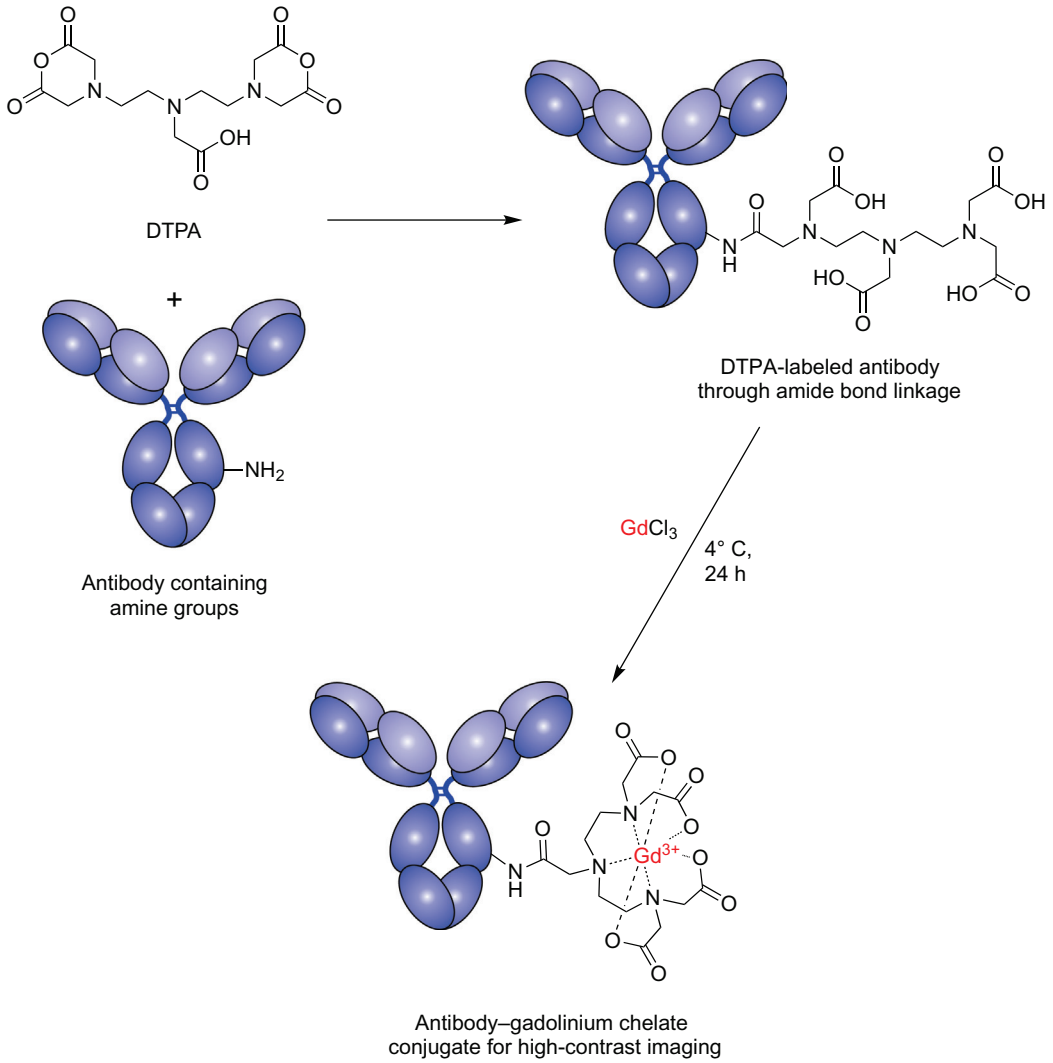

FIGURE 1.118 The chelating compound DTPA can be reacted with the amine groups on antibodies to form an amide bond derivative that is able to bind gadolinium ions useful for high-contrast imaging applications. The conjugate provides targeted delivery of the imaging agent directly to tumor cells *in vivo*.

A similar dendritic contrast agent conjugate was created using a G8 dendrimer with maximal modification of its terminal amines with a DTPA derivative for loading with gadolinium (Kobayashi *et al.*, 2003). The greater size of this G8 dendritic complex compared to the G5 dendrimer used above permitted MRI of the entire lymphatic system in mice to detect various disease states or infections. Thus, the use of a dendrimer-based scaffold can provide increased sensitivity for imaging due to the multivalent nature of the polymer plus it can be modulated for size to permit targeting of the desired organ or cell.

NIR Fluorescent Conjugates for In Vivo Imaging

Diagnostic procedures involving *in vivo* imaging often depend on the creation of a bioconjugate containing a targeting molecule coupled to a detection component, which can be observed from a vantage point outside the body. For instance, the exact location of tumors may be detected using bioconjugates designed to localize highly sensitive imaging agents right at the site of the cancer cells. The majority of *in vivo* imaging is done using PET or MRI with radionuclides or high-contrast agents, respectively (see previous sections). However, one of the latest trends in diagnostic imaging is to make use of fluorescence detection, which can have the advantages of avoiding the use of radioactive substances and extraordinarily expensive instrumentation. In fact, fluorescence-based *in vivo* imaging procedures can make use of relatively portable detection devices that can be used in clinics or even during surgical procedures to image tumors in real time

as operations are taking place (De Grand and Frangioni, 2003; Gioux *et al*., 2005; Troyan *et al*., 2009).

Far-red or NIR fluorescent conjugates can be used to visualize cells directly through skin or tissue (Hilderbrand and Weissleder, 2010). NIR fluorescent dyes attached to antibodies or other targeting molecules can be excited through biological matter, because biomolecules typically have very low absorption potential for light in this unique spectral window between 680 nm and 900 nm (the "biological window"). Any attempt to use fluorescent probes that have lower excitation and emission wavelengths, such as through the UV or visible regions of the spectrum, will encounter severe interference from biomolecules with high absorption characteristics. Naturally absorbing biomolecules include porphyrin-containing proteins, such as the highly abundant protein hemoglobin and the cytochromes, as well as aromatic residues in proteins and small molecules like melanin, lipids, and riboflavin (Figure 1.119). These ubiquitous absorbing components within biosystems are the primary reason why visible light fluorescence imaging cannot work through tissues, consequently restricting light penetration to only a few millimeters at best. In addition, wavelengths of light above about 1000 nm also are not very favorable for *in vivo* imaging, because water and many biomolecules begin to absorb strongly at the higher end of the NIR spectrum (Cheong *et al*., 1990; Chen *et al*., 2004; Khullar *et al*., 2009).

The signals emanating from NIR fluorescent probes conjugated to the appropriate targeting molecules can be combined with imaging technology sensitive to higher wavelengths than visible light and detected through at least several centimeters of tissue *in vivo* (Rao *et al*., 2007). At these wavelengths, the only remaining limitation to tissue penetration is light scattering, which is also minimized at higher wavelengths but still decreases signal with the distance traveled through tissues. Thus, targeted NIR probes can be used to detect the sites of tumors for diagnostic purposes or, using the right bioconjugate designs, they can also be used to detect the activity of certain enzymes indicative of tumorogenesis or apoptotic events.

NIR bioconjugate probes are simpler to use compared to radionuclide probes, because the difficulties encountered in production, safety, and stability of radioisotopes are eliminated through use of simple organic fluorophore labels. Where radiolabeled probes can be dangerous to handle and may be toxic *in vivo*, NIR fluorescent probes typically have low toxicity and require no extraordinary precautions in handling or disposal. Although the high-contrast probes for MRI and the positron emitting probes for PET imaging still are the most widely used detection platforms for *in vivo* applications, the NIR fluorescence field is growing rapidly.

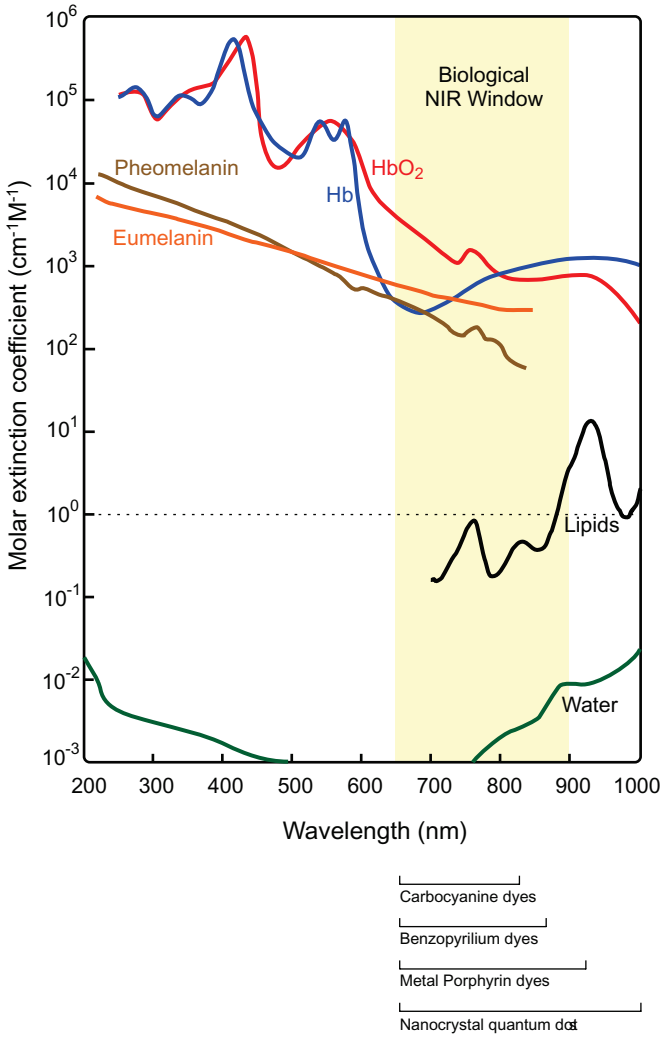

FIGURE 1.119 The biological NIR window in which the absorbance interference due to biomolecules is at a minimum and therefore fluorescent probes can be observed directly through tissues and fluids. *The spectral properties of hemoglobin and water were adapted with permission from Kobayashi, H., Ogawa, M., Alford, R., Choyke, P.L., and Urano, Y. (2010) New strategies for fluorescent probe design in medical diagnostic imaging. Chem. Rev. 110, 2620–2640, figure 1; Copyright 2010, American Chemical Society. The spectral properties of lipids, eumelanin, and pheomelanin were adapted from the Wikipedia page Near-infrared window in biological tissue (http://en.wikipedia.org/wiki/Near-infrared_window_in_biological_tissue; author: Zhun310) and licensed for any use by the Creative Commons Attribution-Share Alike 3.0 Unported license.*

Several strategies can be used to target and fluorescently image biomarkers *in vivo* (Rao *et al*., 2007). In a common targeting design, antibodies or proteins having specific affinity toward a desired protein or biomolecule can be labeled with a NIR fluorescent dye to create the active bioconjugate. In a similar design, antibody fragments, small peptides, or organic ligands having affinity for an active site or receptor binding site on a protein can be used as targeting agents and similarly labeled with a NIR dye. In both of these designs the

imaging bioconjugate is inherently fluorescent and the *in vivo* target becomes progressively labeled with the probe as the complex circulates throughout the cardiovascular system.

In an alternative design approach, probes can be made that are not immediately fluorescent, but generate a NIR signal upon action by a targeted enzyme. For example, probes can be designed to detect specific protease activities *in vivo*, and they function to generate fluorescent signals only upon conversion by the targeted enzyme. In this approach, a short peptide substrate containing an amino acid sequence that is able to be recognized and cleaved by a targeted enzyme *in vivo* is dual labeled with a fluorescent molecule and a quencher to create a FRET (fluorescence resonance energy transfer) signaling agent. The initial probe is dark due to the action of the quencher molecule being held in proximity to the fluorescent molecule—any energy absorbed by the fluor is transferred to the quencher without radiative emission taking place. However, when the peptide is cleaved by the targeted protease, the quenching effect on the probe is relieved as the quencher and fluor are able to diffuse apart, and a fluorescence signal is then generated in the immediate region of the enzymatic activity. Thus, this type of probe is called a peptide molecular beacon, which produces a fluorescent signal in response to the amount of specific protease detected. Regardless of the imaging probe design, the conjugate should be constructed to find its target *in vivo* and create a NIR signal directly at the point of the cells or tissues being monitored. Figure 1.120 illustrates some of the main types of NIR fluorescent probes.

Perhaps the most widely used NIR fluorescence probes are based on carbocyanine dyes that contain either a pentamethine (5-carbon) or heptamethine (7-carbon) bridge. Carbocyanine dyes also typically have aromatic ring structures at both ends of the bridge, which can be of various compositional types (see Chapter 10, Section 8). The most effective dyes for *in vivo* imaging correspond to derivatives of the standard Cy5.5 or Cy7 core structures, which have excitation and emission characteristics within the range of 680 to 900 nm. In addition, the alternative benzopyrillium dyes within the NIR range have also been found successful for imaging applications (Czerney *et al*., 2005) (Figure 1.121). Derivatives of these dyes, such as those containing water-solubilizing sulfonates and amine-reactive NHS esters or thiol-reactive maleimide groups, provide conjugation ability with biomolecules to create targeted *in vivo* NIR probes of many types (Thermo Fisher, Dyomics).

As an alternative NIR platform, quantum dots (QDs) have also been used for *in vivo* imaging purposes in animals. The intense fluorescence and high photostability of QDs are attractive for use in extended imaging applications. Like organic fluorescent probes, they can be designed to have spectral properties in the NIR region, which produces intense fluorescence in the ideal wavelength range for tissue penetration. They can also be conjugated to targeting molecules to provide specific interaction with biomarkers *in vivo*. However, unlike organic fluors, their alloy construction, which uses heavy metals with known toxic properties, has restricted their utility to non-human diagnostic imaging applications (Chapter 10, Section 10).

Bioconjugate targeting complexes containing affinity molecules linked to NIR dyes have been used to image the cardiovascular system, tissue, organs, and cells directly within patients. The types of conjugates that have been created are highly varied depending on the biomarker being targeted. For instance, the short peptide sequence RGD (Arg-Gly-Asp) has been conjugated to a Cy5.5 dye to specifically bind cell surface integrin $\alpha_v\beta_3$ receptors, which are upregulated in many tumors, including glioblastoma (Chen *et al*., 2004) (Figure 1.122). Goldshaid *et al*. (2010) created a multi-purpose *in vivo* imaging conjugate using a cyclic RGD peptide for affinity targeting with a bacteriochlorophyll derivative that displayed photodynamic and fluorescent properties. The probe could be used both to localize breast tumor necrotic domains containing the $\alpha_v\beta_3$ integrin receptors by NIR imaging and to treat them using PDT. Other groups have used multimeric RGD constructs to improve the binding to receptors and increase imaging signals (Cheng *et al*., 2005; Ye *et al*., 2006). Previously, this same small peptide targeting agent was used along with a [^{18}F]galactose label to successfully detect tumors *in vivo* using PET imaging. The ability to use the same targeting component with NIR fluorescence imaging provides a powerful detection scheme, which can be used in situations where PET imaging instrumentation is not available or its use is impractical.

NIR imaging conjugates can also consist of fluorescently labeled antibodies that can target and bind to specific antigens *in vivo*. Bioconjugate probes containing intact IgG-type antibodies are often too large to effectively penetrate cells or the blood brain barrier, but they can be quite useful at targeting surface antigens on cells or tissue structures. The use of antibody fragments, such as recombinant scFv fragments, labeled with NIR dyes can provide bioconjugates small enough in size to access tumor cells throughout the body (Ramjiawan *et al*., 2000). The imaging of xenograft tumors in mice or in tumor cells was carried out using a recombinant Affibody–NIR fluorescent conjugate targeted at epidermal growth factor receptors (EGFRs), which often are dramatically upregulated on the surfaces of cancer cells (Gong *et al*., 2010; Miao *et al*., 2010). The NIR dyes used in these studies consisted of a Cy5.5 molecule, which was a carbocyanine derivative having

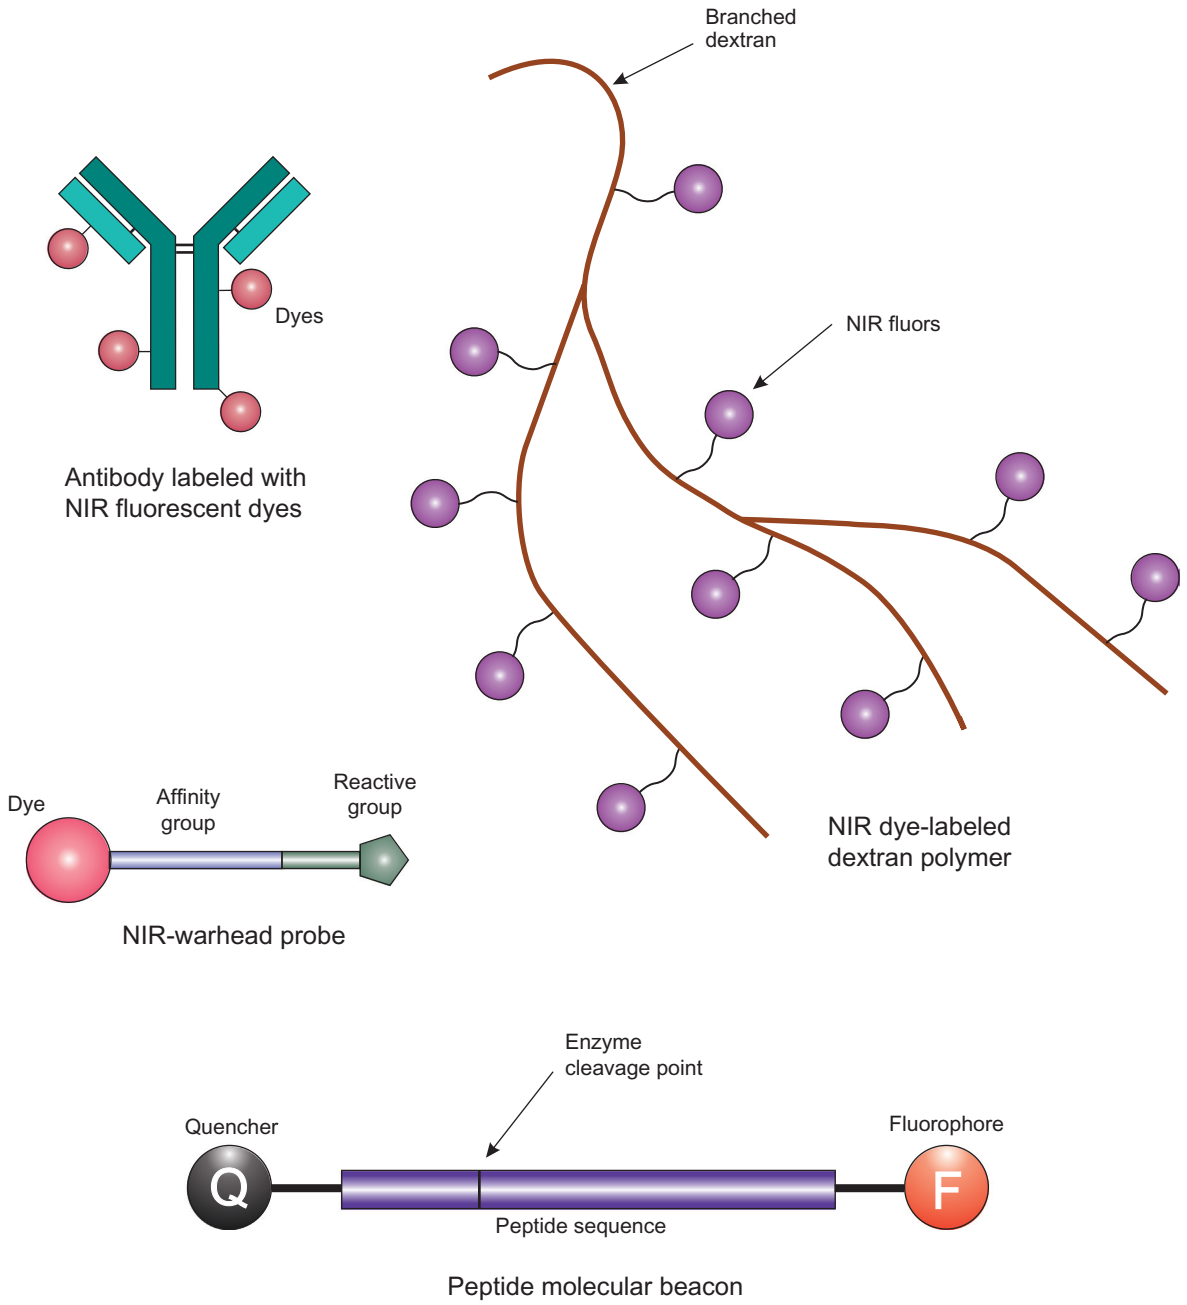

FIGURE 1.120 Probe designs for NIR *in vivo* imaging applications can use a number of conjugate forms. Fluorescent dye-labeled antibodies are perhaps the most common way of targeting an epitope *in vivo*. In addition, polymeric scaffold conjugates have been used to increase the number of dyes delivered to a particular site. NIR warhead probes are used to target an active site on an enzyme while the associated reactive group covalently attaches to a functional group near or within the binding region and the dye provides the detectable fluorescent signal. A molecular beacon probe typically includes two dyes attached to either end of a short peptide that can FRET signal between each other when the peptide is intact. The use of a quencher in this design results in a dark probe upon administration. Once the specific peptide sequence is cleaved by a targeted protease, however, the quencher moves away from the dye and fluorescence is restored.

spectral properties that produced emission near 800 nm (IRDye800CW, LI-COR), well into the region where biomolecule absorption will not interfere with *in vivo* imaging. Monoclonal antibodies have also been conjugated with QDs to successfully target cancer using animal models; however, the large size of nanoparticle conjugates typically limits them to cell surface epitopes, which are more easily accessed by the vascular system (Gao *et al.*, 2004).

Imaging bioconjugates can also be constructed by using antibodies that previously have been validated as therapeutics for targeting specific tumor antigens

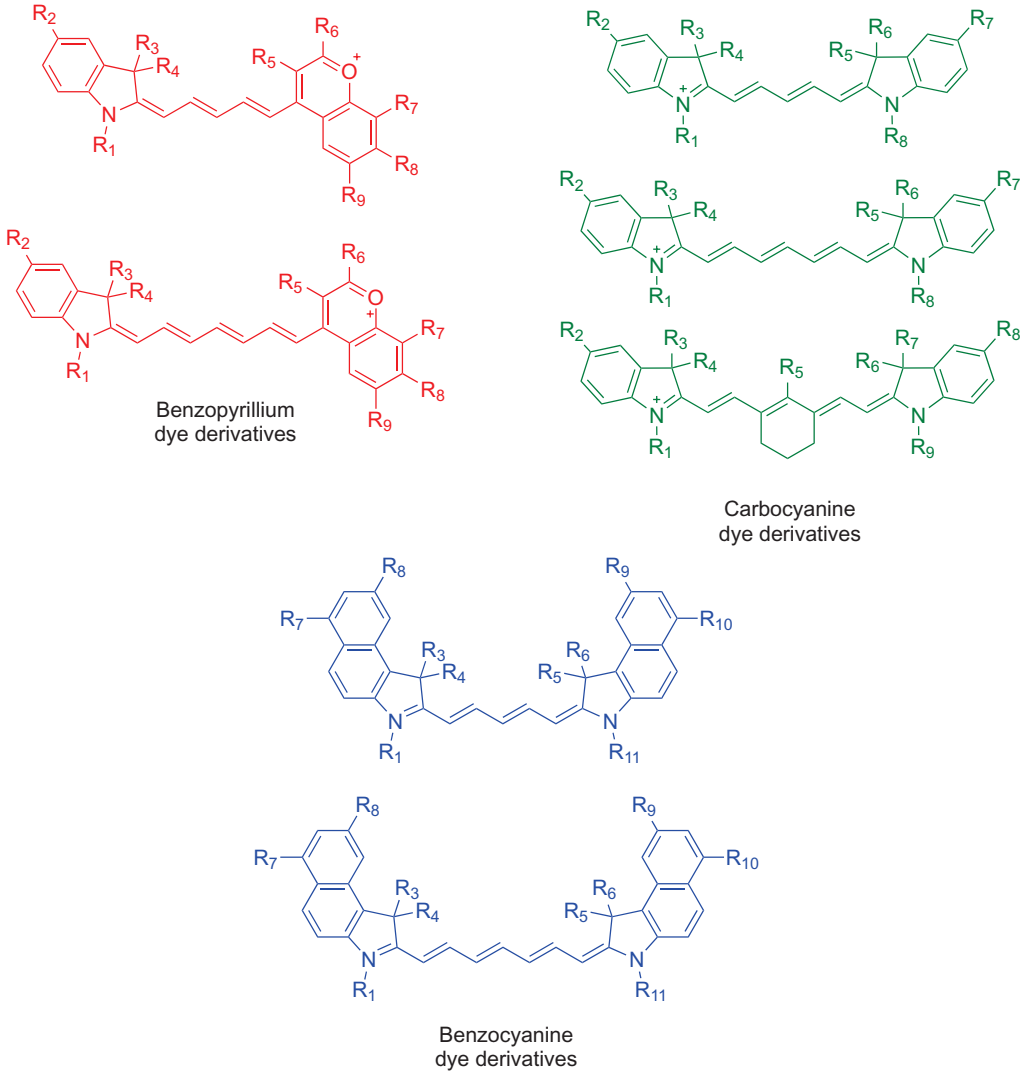

FIGURE 1.121 Some dye types that are commonly used for NIR *in vivo* imaging purposes.

in vivo. For instance, Portnoy *et al*. (2011) reported on the use of a liposome conjugate containing the NIR fluorescent probe indocyanine green with the anti-EGFR antibody Cetuximab. Selective binding of the bioconjugate to colon carcinoma cells that over-express EGFR was used to successfully image the tumor in cell based assays. It was also found that the dye had greater fluorescent signal when associated with the liposome than when using the corresponding dye directly conjugated with the antibody.

Other NIR fluorescent constructs can be designed with quenched dyes and certain peptide sequences to image cells expressing particular proteases. The enzymes are able to cleave the peptide linker, release the quenching on the fluorescent label, and produce a NIR signal within the associated cells (Weissleder *et al*., 1999; Funovics *et al*., 2003; McIntyre *et al*., 2004). Enzyme-activatable, NIR fluorogenic probes are capable of highly sensitive imaging due to the catalytic nature of signal generation upon encounter with the targeted enzyme (Tung, 2004). Unlike the use of affinity targeting probes that bind to an epitope and carry with it fluorescent dyes but produce no additional fluorescent products upon binding, enzyme-sensitive molecular beacon probes continually generate fluorescence in proximity to the protease so long as additional substrate is available (Rao *et al*., 2007). For instance, using this type of conjugate, cells can be detected that produce an abundance of cathepsin enzymes, which are associated with many tumor types (Nomura and Katunuma, 2005). In this case, a cathepsin-specific amino acid sequence is used as the linker in the molecular beacon design, which can get cleaved in the presence of the enzyme.

Alternatively, cells that produce caspases might be imaged using a similar conjugate design but another

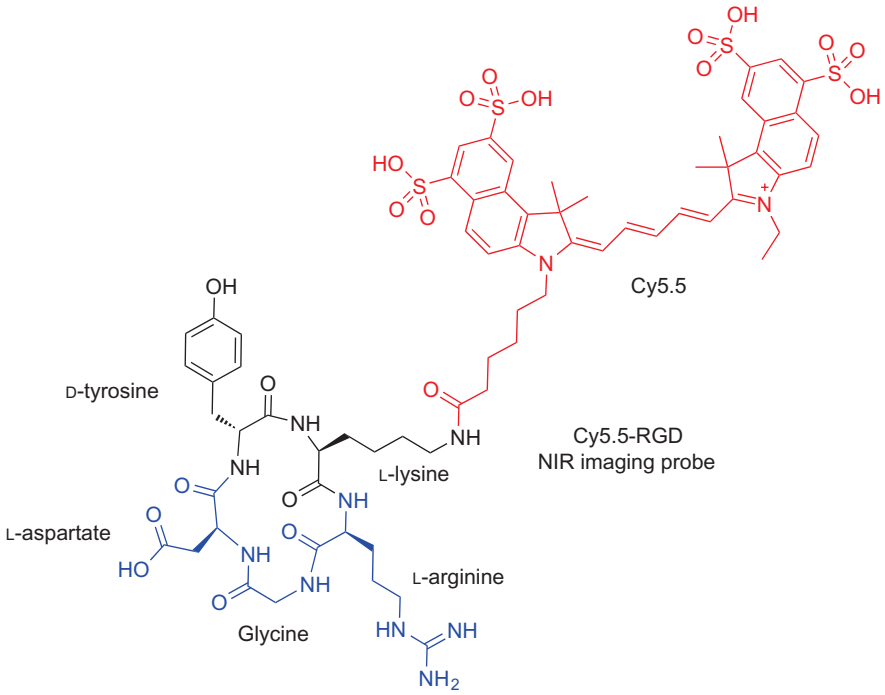

FIGURE 1.122 A conjugate of the integrin binding peptide RGD with the NIR imaging dye Cy5.5 provides a targeted probe for *in vivo*.

amino acid sequence in the core structure, which can then be used as an indicator of apoptosis in cancer cells after a successful treatment regimen (see previous section on FRET peptide probes in this chapter). The design of this type of imaging probe usually consists of a molecular beacon with a fluorescent molecule at one end of the peptide and a quencher molecule on the other side of the cleavage point in the amino acid sequence (Edgington *et al*., 2009; Rai *et al*., 2010) (Figure 1.123). In solution, the probe generates no fluorescence signature, because the quencher molecule is held close enough to the fluor to effectively absorb any of its emission energy. As activated caspases of the apoptotic cascade within a cell cleave the labeled peptide probe, the tether linking the fluor and the quencher is hydrolytically broken and the FRET quenching process no longer occurs. This proteolytic cleavage event generates a fluorescent signal proportional to the amount of caspase enzyme activated in the cell or tissue. The fluorescent signal is thus an indicator of apoptotic cell death and can be used as a sign of a potentially effective tumor treatment by a drug candidate.

A major challenge of small molecular beacon conjugates for use *in vivo*, such as protease probes, is their rapid clearance from circulation, which limits the time available for them to interact with the targeted proteases. Their small size, however, can also be an advantage for being able to penetrate cell membranes and interact with intracellular targets. For extracellular protease detection, such as targeting of matrix metalloproteinases (MMPs), larger poly-amino acid scaffolds or PEG-modified conjugates have been used to increase the probe size and therefore better retain it within the vascular system for longer periods (Bremer *et al*., 2001). In addition, Zhu *et al*. (2011) designed a bioconjugate probe for MMPs that allowed real-time video imaging *in vivo* for up to 24 hours post injection. In the construction of this probe, it was found that modification of the molecular beacon with discrete $mPEG_{12}$ chains resulted in an optimal signal for imaging (Figure 1.124). See Chapter 18 for further discussion on the use and advantages of short, discrete PEG compounds in bioconjugate design.

Carbocyanine dyes have also been used in a quenched FRET probe system without the use of a nonfluorescent absorbing partner as the energy acceptor. Weissleder *et al*. (1999) used a poly-L-lysine polymer that was modified with approximately 92 mPEG molecules along with 11 Cy5.5 NIR fluorescent labels. The mPEG modifications provided increased solubility and *in vivo* stability, thus extending the half-life of the probe in circulation. After modification, the lysine polymer backbone still contained enough unmodified lysines to act as an efficient substrate for proteases. In addition, the high number of Cy5.5 dyes attached to the polymer caused dye–dye interactions resulting in quenching, which caused a 15-fold lowering of fluorescence signal compared to the free dye. Once the poly-lysine

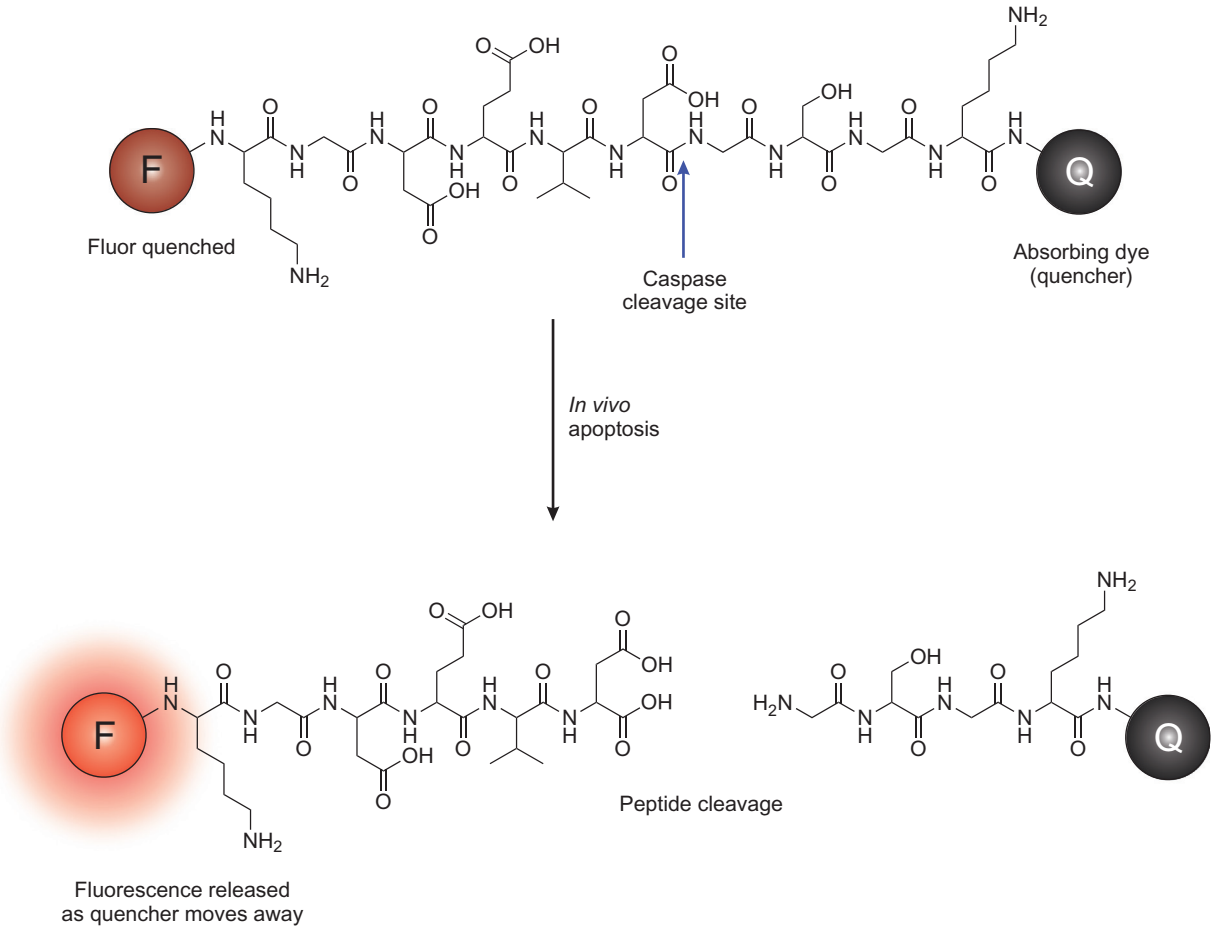

FIGURE 1.123 A molecular beacon probe for caspase enzymes can be constructed from a caspase-specific peptide sequence with a NIR fluorescent dye on one end and a quencher on the other end. When the probe is cleaved in the presence of caspase enzymes the dye will be released and its fluorescent signal restored.

chain was proteolytically cleaved by an enzyme *in vivo*, the probe liberated dye molecules on short peptide segments, which relieved the fluorescence quenching and resulted in an increase in signal at the site of the cells producing the proteases (Figure 1.125) A similar design was used to detect caspase-1 *in vivo* by conjugating the cleavable peptide substrate Gly-Trp-Glu-His-Asp-Gly-Lys containing the NIR fluorescent probe Cy5.5 to a partially PEGylated poly-L-lysine polymer (Messerli *et al*., 2004).

Zhang *et al*. (2009) designed an activatable NIR caspase-3 probe by using two derivatives of a heptamethine carbocyanine dye (Cy7), which could efficiently FRET quench between them and thus only yield a fluorescent signal if enzyme was present. The dyes were linked on the ends of a core DEVD amino acid sequence (Asp-Glu-Val-Asp), which is known to be specific for caspase-3. Upon cleavage of the short peptide, an *in vivo* fluorescence image could be detected using an excitation laser at 785 nm with emission at 805 nm.

In another bioconjugate design for targeting proteases *in vivo*, a specific peptide sequence can be labeled with a fluorescent molecule at one end and also contain a reactive group at the other end. Unlike enzyme activatable probes that catalytically produce a NIR fluorescent signal upon cleavage, these NIR probes are able to bind to the active site of a targeted enzyme and link covalently to a nearby functional group, usually a nucleophile, thus permanently tagging the enzyme with a single fluorescent label (Griffin *et al*., 2007; Cursio *et al*., 2008, 2009; Delgado-Martín *et al*., 2009; Erman *et al*., 2009). The peptide sequence typically used in a covalent probe of this type is an inhibitor of the enzyme active site and not susceptible to cleavage by the enzyme. In addition, this "warhead" probe design must contain a reactive group that does not just indiscriminately couple to other proteins or functional groups present on biomolecules, but only reacts if it is held in proximity to a nucleophile at the targeted enzyme active site.

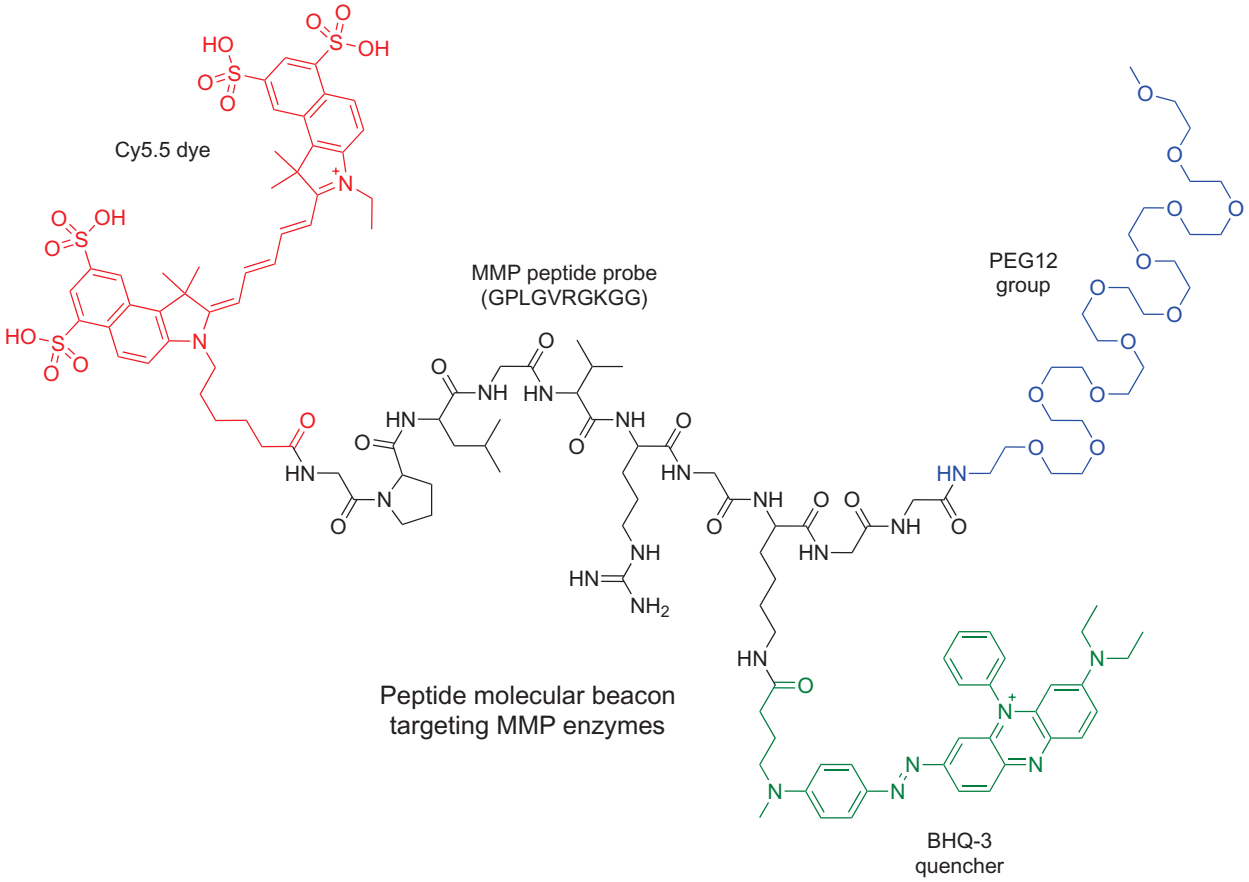

FIGURE 1.124 A conjugate for targeting MMP activity within cells or *in vivo* has been constructed using a peptide sequence combined with the fluorescent dye Cy5.5 and the quencher molecule BHQ-3. Also added to this conjugate was a PEG group to provide water solubility and enhanced life time in circulation *in vivo*.

Warhead NIR probes have been designed to contain reactive groups such as epoxide, fluoromethyl ketone (FMK), chloromethyl ketone (CMK), aldehyde, and difluorophenoxy methyl ketone (OPh) (Blum *et al.*, 2009). Examples of these probes are shown in Figure 1.126. Since the NIR fluorescent label is not quenched in this probe design, excess probe that does not covalently link to the enzyme must be allowed to wash free of the targeted area. For *in vivo* imaging this is done merely by extending the time of interaction for several hours to permit the circulatory system to clear excess probe. For cell-based imaging applications, the cells are washed with buffer to remove excess reagent before imaging the bound probe, which has remained within the cells through covalently linking with the enzyme target.

3.6. Vaccines and Immune Modulation

A conjugate vaccine is a therapeutic agent designed to stimulate the immune system to recognize and attack a potential pathogen invader or a diseased cell. Conjugate vaccines can also be used to generate protective IgG antibodies against allergy-related antigens to prevent the binding of IgE and modulate an allergic reaction. Such immunogen conjugates are an advanced form of the original vaccines that consisted of inactivated or attenuated viruses or bacteria cells, which have been administered to healthy individuals for decades to develop immunity toward many dangerous diseases. Since the very beginnings of this technology with the cholera vaccine in the late 1800s, vaccine therapy has progressed from the use of inactivated whole pathogens to more elaborate designer hapten-carrier immunogen conjugates that build protective immunity using key peptide sequences or other antigenic epitopes from viruses or bacteria. Immunogen conjugates typically consist of a carrier molecule that has a number of haptens linked onto its surface. Methods for the preparation of hapten-carrier immunogen conjugates are described in Chapter 19.

Immunogen conjugates can take on many different forms depending on the type of carrier molecule chosen and the target epitope selected to link to the carrier. The final complex is the immunogen used for immunization

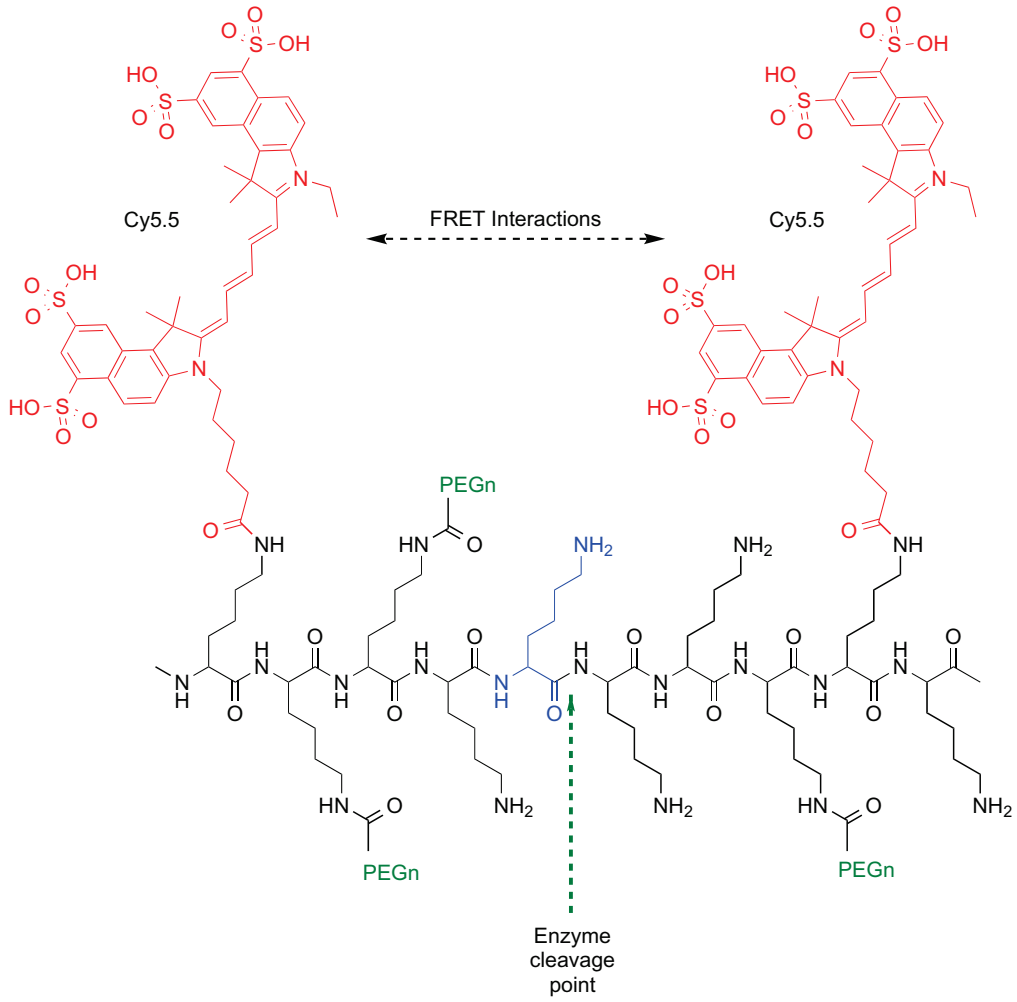

FIGURE 1.125 A FRET quenching molecular beacon style probe can be created by using two fluorescent dyes that are attached very close to each other along the peptide backbone. In this case, the emission from one fluor will be absorbed by the other fluor, thus effectively quenching its fluorescence signature. Once the peptide is cleaved by an enzyme, however, the fluorescent dyes are able to move away from each other to restore fluorescence.

and it usually consists of a large macromolecular core (the "carrier") and a number of small molecule haptens attached to it through various covalent conjugation strategies. Suitable carriers for the attachment of haptens can consist of foreign proteins, synthetic polymers, or lipid micelles that have functional groups or reactive groups on their surface to facilitate a conjugation reaction.

Protein carriers that are commonly used include bovine serum albumin (BSA), keyhole limpet hemocyanin (KLH), thyroglobulin (THY), ovalbumin (OVA), tetanus toxoid, diphtheria toxoid, and tuberculin purified protein derivative (PPD). The two carriers KLH and BSA are widely used for routine immunogen preparation; however, PPD has been found to elicit high titer specificities to coupled antigens with a higher percentage of antigen-specific antibodies being produced from polyclonal or monoclonal production (De Silva *et al.*, 1999).

Synthetic carrier constructs have also been used in the design of conjugate vaccines or immunogens. For instance, a popular peptide-like carrier consists of a polylysine core typically containing three or eight branched amino acids to which peptide haptens may be attached at each pendent side-chain amine group. This design is called the "multiple antigenic peptide" (MAP) system and the final conjugate typically has up to eight copies of peptide antigens attached to each core structure.

The hapten component of a conjugate vaccine is usually much smaller than the carrier and can consist of protein fragments, short peptide sequences, carbohydrates or glycans, or other primary immunogenic portions of a targeted pathogen. Similarly, to prepare immunogen conjugates toward allergens, key epitopes are coupled to the carrier, which are known to elicit strong allergenic responses *in vivo*. In all cases, the carrier molecule is designed to aid in developing an

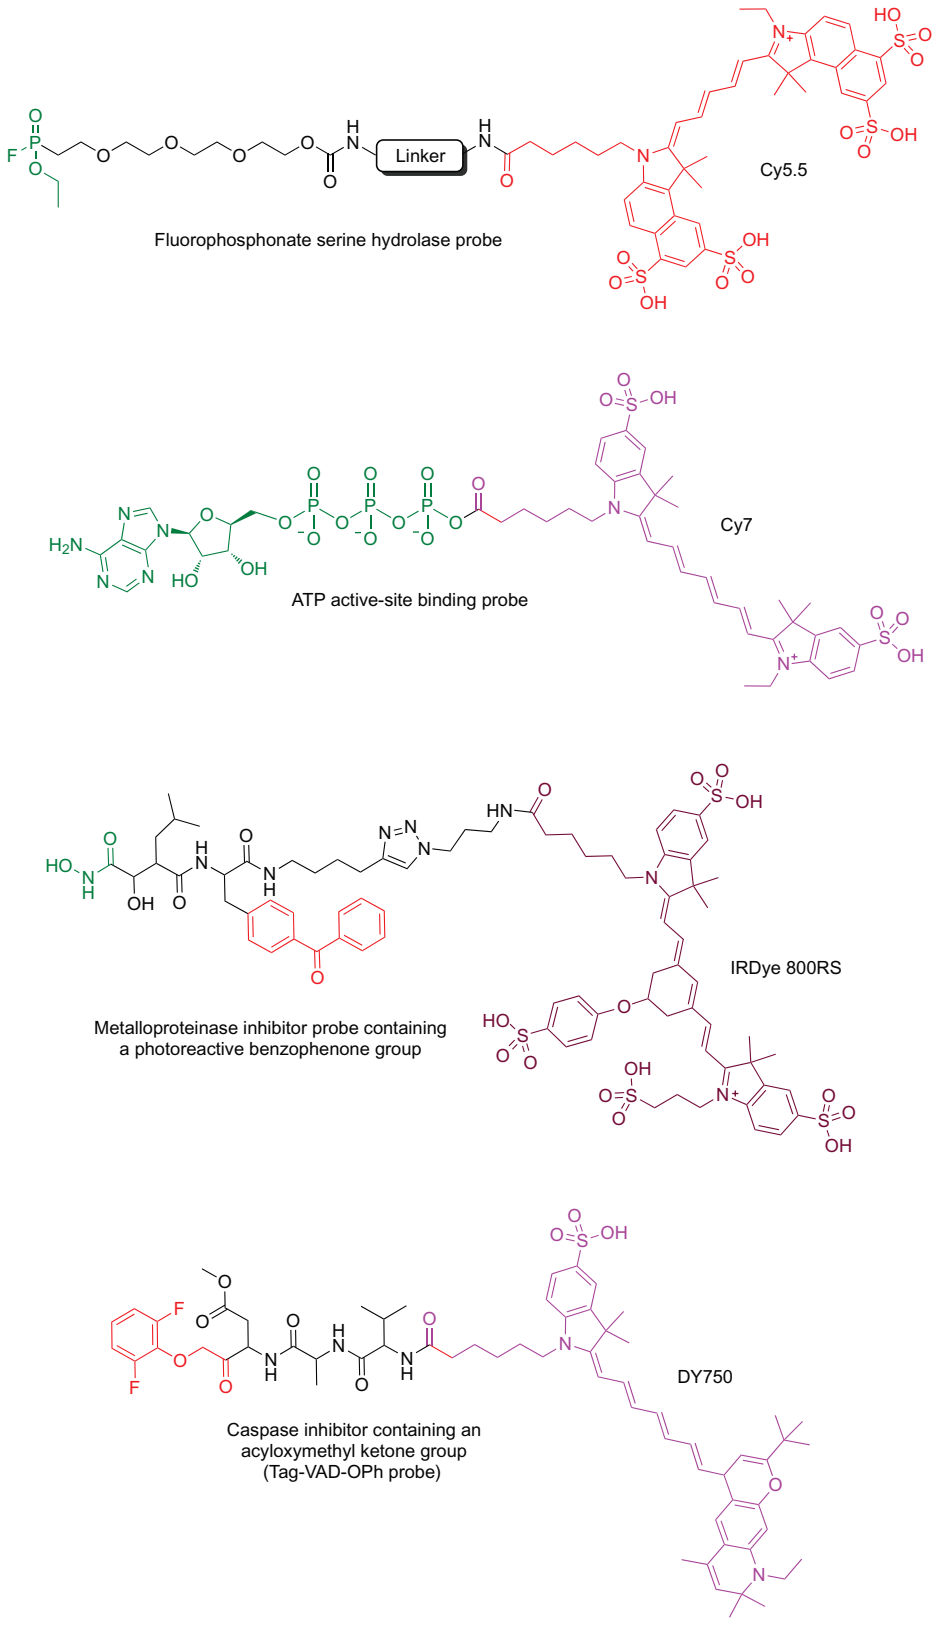

FIGURE 1.126 NIR fluorescent active site probes can be constructed from an affinity warhead type probe containing an affinity group for an active site on a particular enzyme and a reactive group for covalently linking it to the enzyme once bound. The fluorescent dyes used in these conjugates have absorbance and emission properties between about 680 nm and 820 nm, within the NIR window for *in vivo* imaging application.

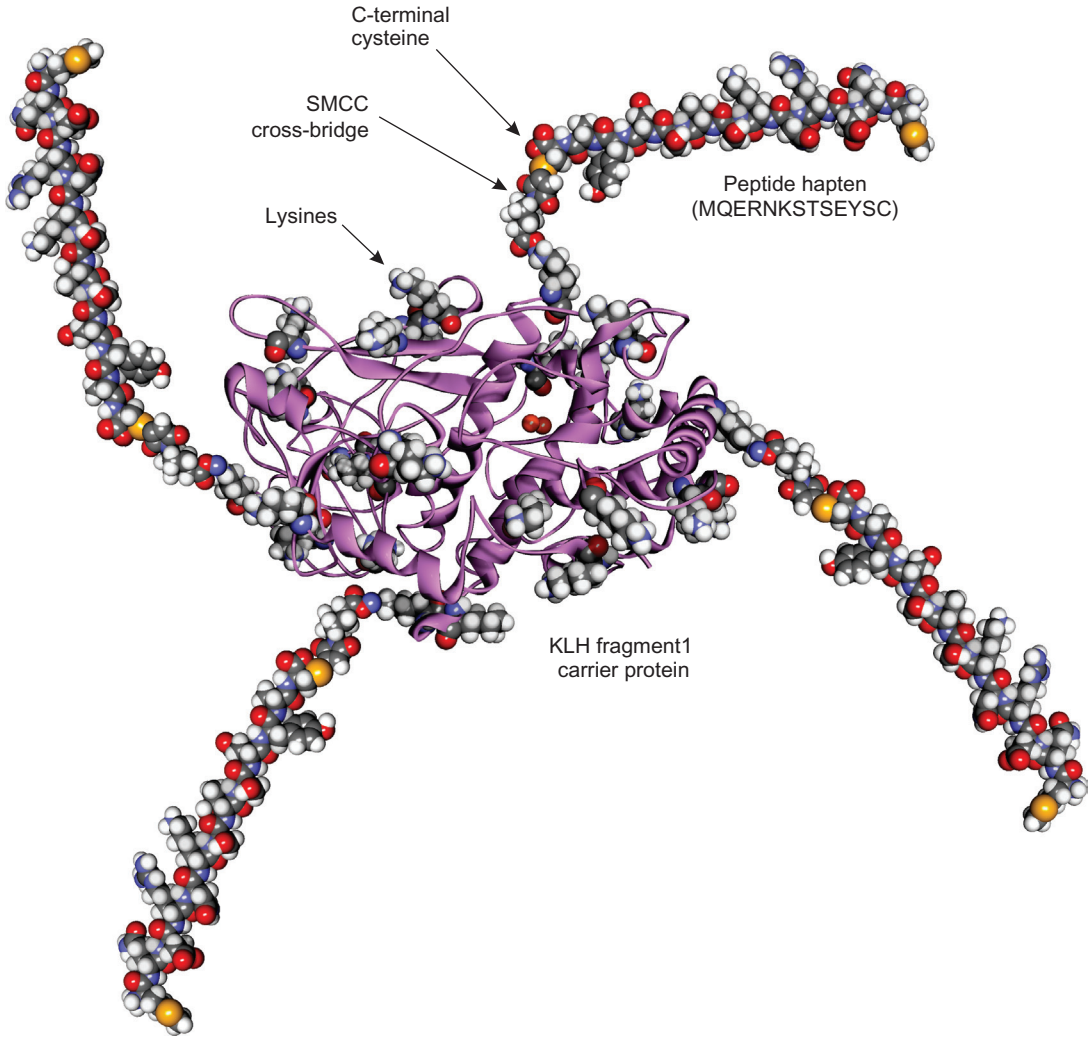

FIGURE 1.127 Vaccine or immunogen conjugates typically are prepared by conjugating a peptide hapten to a carrier protein such as keyhole limpet hemocyanin (KLH), which provides the immunogenicity needed to elicit an immune response to the peptide. Peptides can be synthesized to contain a terminal cysteine thiol group for convenient conjugation using SMCC-activated KLH.

immunogenic response to the bound hapten, whereas separately or alone the hapten would have little or no immunogen response. The basic design of an immunogen conjugate is illustrated in Figure 1.127, which shows peptide haptens coupled to the KLH functional unit 1 carrier protein through SMCC crosslinks.

The research into conjugate vaccines is growing, as the design allows safe and effective therapeutics to be developed without the risks associated with attenuated pathogens or intact allergens. For example, an effective vaccine against *Streptococcus pneumonia* bacteria was developed using the most common strains of the pathogen observed in the United States but instead of using all the different strains in the form of intact bacteria and attenuating them into a mixed cocktail, the key bacteria capsule polysaccharides were isolated and coupled to a nontoxic recombinant mutant of diphtheria toxin, CRM_{197}. The unique carbohydrates were conjugated to the amines on the carrier protein through reductive amination using their reducing ends to form the final immunogen complexes (Chapter 19, Section 8). These polysaccharide immunogen conjugates were then mixed to create the final vaccine, which in its various forms contains the carbohydrate molecules from 7, 10, 13, or 23 different bacteria strains. This type of conjugate vaccine was developed and marketed by a number of companies, including Wyeth Lederle Vaccines, Pfizer, and GlaxoSmithKline under the trademarks PCV7, PPV23, Prevnar, Synflorix, or Prevnar 13. The efficacy and safety of these conjugate vaccines were reviewed by DeStefano *et al*. (2008).

The first instance of a conjugate vaccine developed using the capsular polysaccharides of a bacterium was against *Haemophilus influenza* type b, which proved

to be very successful, especially in young children (Peltola, 2000). This approach to vaccine development was extended to other bacterial pathogens, including those approved to prevent meningococcal disease (Maiden and Spratt, 1999; Miller *et al*., 2001; Mueller *et al*., 2006; Trotter and Ramsay, 2007). There are many polysaccharide-encapsulated pathogens that might be successfully prevented using immunogen conjugates consisting of protein–carbohydrate immunogens. The theory of how these conjugate vaccines work effectively is that the polysaccharide chain is able to interact with multiple B-cell receptors on the immune cell surface, thus crosslinking the receptors and stimulating the production of immunoglobulins and memory B cells (Pollard *et al*., 2009). A direct comparison of the protein conjugate vaccine *versus* the use of free polysaccharide vaccine demonstrated the superior results of the conjugate vaccine in chronic obstructive pulmonary disease (Dransfield *et al*., 2009).

The latest development in the use of conjugate vaccines for the prevention of infections is the use of combination vaccines to treat and prevent two or more different bacterial infectious agents simultaneously. For instance, a combination investigational vaccine was created through pooling of two polysaccharide–tetanus toxoid conjugates made from the polysaccharides of *Haemophilus influenza* type b and *Neisseria meningitides* serogroups C and Y (Nolan *et al*., 2011). The results of a clinical study showed that the combination vaccine worked equally well compared to the use of separate conjugate vaccines. Thus, there may be significant potential to create a pan-bacteria vaccine using bioconjugate techniques to produce effective immunogen conjugates.

Cancer Vaccines

Another area where conjugate vaccines are beginning to find use is in the development of vaccines to prevent or treat certain cancers. Cancer immunotherapy provides a powerful alternative to the commonly used treatments including surgery, radiotherapy, and chemotherapy. If the immune system can be activated against certain tumor specific biomarkers that are not normally present on cells or tissues, it may be possible to provoke an innate immune response consisting of antibodies and lymphoid cells acting in concert to destroy the tumor (Chaudhuri *et al*., 2009). It is known that the immune system has a potent ability to rapidly destroy tissue when activated. For instance, acute transplant rejection due to a mismatch of human leukocyte antigen (HLA) on a xenograft organ can occur within hours and result in total tissue destruction (Frohn *et al*., 2001). The use of conjugate vaccines to target cancer is an active area of research to get the immune system to similarly react to the presence of tumor tissue.

There are at least three ways in which research into cancer vaccines is being applied: as a prophylactic to prevent the development of future tumor types (known as cancer preventive vaccines); as a vaccine to prevent infections by certain cancer-causing viruses (also a cancer preventative); or as a treatment to stimulate the immune system to respond to existing tumors (known as cancer treatment vaccines) (Giarelli, 2007). Effective vaccine therapy against cancer is greatly dependent upon the cellular immune response to unique tumor antigens, primarily on tumor cell surfaces. Changes in cancerous cells with respect to proteins displayed on outer membrane surfaces or changes in post-translational modifications on cell surfaces, particularly glycans, can result in the appearance of tumor-specific biomarkers, which can be used in designing effective immunotherapy (Pashov *et al*., 2010).

Tumor-specific biomarkers have been used in active immunotherapy to stimulate a patient's own natural immune system to respond to the presence of tumor cells. The goal of such treatment is to induce the formation of an initial immune response combined with immunological memory to continue the attack upon cancer cells beyond the time frame of the treatment regimen. The ideal treatment with cancer vaccines will continue to protect against tumor recurrence without the need for additional treatment (Gulley *et al*., 2007; Kipp and McNeel, 2007; Marrari *et al*., 2007; Rescigno *et al*., 2007).

Using this approach, conjugate vaccines have been developed to prevent or treat cancers using tumor-specific epitopes in the conjugate vaccine design. In this case, a biomarker characteristic of a tumor type is used to make an immunogen complex to stimulate the immune system to recognize the cancer cells as danger and attack them. The first cancer vaccine of this design was approved by the FDA in April of 2010 and is manufactured by Dendreon under the name Provenge. The key bioconjugate used in this treatment consists of prostatic acid phosphatase (PAP) covalently linked to the protein granulocyte–macrophage colony-stimulating factor (GM-CSF). The PAP component is a biomarker present on the majority of prostate cancer cells while GM-CSF is able to stimulate the immune system to better display antigens on antigen-presenting cells (APCs). In use, the PAP–GM-CSF conjugate functions as the immunogen in an *ex vivo* treatment of APCs isolated from the blood of the prostate cancer patient (Kipp and McNeel, 2007; Marrari *et al*., 2007; Higano *et al*., 2009; Kantoff *et al*., 2010). It is believed that the mode of action of this conjugate vaccine is that PAP–GM-CSF gets taken up by the APCs during the *ex vivo* procedure and gets processed into small peptides, some of which end up being displayed on the cell surfaces in the binding pocket of the HLA complexes. Once the APCs are

re-administered into the patient, these peptide-HLA complexes are able to interact with receptors on B cells and T cells, thus activating the key components of the immune system to respond with a humoral (antibody) and cellular (T lymphocyte) attack on the prostate tumor cells.

There are a number of other ongoing clinical studies that use *ex vivo* treatment of APCs with a conjugate immunogen in active immunotherapy procedures (Baron-Bodo *et al*., 2005; Goldman and DeFrancesco, 2009). These include the use of the HER2-based immunogen Lapuleucel-T, a fusion conjugate of the HER2/neu antigen linked to GM-CSF, which is designed to treat breast cancer (Park *et al*., 2007; Peethambaram, *et al*., 2009), as well as a vaccinia virus–prostate-specific antigen (PSA) immunogen conjugate to treat metastatic prostate cancer (Kantoff *et al*., 2010).

In addition to unique protein biomarkers on the surfaces of cancer cells, tumors often display aberrant glycosylation patterns on normally glycosylated proteins or glycolipids. It has been observed that some cancer patients develop antibodies to tumor-associated carbohydrate antigens (TACAs), which have actually been associated with longer survival rates among these patients (Vollmers and Brandlein, 2009). It has been speculated that these tumor-specific antibodies keep the cancer somewhat in check even though complete tumor destruction may not be possible simply through a humoral response. Aberrant glycosylation on tumor cells may provide viable epitopes for targeting in cancer immunotherapy just as unique carbohydrates associated with pathogens have been used successfully in the development of conjugate vaccines against various bacteria. Bioconjugation will no doubt contribute heavily to the continued development of these new cancer vaccines.

The National Cancer Institute lists a number of ongoing clinical trials investigating the use of cancer vaccines (*Cancer Vaccines*, NCI Factsheet, U.S. Department of Health and Human Services, August 4, 2010, p. 5). For instance, one of the drug studies involving metastatic melanoma in brain cancer is using a complex between Gp96, a non-polymorphic inducible heat-shock protein (HSP), and antigenic peptides that originate from patient tumor cells. Heat shock proteins are among the most abundant intracellular proteins and they are adept at binding to antigen-presenting cells (Amato, 2008). Purification of Gp96 from tumor biopsies carries along with it the critical peptide epitopes characteristic of the patient's cancer cells. Gp96 is a peptide shuttle protein that can elicit powerful T-cell responses against the tumor peptide epitopes it has bound to it, resulting in protective immunity. Tumor-derived heat-shock protein–peptide complexes (HSPPCs) are examples of noncovalent immunogen complexes having potent anti-tumor characteristics, which can be used against many tumor types (Tosti *et al*., 2009; Eton *et al*., 2010). The clinical trial using HSPPC-96 utilizes a conjugate vaccine called Vitespen (formerly Oncophage) that could end up being the first of many autologous vaccines, which are derived from tumor biopsies of individual cancer patients.

Another route to preventing cancer through vaccines is to target certain viruses that have been linked to the development of particular types of cancer. Three vaccines have already been introduced that prevent viral infections that are known to lead to cancer in certain instances. Human papillomavirus (HPV) conjugate vaccine has been introduced by two companies, Merck and GlaxoSmithKline, under the drug names Gardasil and Cervarix, respectively. Both vaccines consist of a multi-protein complex that contains virus coat proteins made recombinantly and self-assembled into virus-like particles (VLPs). These complexes are non-covalently held together by protein–protein interactions, which naturally take place when virus particles are assembled *in vivo*. However, VLPs are non-pathogenic since they do not contain any genetic information, just the outer envelope or capsid structural proteins. VLP complexes are strongly immunogenic and elicit excellent T-cell and B-cell immune responses in immunized patients (Chackerian and Schiller, 2012).

A third virus preventative vaccine was introduced in 1981 against hepatitis B virus (HBV), which aids in the prevention of hepatocellular carcinoma, which is a type of liver cancer (Chang *et al*., 1997). The initial vaccine consisted of inactivated virus, but it was replaced in 1986 with a recombinant form consisting of the hepatitis B surface antigen (HBsAg), which is one of the envelope proteins within the virus particle (Merck, Recombivax). The purified HBsAg is crosslinked with formaldehyde, making a large complex that is then used with adjuvant to create the final vaccine.

Other vaccines that have a cancer preventative aspect include hepatitis C virus (for the prevention of hepatocellular carcinoma), Epstein–Barr virus (prevents Burkitt lymphoma, non-Hodgkin lymphoma, Hodgkin lymphoma, and nasopharyngeal carcinoma), human T-cell lymphotropic virus 1 (prevents T-cell leukemia), *Helicobacter pylori* (prevents stomach cancer), schistosomes (a parasite that causes bladder cancer), and liver flukes (a parasite that causes cholangiocarinoma, a type of liver cancer) (obtained from http://www.cancer.gov/cancertopics/factsheet).

Immunogen Conjugates in the Production of Antibodies

Immunogen conjugates have also been used extensively for the production and harvesting of specific antibodies in animals. Generation of polyclonal and

monoclonal antibodies has been carried out using carrier conjugates with short peptide sequences, protein fragments or domains, glycans, carbohydrates, small organic compounds, and other molecules of biological or non-biological origin. Even small neurotransmitters and biogenic amine compounds can be conjugated to suitable carriers to make highly specific antibodies against them (Huisman *et al*., 2009).

The preparation of hapten-carrier conjugates can be carried out through a number of routes (Chapter 19) and the result is an immunogenic complex that can produce a specific antibody response to the coupled hapten within an animal. After immunization, boosting, and harvesting of the antisera, the specific antibody can then be isolated using affinity chromatography techniques and applied toward many different applications in biological targeting and detection (see previous sections, in this chapter; Harlow and Lane, 1988, 1999). The use of immunogen conjugates in the generation of antibodies has been instrumental in the growth of the antibody business for life science research applications to at least $3 billion in annual revenues shared among dozens of antibody producers, while the market for diagnostic antibodies is approximately $10 billion per annum, and the market for therapeutic antibodies is estimated to be at least $53 billion (*Life Science Tools and Reagents: Global Markets*, BCC Research, Wellesley, MA, 2011, p. 74).

Conjugate vaccines for immunization therapy and immunogen conjugates for antibody production both have many advantages. For *in vivo* therapeutic use, conjugate vaccines can be significantly less toxic than the corresponding use of attenuated pathogens. The conjugation of key immunogenic epitopes from a bacteria or virus to a carrier protein entirely avoids the use of whole biological pathogens, which can have unexpected negative effects in patients. In addition, the use of immunogen conjugates to produce antibodies in animals can be carried out using highly specific peptide sequences, polysaccharide sequences, or other small molecule haptens that can generate the desired antibody binding specificity with minimal cross-reactivity toward other epitopes. Antibodies can also be generated to discrete fragments of biological molecules or pathogens that otherwise in their native form would be highly toxic *in vivo*, thus entirely avoiding any animal toxicity side effects.

4. SUMMARY

It is amazing that the field of bioconjugation has affected nearly every technology area, including having significant impact on life science research, diagnostics, therapeutics, organic chemistry, material research, and many other specialized disciplines within the sciences. The ability to produce unique functional conjugates can make possible the creation of a virtually limitless selection of reagents having properties of enormous diversity. The use of such reagents can facilitate quantification, detection, purification, synthesis, imaging, therapy, diagnosis, or almost any other purpose the imagination can conceive.

The chapters of this book are designed to cover the chemistry, reagents, and applications of bioconjugation with a view toward making the techniques understandable and practical. They were assembled and outlined based upon reagent types, common reactions, or by an underlying focus on a particular application or topic. Information is liberally cross-referenced to other areas within the book where the same reactions or similar reagents can be used to make additional bioconjugates for different fields of use. The best way to find all of the available information on a specific reagent, reaction, bioconjugate, or application is to refer to the Table of Contents and the Index. Often, information presented on a topic in one chapter can be supplemented by additional discussion in another chapter; the end result is hopefully to paint a more complete picture of the growing world of bioconjugate techniques.

CHAPTER

2

Functional Targets for Bioconjugation

Modification and conjugation techniques are dependent on two interrelated chemistries: the reactive functionalities present on the various crosslinking or derivatizing reagents and the functional groups present on the target macromolecules to be modified. Without both types of functional groups being available and chemically compatible, the process of derivatization would be impossible. Reactive functionalities on crosslinking reagents, tags, and probes provide the means to specifically label certain target groups on ligands, peptides, proteins, carbohydrates, lipids, synthetic polymers, nucleic acids, and oligonucleotides. Knowledge of the basic mechanisms by which the reactive groups couple to target functionalities provides the means to intelligently design a modification or conjugation strategy. Choosing the correct reagent systems that can react with the chemical groups available on target molecules forms the basis for successful chemical modification.

The process of designing a derivatization scheme that works well in a given application is not as difficult as it may seem at first glance. A basic understanding of about a dozen reactive functionalities that are commonly present on modification and crosslinking reagents combined with knowledge of about half that many functional target groups can provide the minimum skills necessary to plan a successful experiment.

Fortunately, the principal reactive functionalities commonly encountered on bioconjugate reagents are now present on scores of commercially obtainable compounds. The resource that this arsenal of reagents provides can assist in solving almost any conceivable modification or conjugation problem. The following sections describe the predominant targets for these reagent systems. The functionalities discussed are found on virtually every conceivable biological molecule, including amino acids, peptides, proteins, sugars, carbohydrates, polysaccharides, nucleic acids, oligonucleotides, lipids, and complex organic compounds. A careful understanding of target molecule structure and reactivity provides the foundation for the successful use of all of the modification and conjugation techniques discussed in this book.

1. MODIFICATION OF AMINO ACIDS, PEPTIDES, AND PROTEINS

Protein molecules are perhaps the most common targets for modification or conjugation techniques. As the mediators of specific activities and functions within living organisms, proteins can be used *in vitro* and *in vivo* to perform certain tasks. Having enough of a protein that can bind a particular target molecule can result in a way to detect or assay the target providing the protein can be followed or measured. If such a protein does not possess an easily detectable component, it can often be modified to contain a chemical or biological tracer to allow detectability. This type of protein complex can be designed to retain its ability to bind its natural target, while the tracer portion can provide the means to find and measure the location and amount of target molecules.

Detection, assay, tracking, or targeting of biological molecules using the appropriately modified proteins are the main areas of application for modification and conjugation systems. The ability to produce a labeled protein having specificity for another molecule provides the key component for much of biological research, clinical diagnostics, and human therapeutics.

In this section, the structure, function, and reactivity of amino acids, peptides, and proteins will be discussed with the goal of providing a foundation for successful derivatization. The interplay of amino acid functionality and the three-dimensional folding of polypeptide chains will be seen as forming the basis for protein activity. Understanding how the attachment of foreign molecules can affect this tenuous relationship, and thus alter protein function, ultimately will create a rational approach to protein chemistry and modification.

1.1. Protein Structure and Reactivity

Amino Acids

Peptides and proteins are composed of amino acids polymerized together through the formation of peptide (amide) bonds. The peptide-bonded polymer that forms the backbone of polypeptide structure is called the α-chain. The peptide bonds of the α-chain are rigid planar units formed by the reaction of the α-amino group of one amino acid with the α-carboxyl group of another (Figure 2.1). The peptide bond possesses no rotational freedom due to the partial double-bond character of the carbonyl–amino amide bond. The bonds around the α-carbon atom, however, are true single bonds with considerable freedom of movement.

The sequence and properties of the amino acid constituents determine protein structure, reactivity, and function. Each amino acid is composed of an amino group and a carboxyl group bound to a central carbon, termed the α-carbon. Also bound to the α-carbon are a hydrogen atom and a side chain unique to each amino acid (Figure 2.2). There are 20 common amino acids found throughout nature, each containing an identifying side chain of particular chemical structure, charge, hydrogen bonding capability, hydrophilicity (or hydrophobicity), and reactivity. The side chains do not participate in polypeptide formation and are thus free to interact and react with their environment.

Amino acids may be grouped by type depending on the characteristics of their side chains. There are seven amino acids that contain aliphatic side chains, which are relatively nonpolar and hydrophobic: glycine, alanine, valine, leucine, isoleucine, methionine, and proline (Figure 2.3). Glycine is the simplest amino acid, its side chain consisting of only a hydrogen atom. Alanine is next in line, possessing just a single methyl group for its side chain. Valine, leucine, and isoleucine are slightly more complex with three or four carbon branched-chain constituents. Methionine is unique in that it is the only reactive aliphatic amino acid, containing a thioether group at the terminus of its hydrocarbon chain. Proline is actually the only *imino* acid. Its side chain forms a pyrrolidine ring structure with its α-amino group. Thus, it is the only amino acid containing a secondary α-amine. Due to its unique structure, proline often causes severe turns in a polypeptide chain. Proteins rich in proline, such as collagen, have tightly formed structures of high density. Collagen also contains a rare derivative of proline, 4-hydroxyproline, found in only a few other proteins. Proline, however, cannot be accommodated in normal α-helical structures, except at the ends where it may create the turning point for the chain. Poly-proline α-helical structures have been formed, but the structural characteristics of these artificial polypeptides are quite different from native protein helices.

Phenylalanine and tryptophan contain aromatic side chains that, like the aliphatic amino acids, are also relatively nonpolar and hydrophobic (Figure 2.4). Phenylalanine is unreactive toward common derivatizing reagents, whereas the indolyl ring of tryptophan is quite reactive, if accessible. The presence of tryptophan

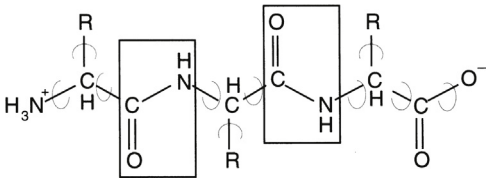

FIGURE 2.1 Rigid peptide bonds link amino acid residues together to form proteins. Other bonds within the polypeptide structure may exhibit considerable freedom of rotation.

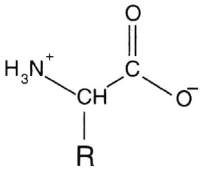

FIGURE 2.2 Individual amino acids consist of a primary (α) amine, a carboxylic acid group, and a unique side-chain structure (R). At physiological pH, the amine is protonated and bears a positive charge, while the carboxylate is ionized and possesses a negative charge.

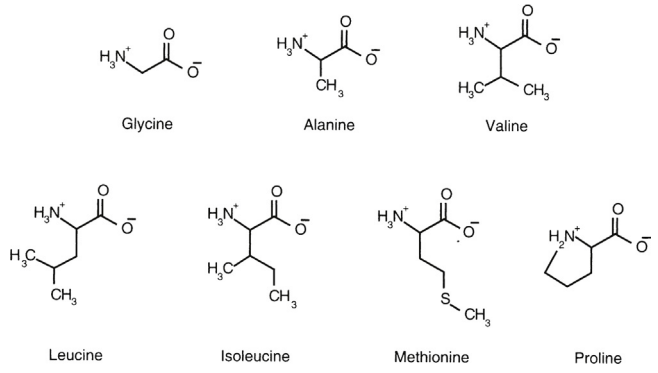

FIGURE 2.3 Common aliphatic amino acids.

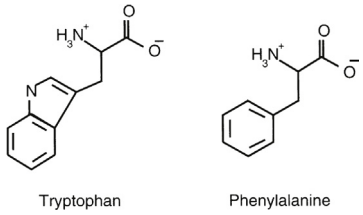

FIGURE 2.4 The two aromatic amino acids that have nonpolar and nonionizable side-chain groups.

in a protein contributes more to its total absorption at 275 to 280 nm on a mole-per-mole basis than any other amino acid. The phenylalanine content, however, adds very little to the overall absorbance in this range.

All of the aliphatic and aromatic hydrophobic residues are often located at the interior of protein molecules or in areas that interact with other nonpolar structures such as lipids. They usually form the hydrophobic core of proteins and are not readily accessible to water or other hydrophilic molecules.

There is another group of amino acids that contains relatively polar constituents and are thus hydrophilic in character. Asparagine, glutamine, threonine, and serine (Figure 2.5) are usually found in hydrophilic regions of a protein molecule, especially at or near the surface where they can be hydrated with the surrounding aqueous environment. Asparagine, threonine, and serine are often found post-translationally modified with carbohydrate in *N*-glycosidic (asp) and *O*-glycosidic linkages (thr and ser). Though these side chains are enzymatically derivatized in nature, the hydroxyl and amide portions have relatively the same nucleophilicity as that of water and are therefore difficult to modify with common reagent systems under aqueous conditions.

The most significant amino acids for modification and conjugation purposes are the ones containing ionizable side chains: aspartic acid, glutamic acid, lysine, arginine, cysteine, histidine, and tyrosine (Figure 2.6). In their unprotonated state, each of these side chains can be potent nucleophiles to engage in addition reactions (see the discussion on nucleophilicity below).

Both aspartic and glutamic acids contain carboxylate groups that have similar ionization properties to the C-terminal α-carboxylate. The theoretical pK_a of the β-carboxyl of aspartic acid (3.7–4.0) and the γ-carboxyl of glutamic acid (4.2–4.5) are somewhat higher than the α-carboxyl groups at the C-terminal of a polypeptide chain (2.1–2.4). At pH values above their pK_a, these groups are generally ionized to negatively charged carboxylates. Thus, at physiological pH, they contribute to the overall negative charge contribution of an intact protein (see following section).

Carboxylate groups in proteins may be derivatized through the use of amide bond-forming agents or through active ester or reactive carbonyl intermediates (Figure 2.7). The carboxylate actually becomes the acylating agent to the modifying group. Amine-containing nucleophiles can couple to an activated carboxylate to give amide derivatives. Hydrazide compounds react similarly to amines. While a thiol group is reactive toward an activated carboxylate and results in a thioester linkage, it forms relatively unstable derivatives, which can exchange with other nucleophiles such as amines or hydrolyze in aqueous solutions.

Lysine, arginine, and histidine have ionizable amine-containing side chains that, along with the N-terminal α-amine, contribute to a protein's overall net positive charge. Lysine contains a straight four-carbon chain terminating in a primary amine group. The ε-amine of lysine differs in pK_1 from the primary α-amines by having a slightly higher ionization point (pK_a of 9.3–9.5 for lysine *versus* pK_a of 7.6–8.0 for α-amines). At pH values lower than the pK_a of these groups, the amines are generally protonated and possess a positive charge. At pH values greater than the pK_a, the

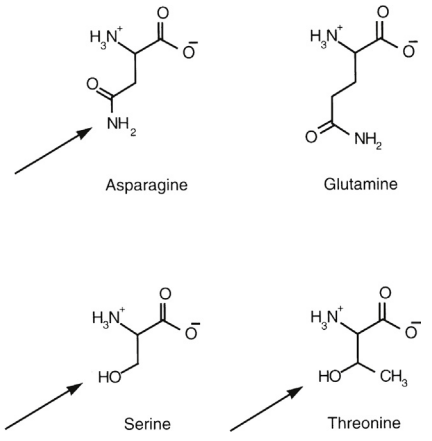

FIGURE 2.5 The four amino acids with polar, uncharged side chains. The arrows show the attachment points for carbohydrate that may be present in post-translational modifications on glycoproteins.

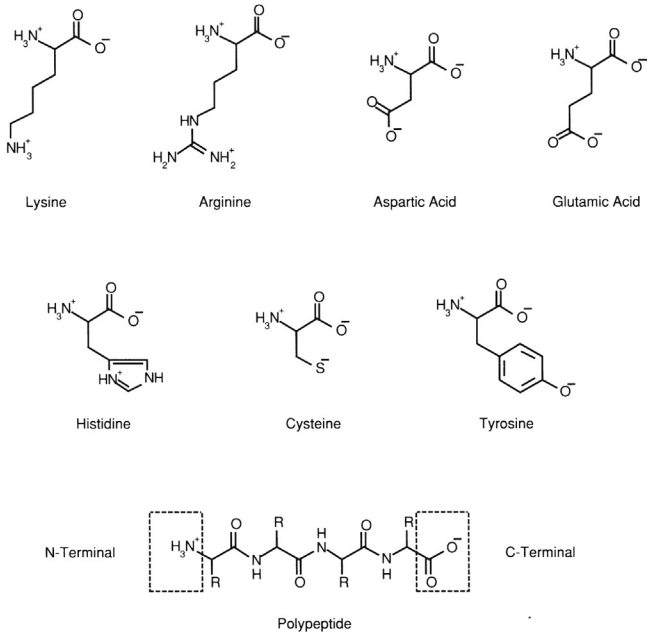

FIGURE 2.6 The amino acids with ionizable side chain groups possess some of the most important functional groups for bioconjugate applications. The C- and N-terminals of each polypeptide chain also are included in this group.

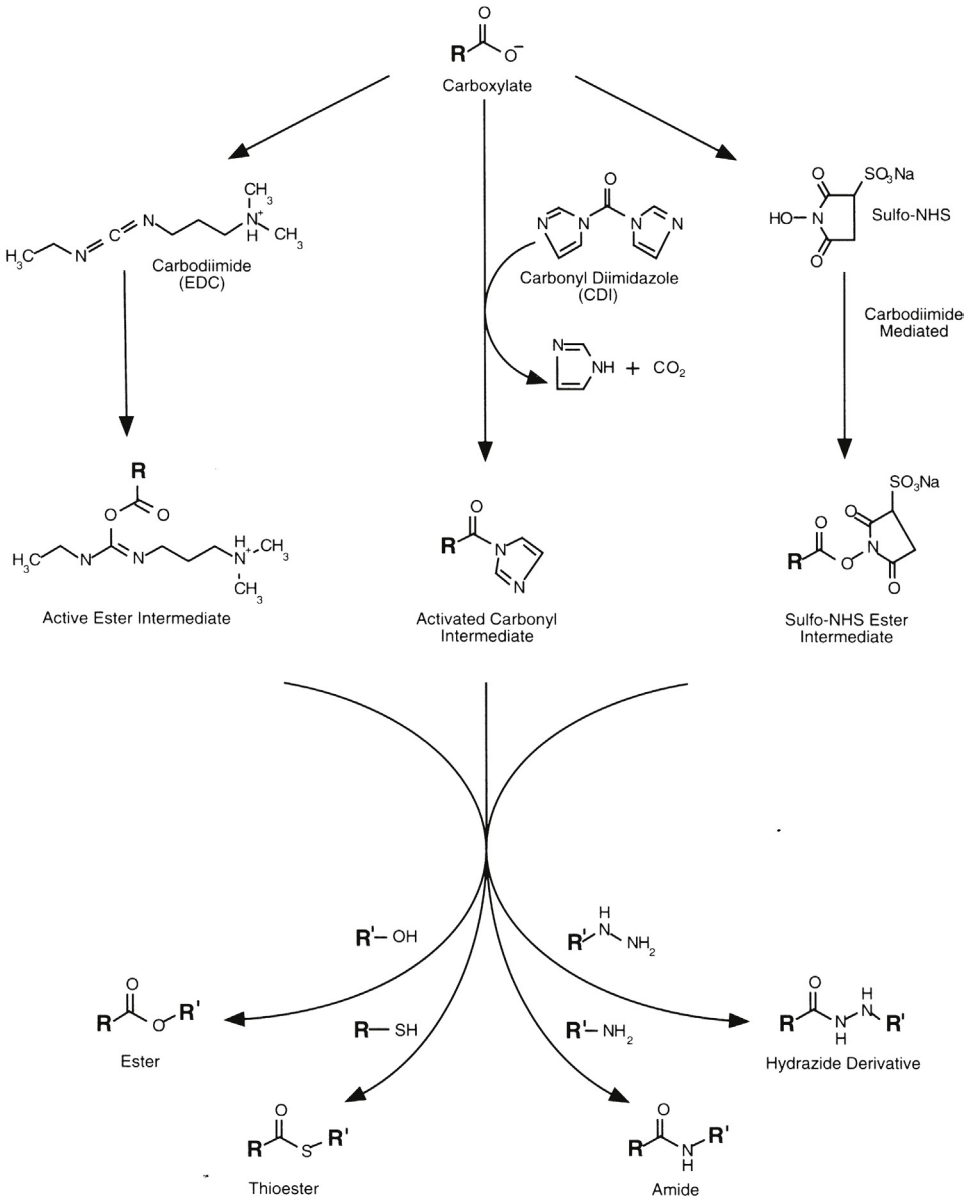

FIGURE 2.7 Derivatives of carboxylic acids can be prepared through the use of active intermediates that react with target functional groups to give acylated products.

amines are unprotonated and contribute no net charge. Arginine contains a strongly basic chemical constituent on its side chain called a guanidino group. The ionization point of this residue is so high ($pK_a > 12.0$) that it is virtually always protonated and carriers a positive charge. The histidine side chain is an imidazole ring that is potentially protonated at slightly acidic pH values ($pK_a = 6.7–7.1$). Thus, at physiological pH, these residues contribute to the overall net positive charge of an intact protein molecule.

The amine-containing side chains in lysine, arginine, and histidine typically are exposed on the surface of proteins and can be derivatized with ease. The most important reactions that can occur with these residues are alkylation and acylation (Figure 2.8). In alkylation, an active alkyl group is transferred to the amine nucleophile with loss of one hydrogen. In acylation, an active carbonyl group undergoes addition to the amine. Alkylating reagents are highly varied and the reaction with an amine nucleophile is difficult to generalize. Acylating reagents, however, usually proceed through a carbonyl addition mechanism as shown in Figure 2.9. The imidazole ring of histidine is also an important reactive species in electrophilic reactions, such as in iodination using radioactive ^{125}I or ^{131}I (Chapter 12, Section 2).

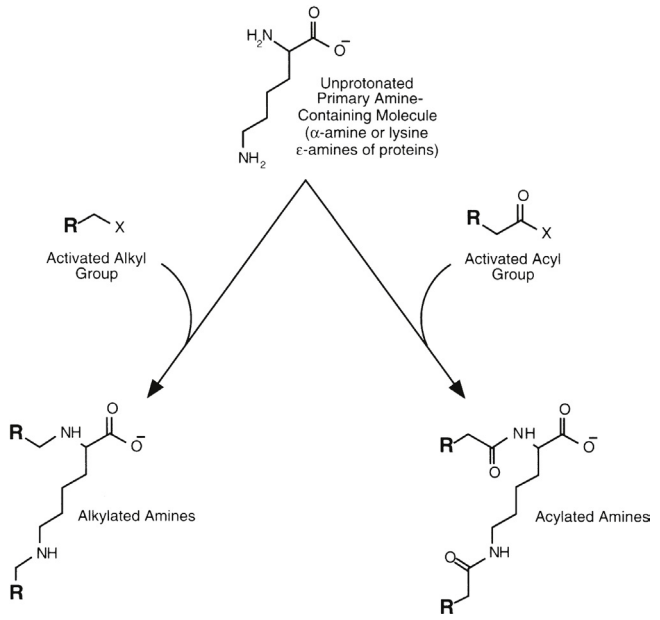

FIGURE 2.8 Derivatives of amines can be prepared from acylating or alkylating agents to give amide, secondary amine, or tertiary amine bonds.

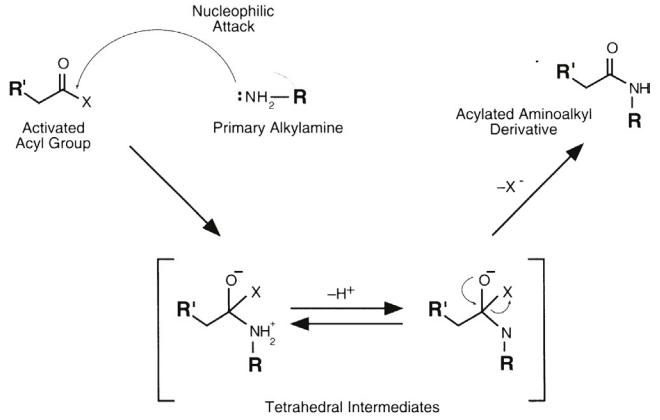

FIGURE 2.9 The mechanism of acylation proceeds through the attack of a nucleophile, generating a tetrahedral intermediate, which then goes on to form the product.

Cysteine is the only amino acid containing a sulfhydryl group. At physiological pH, this residue is normally protonated and possesses no charge. Ionization only occurs at high pH (pK_a = 8.8–9.1) and results in a negatively charged thiolate residue. The most important reaction of cysteine groups in proteins is the formation of disulfide crosslinks with another cysteine molecule. Cysteine disulfides (called cystine residues) are often key points in stabilizing protein structure and conformation. They frequently occur between polypeptide subunits, creating a covalent linkage to hold two chains together. Cysteine and cystine groups are relatively hydrophobic and usually can be found within the core of a protein. For this reason, it is often difficult to fully reduce the disulfides of large proteins without a deforming agent present to open up the inner structure and make them accessible (see Section 4.1).

Cysteine sulfhydryls and cystine disulfides may undergo a variety of reactions, including alkylation to form stable thioether derivatives, acylation to form relatively unstable thioesters, and a number of oxidation and reduction processes (Figure 2.10). Derivatization of the side chain sulfhydryl of cysteine is one of the most important reactions of modification and conjugation techniques for proteins.

Tyrosine contains a phenolic side chain with a pK_a of about 9.7 to 10.1. Due to its aromatic character, tyrosine is second only to tryptophan in contributing to a protein's overall absorptivity at 275 to 280 nm. Although the amino acid is only sparingly soluble in water, the ionizable nature of the phenolic group makes it often appear in hydrophilic regions of a protein—usually at or near the surface. Thus, tyrosine derivatization proceeds without much need for deforming agents to further open protein structure.

Tyrosine may be targeted specifically for modification through its phenolate anion by acylation, through electrophilic reactions such as the addition of iodine or diazonium ions, and by Mannich condensation reactions. The electrophilic substitution reactions on tyrosine's ring all occur at the *ortho* position to the –OH group (Figure 2.11). Most of these reactions proceed effectively only when tyrosine's ring is ionized to the phenolate anion form.

In summary, protein molecules may contain up to nine amino acids that are readily derivatizable at their side chains: aspartic acid, glutamic acid, lysine, arginine, cysteine, histidine, tyrosine, methionine, and tryptophan. These nine residues contain eight principal functionalities with sufficient reactivity for modification reactions: primary amines, carboxylates, sulfhydryls (or disulfides), thioethers, imidazoles, guanidinyl groups, and phenolic and indolyl rings. All of these side-chain functionalities in addition to the N-terminal α-amino and the C-terminal α-carboxylate form the full complement of polypeptide reactivity within proteins (Figure 2.12).

Nucleophilic Reactions and the pI of Amino Acid Side Chains

Ionizable groups within proteins can exist in one of two forms: protonated or unprotonated. Carboxylate groups below their pK_a values exist in the protonated state and are therefore in the conjugate acid form and carry no charge. However, at pH values above the pK_a of the carboxylic group, the acid is ionized and therefore unprotonated to a negative charge. This same relationship is true of the –OH group on the phenol ring of tyrosine. At pH values below its pK_a, tyrosine's side

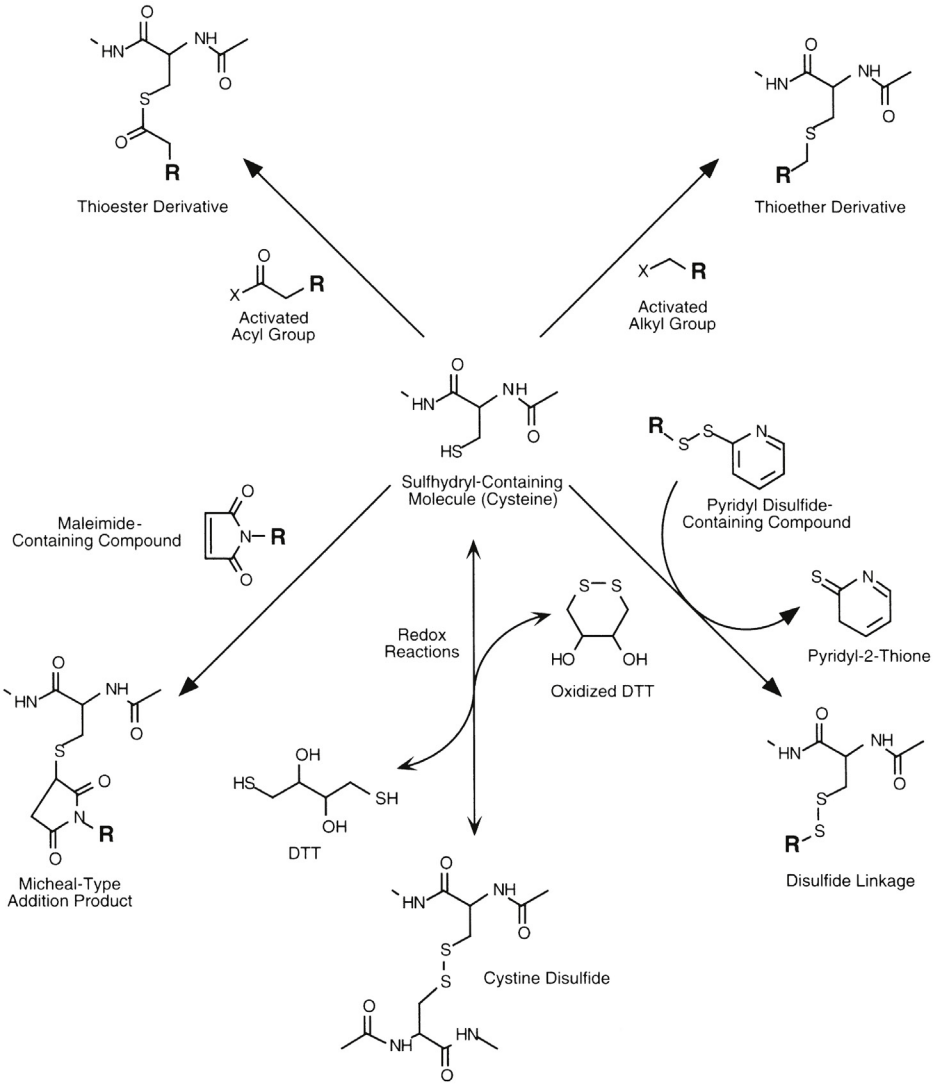

FIGURE 2.10 Sulfhydryl groups may undergo a number of additional reactions, including acylation and alkylation. Thiols also may participate in redox reactions, which generate reversible disulfide linkages.

chain is uncharged. Above the pK_a, however, the hydrogen ionizes off, leaving a negatively charged phenolate. Conversely, amine nucleophiles below their pK_a values are in a protonated state and possess a positive charge. At pH values above the pK_a of the amino group, it is then ionized and unprotonated to neutrality.

Each type of ionizable group in proteins will have a unique pK_a based upon the theoretical value for the amino acid and modulated from that value by its own surrounding microenvironment. Minute environmental changes will cause amine-containing residues at different structural locations to have different ionization potentials, even if the groups are otherwise chemically identical.

Thus, the actual pK_a of each ionizable group within protein molecules may range considerably lower or higher than the theoretical values as the microenvironment of individual groups changes. Identical side chains in differing parts of a protein molecule may have widely varying pK_a values depending on the immediate chemical milieu. Such factors as the presence of other amino acid side chains in the vicinity, salts, buffers, temperature, ionic strength, and other effects of the solvent medium all play crucial roles in creating microenvironmental changes that affect the ionization potential of these groups (Tanford and Hauenstein, 1956; Schewale and Brew, 1982).

The Henderson–Hasselbalch equation (1) explains the relationship of pH and pK_a to the relative ratios of protonated (acid) and unprotonated (base) forms of an ionizable group. Note that the ionized form of such a group does not have to possess a negative charge, as in the case of unprotonated primary amines. Indeed,

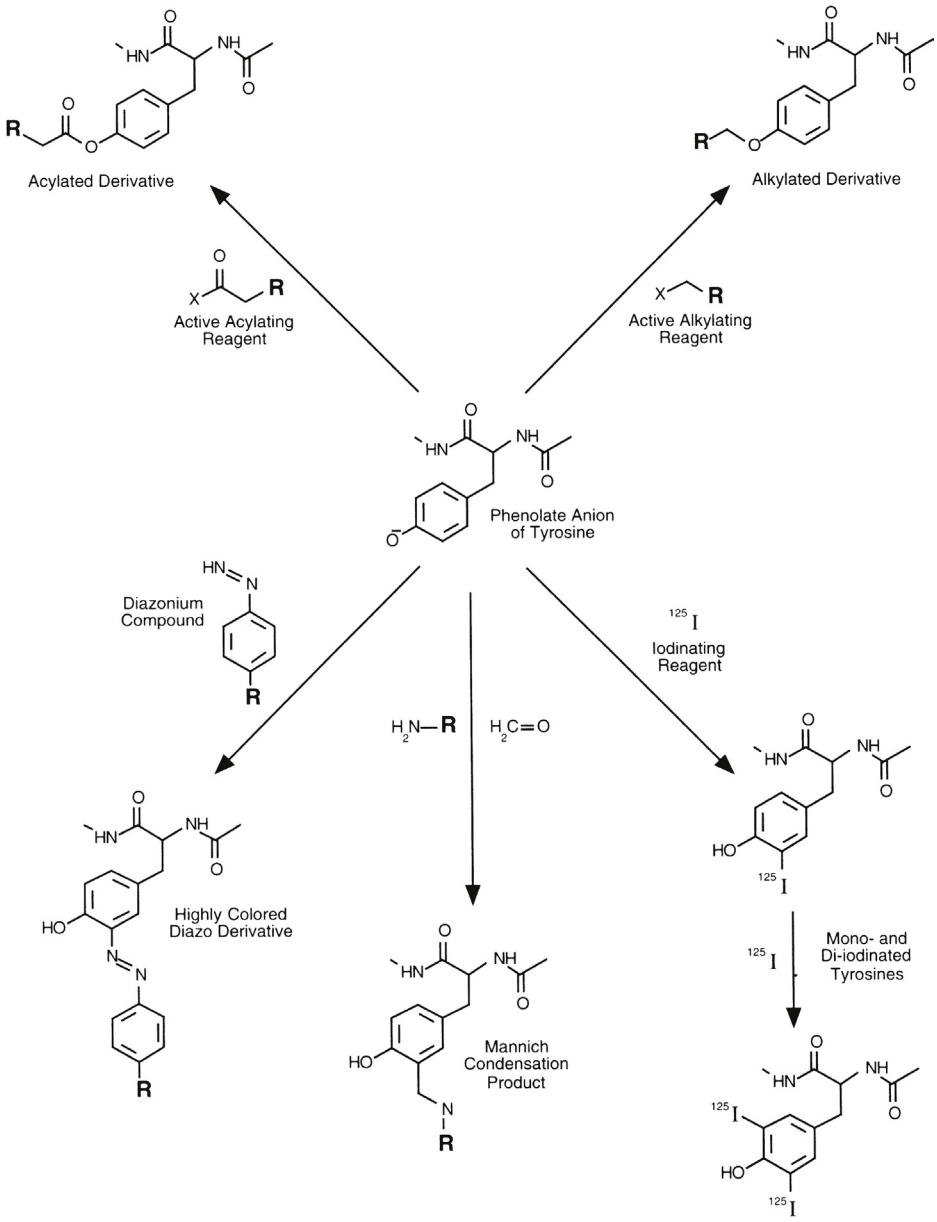

FIGURE 2.11 Tyrosine residues are subject to nucleophilic and electrophilic reactions. The unprotonated phenolate ion may be alkylated or acylated using a variety of bioconjugate reagents. Its aromatic ring also may undergo electrophilic addition using diazonium chemistry or Mannich condensation, or be halogenated with radioactive isotopes such as ^{125}I.

in that instance it is the protonated amine that bears a charge of positive one. According to the mathematical implications of this equation, an ionizable group at its pK_a value is exactly 50% ionized. This means that aspartic acid side chains placed in a medium with a pH equal to its pK_a should have half of its carboxylates ionized to a negative charge and half of them unionized with no charge.

$$pH = pK_a + \log\{[base]/[acid]\} \quad (1)$$

Further implications of this equation are that at one pH unit below or above the pK_a, an ionizable group will be 91% unionized (protonated) or 91% ionized (unprotonated), respectively. Two pH units below or above translate to a 99% unionized or 99% ionized state.

The absolute ratio of protonated : unprotonated forms will change from this theoretical approach based upon the microenvironment each group experiences. The reactivity of amino acid side chains is directly related to them being in an unprotonated or ionized state. Many reactions of modification and conjugation

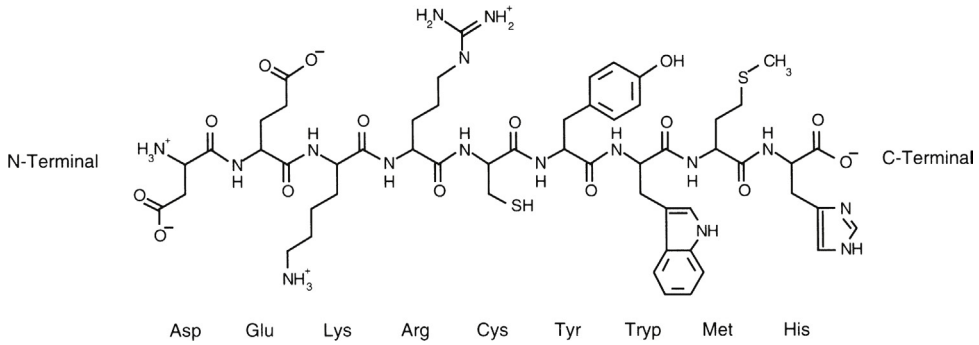

FIGURE 2.12 The more important polypeptide functional groups are represented by these nine amino acids. Bioconjugate chemistry may occur through the C- and N-terminals of each polypeptide chain, the carboxylate groups of aspartic and glutamic acids, the ε-amine of lysine, the guanidino group of arginine, the sulfhydryl group of cysteine, the phenolate ring of tyrosine, the indol ring of tryptophan, the thioether of methionine, and the imidazole ring of histidine.

occur efficiently only when the nucleophilic species is in an ionized form. As the unprotonated form increases in concentration, the relative nucleophilicity of the ionizable group increases. Many of the reactive groups commonly used for protein modification will couple in greater yield as the pH of the reaction is raised closer to the pK_a of the ionizable target. However, continuing to increase the pH beyond the pK_a may not be necessary for increased yield, and may even be detrimental, because many reactive groups will begin to lose activity through hydrolysis at high pHs.

A nucleophile is any atom containing an unshared pair of electrons or an excess of electrons able to participate in covalent bond formation. Nucleophilic attack at an atomic center of electron deficiency or positive charge is the basis for many of the coupling reactions that occur in chemical modification. Thus, an uncharged amine group is a more powerful nucleophile than the protonated form bearing a positive charge. Likewise, a negatively charged carboxylate has greater nucleophilicity than its uncharged, protonated conjugate acid form. In addition, an unprotonated thiolate, bearing a negative charge (RS^-), is a much more powerful nucleophile than its protonated, uncharged sulfhydryl form.

According to the theory of nucleophilicity (Edwards and Pearson, 1962; Bunnett, 1963; Pearson *et al.*, 1968), the relative order of nucleophilicity relative to the major groups in biological molecules can be summarized as follows:

$$R{-}S^- > R{-}SH$$

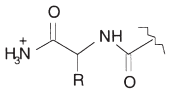
$$R{-}NH_2 > R{-}NH_3^+$$

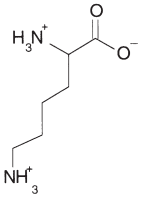
$$R{-}COO^- > R{-}COOH$$

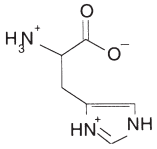
$$R{-}O^- > R{-}OH$$

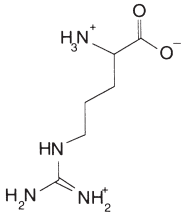
$$R{-}OH = H{-}OH$$

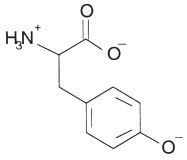
and finally,

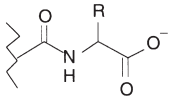


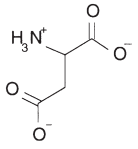


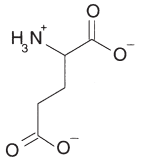


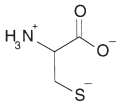












$$R{-}S^- > R{-}NH_2 > R{-}COO^- = R{-}O^-$$

Using these relationships, it is obvious that the strongest nucleophile in protein molecules is the sulfhydryl group of cysteine, particularly in the ionized, thiolate form. Next in line are the amine groups in their uncharged, unprotonated forms, including the α-amines at the N-terminals, the ε-amines of lysine side chains, the secondary amines of histidine imidazolyl groups and tryptophan indole rings, and the guanidino amines of arginine residues. Finally, the least potent nucleophiles are the oxygen-containing ionizable groups including the α-carboxylate at the C-terminal, the β-carboxyl of aspartic acid, the γ-carboxyl of glutamic acid, and the phenolate of tyrosine residues.

According to the theoretical pK_a values for the ionizable side chains of amino acids, nucleophilic substitution reactions involving primary amines or sulfhydryl groups on proteins should not be efficient below a pH of about 8.5 (Table 2.1). In practice, however, reactions can be carried out with these groups in high yield at pH values not much higher than neutrality. This discrepancy relates to the changes in pK_a due to microenvironmental effects experienced by the residues within the three-dimensional structure of the protein molecule. In reality, the ε-amine groups on lysine side chains within proteins, having theoretical pK_as of over 10, nonetheless exist in sufficient quantity in an unprotonated form even at a pH of 7.2 that modification easily occurs.

One important point should be noted, however. The changes that occur in the pK_a of ionizable groups in protein molecules due to microenvironmental effects sometimes make it difficult to select certain residues for modification simply by careful modulation of reaction pH. For instance, at least in theory, overlap of the pK_a range for sulfhydryls and amine-containing residues

TABLE 2.1 pK_a of Ionizable Amino Acids

Group Location	Functionality	pK_a Range
α-Amine; N-terminus		7.6–8
Lysine's ε-amine		9.3–9.5
Histidine's imidazolyl nitrogen		6.7–7.1
Arginine's guanidinyl group		>12
Tyrosine's phenolic hydroxyl		9.7–10.1
α-Carboxyl; C-terminus		2.1–2.4
Aspartic acid's γ-carboxyl		3.7–4
Gutamic acid's γ-carboxyl		4.2–4.5
Cysteine's sulfhydryl		8.8–9.1

would eliminate any chance of directing a reaction toward –SH groups solely by adjusting the pH of the reaction medium. However, because of the microenvironmental changes that occur in complex biomolecules,

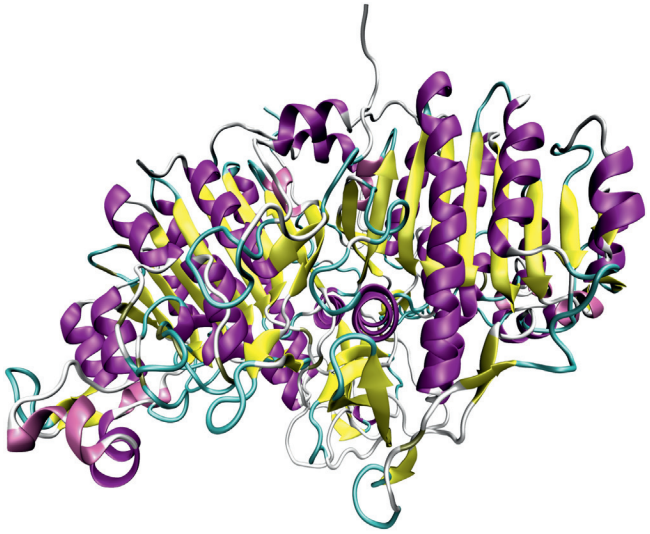


FIGURE 2.13 The α-chain structure of alkaline phosphatase illustrates the complex nature of polypeptide structure within proteins (Kim and Wyckoff, 1991).

pH sometimes can be used along with the right reactive group to target thiols without amine modification. Thus, in practice, to effectively site-direct a modification reaction, the proper choice of reactive group and reaction conditions can result in highly discrete conjugation to certain sites within proteins.

Secondary, Tertiary, and Quaternary Structure

Amino acids are linked through peptide bonds to form long polypeptide chains. The *primary* structure of protein molecules is simply the linear sequence of each residue along the α-chain. Each amino acid in the chain interacts with surrounding groups through various weak, noncovalent interactions and through its unique side-chain functionalities. Noncovalent forces such as hydrogen bonding and ionic and hydrophobic interactions combine to create each protein's unique organization.

The sequence and types of amino acids and the way that they are folded provide protein molecules with specific structure, activity, and function. Ionic charge, hydrogen bonding capability, and hydrophobicity are the major determinants for the resultant three-dimensional structure of protein molecules. The α-chain is twisted, folded, and formed into globular structures, α-helicies, and β-sheets based upon the side-chain amino acid sequence and weak intramolecular interactions such as hydrogen bonding between different parts of the peptide backbone (Figure 2.13). Major secondary structures of proteins such as α-helicies and β-sheets are held together solely by massive hydrogen bonding created through the carbonyl oxygens of peptide bonds interacting with the hydrogen atoms of other peptide bonds (Figure 2.14).

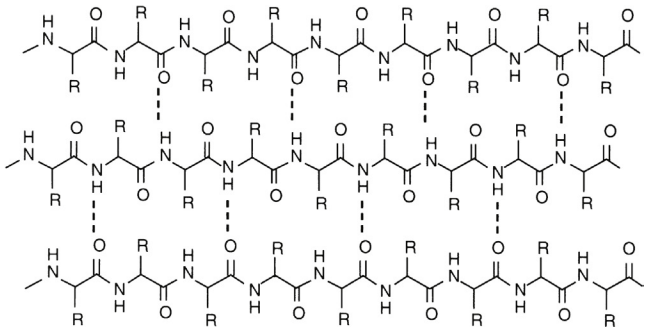

FIGURE 2.14 Secondary structures within proteins may be stabilized through hydrogen bonding between adjacent α-chains, forming β-sheet conformations.

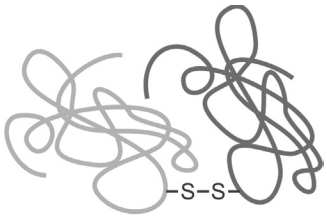

FIGURE 2.15 Polypeptide chains may be bound together through disulfide linkages occurring between cysteine residues within each subunit.

In addition, negatively charged residues may become bonded to positively charged groups through ionic interactions. Nonpolar side chains may attract other nonpolar residues and form regions of hydrophobicity to the exclusion of water and other ionic groups. Occasionally, disulfide bonds are also found holding different regions of the polypeptide chain together. All of these forces combine to create the *secondary* structure of proteins, which is the way the polypeptide chain folds in local areas to form larger, sometimes periodic structures.

On a larger scale, the unique folding and structure of one complete polypeptide chain is termed the *tertiary* structure of protein molecules. The difference between local secondary structure and complete polypeptide tertiary structure is arbitrary and sometimes of little practical difference.

Larger proteins often contain more than one polypeptide chain. These multi-subunit proteins have a more complex shape, but are still formed from the same forces that twist and fold the local polypeptide. The unique 3-dimensional interaction between different polypeptides in multi-subunit proteins is called the *quaternary* structure. Subunits may be held together by noncovalent contacts, such as hydrophobic or ionic interactions, or by covalent disulfide bonds formed from the cysteine residue of one polypeptide chain being crosslinked to a cysteine sulfhydryl of another chain (Figure 2.15).

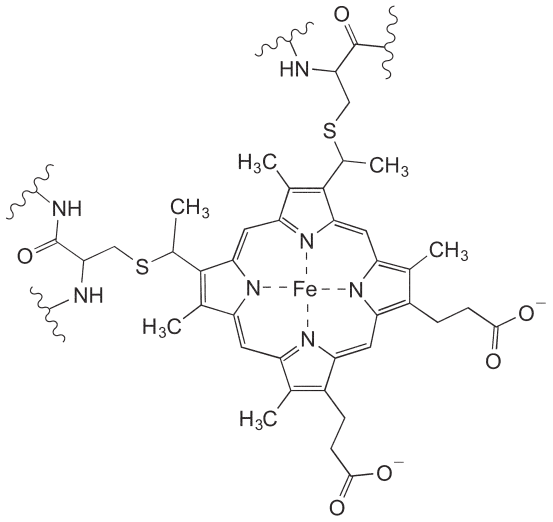

FIGURE 2.16 The heme ring of cytochrome *c* is a non-amino-acid, prosthetic group bound to the protein through two cysteine residues.

Thus, aside from the covalently polymerized α-chain itself, the majority of protein structure is determined by weaker, non-covalent interactions that potentially can be disturbed by environmental changes. It is for this reason that protein structure can be easily disrupted or denatured by fluctuations in pH or temperature or by substances that can alter the structure of water, such as detergents or chaotropes.

Not surprisingly, chemical modification to the amino acid constituents of a polypeptide chain may also cause significant disruption in the overall three-dimensional structure of a protein. If amino acid residues critical to folding near functionally important regions are modified with chemical groups that change the charge, hydrophilicity, or hydrogen bonding character of the polypeptide chain, protein structure may be altered and activity may be compromised. This concept will be discussed further in subsequent sections.

Prosthetic Groups, Cofactors, and Post-Translational Modifications

Proteins may contain structures other than polypeptide chains that are important for biological function. Prosthetic groups and cofactors are small organic compounds that are sometimes tightly bound to a protein and aid in forming the active center. A prosthetic group is usually carried within the three-dimensional protein structure in a firm-fitting pocket or even attached through covalent bonds, such as the heme ring associated with cytochrome *c* molecules which is bonded through thioether linkages with adjacent cysteine residues (Figure 2.16). Cofactors, by contrast, may be bound only transiently to proteins during periods of activity. Enzymes often require cofactors to act as

donors or acceptors of chemical groups that are added to or cleaved from a substrate molecule. Some common cofactors are ATP, ascorbic acid, coenzyme A, NAD, NADP, FAD, FMN, and biotin. Sometimes, the enzyme cofactor is also an energy source for the catalytic reaction, as in the case of ATP dependent reactions.

Frequently, metal ions are associated with the prosthetic group or cofactor. Heme rings usually contain a chelated iron atom. Occasionally, however, these metals are merely bound within folded polypeptide regions with no additional organic constituents required. Many metal ions are known to participate in enzymatic activity. One or more of the ions of Na, K, Ca, Zn, Cu, Mg, and Mn, as well as Co and Mo, are often required by enzymes to maintain activity.

Prosthetic groups and cofactors, whether organic or metallic, may be removed from a protein to create an inactive *apo* protein or enzyme. Loss of these groups may occur through environmental changes, such as removing metal ions from solution or adding denaturants to unfold protein structure. In many cases, simply re-introducing the needed group into the surrounding medium can restore full activity.

In addition to small organic molecules or metal ions, proteins may have other components tightly associated with them. Nucleoproteins, for instance, contain noncovalently bound DNA or RNA, as in some of the structural proteins of viruses. Lipoproteins contain associated lipids or fatty acids and may also carry cholesterol, as in the high-density and low-density lipoproteins in serum.

During modification or conjugation reactions, prosthetic groups and other associated molecules may be lost or damaged. Metal ions temporarily may be removed by the inclusion of a chelating agent added to maintain sulfhydryl stability during coupling through the –SH groups of a protein. To restore activity after conjugation, it is necessary to remove the chelator and add the required metal salts. Other changes to the prosthetic carriers may not be so easily corrected. For instance, heme-containing molecules are sensitive to the presence of agents that can form a coordination complex with or modify the oxidation state of the chelated metal ion. Some reagent systems may permanently inactivate the heme-containing protein.

Thus, loss of activity can occur not only through changes to the amino acid constituents of a protein, but through prosthetic group or cofactor loss or damage as well. Most of these potential difficulties can be overcome through careful selection of the reaction conditions and through knowledge of the cofactor dependencies that are critical to the activity of the protein being modified.

Post-translational modifications to protein structure are covalent changes that occur as the result of controlled enzymatic reactions or due to chemical reactions not under enzymatic regulation. One of the most common cellular modifications performed on proteins after ribosomal synthesis is glycosylation. Proteins newly synthesized on ribosomes may be transported to the Golgi apparatus, where specific glycosyl transferases catalyze the coupling of carbohydrate residues to the polypeptide chains. Glycoproteins and mucoproteins are formed by the coupling of polysaccharides through *O*-glycosidic linkages to serine, threonine, or hydroxylysine and through *N*-glycosidic linkages with the amide side-chain group of asparagine.

The structure of most glycoprotein carbohydrate is branched with the sugars mannose, *N*-acetylglucosamine (GlcNAc), sialic acid, glactose, and L-fucose being prevalent. Asparagine-linked polysaccharides are well characterized and are known to be constructed of a core unit consisting of three mannose residues and two *N*-acetylglucosamine residues. The GlcNAc residues are bound to the Asp side-chain amide nitrogen through a β1 linkage (Kornfield and Kornfield, 1985). The three mannose groups then usually form the first branch point in the oligosaccharide chain (Section 2.1.2).

The content by weight of carbohydrate in glycoproteins may vary from only a few percent to over 50% in some proteins in mucous secretions. Although the function of the polysaccharide in most glycoproteins is unknown, in some cases it may provide hydrophilicity, recognition, and points of non-covalent interaction with other proteins through lectin-like affinity binding.

The presence of carbohydrate on protein or peptide molecules can provide important points of attachment for modification or conjugation reactions. Coupling exclusively through polysaccharide chains can often direct the reaction away from active centers or critical points in the polypeptide chain, thus preserving activity. Polysaccharides can be specifically targeted on glycoproteins through mild sodium periodate oxidation. Periodate cleaves adjacent hydroxyl groups in sugar residues to create highly reactive aldehyde functionalities (Chapter 3, Section 4.4). The level of periodate addition can be adjusted to selectively cleave only certain sugars in the polysaccharide chain. For instance, a concentration of 1-m*M* sodium periodate at temperatures less than 4°C specifically oxidizes sialic acid residues to contain aldehydes, leaving all other monosaccharides untouched. Increasing the concentration to 10-m*M* and carrying out the reaction at room temperature, however, will cause oxidation of other sugars in the carbohydrate chain, including galactose and mannose. The generated aldehydes can then be used in coupling reactions with amine-or hydrazide-containing molecules to form covalent linkages. Amines can react with formyl groups under reductive amination conditions using a suitable reducing agent such as sodium cyanoborohydride. The result of this reaction is a stable secondary amine linkage (Chapter 3, Section 5.3).

Alternatively, hydrazides spontaneously react with aldehydes to form hydrazone linkages, although the addition of a reducing agent increases the efficiency of the reaction (Chapter 3, Section 5.1).

Another form of post-translational modification that may add carbohydrate to a polypeptide is non-enzymatic glycation. This reaction occurs between the reducing ends of sugar molecules and the amino groups of proteins and peptides. See Section 2.1 in this chapter for further details and the reaction sequence behind this modification.

Protecting the Native Conformation and Activity of Proteins

The goal of most protein modification or conjugation procedures is to create a stable product with good retention of the native state and activity. Ideally, any derivatization should result in a protein that performs exactly as it would in its unmodified form, but with the added functionality imparted by whatever is conjugated to it. Thus, an antibody molecule tagged with a fluorophore should retain its ability to bind to antigen and also have the added functionality of fluorescence.

One of the best ways to ensure retention of activity in protein molecules is to avoid carrying out chemistry at the active center. The active center is that portion of the protein where ligand, antigen, or substrate binding occurs. In simpler terms, the active center (or active site) is that part that has specific interaction with another substance (Means and Feeney, 1971). For the preparation of enzyme derivatives, it is important to protect the site of catalysis where conversion of substrate to product happens. For instance, when working with antibody molecules, it is crucial to stay away from the two antigen binding sites.

The best chemical procedures avoid the active site by selecting functional groups away from that area or by protecting the site through the incorporation of additives. In some cases, the inclusion of substrates, cofactors, ligands, inhibitors, or antigens in the modification reaction will protect the active site. Addition of the appropriate substance can bind the active site and mask it from modification by crosslinking agents. In enzyme derivatization procedures, this is often just a matter of adding a reversible inhibitor or substrate analog. For instance, when working with alkaline phosphatase merely carrying out the reaction in phosphate buffer protects the active center from chemical modification, since phosphate ions bind in the catalytic site. With trypsin, the incorporation of benzamidine similarly masks and protects the active site.

However, protecting the antigen binding sites on an antibody molecule by using this method is often more difficult. Inclusion of antigen to mask the binding sites is effective in blocking these areas, but it may also cause irreversible crosslinking of the antigen to the antibody. This is especially true when the antigen is a peptide or a protein having the same chemical functionalities as the antibody. Any modification reactions that are directed at the antibody may modify the antigen as well. Therefore, only use this method if the antigen is lacking in the chemical targets that are going to be used on the antibody. For instance, if the polysaccharide chains on the antibody are targeted for modification, then using a protein antigen that does not contain carbohydrate to block the antigen binding sites may work well.

An equally effective method of protecting the activity of a protein is by using site-directed reactions that result in modifications away from the active center. In some cases, specific functionalities are known to be present only at restricted sites within the three-dimensional structure of a protein. If these functionalities are not present close to the active site, then using them exclusively for modification reactions should ensure good retention of activity. For instance, sulfhydryl groups or carbohydrate chains are often present in limited quantity and in specific regions on a protein. Selecting reagent systems that target these groups ensures derivatization only at restricted sites within the protein molecule, thus potentially avoiding the active center.

Surprisingly, the goal of some protein crosslinking schemes is to somewhat alter the native presentation of the conjugate. This is especially true in hapten–carrier conjugation as used for immunogen or vaccine preparation. In this case, the main objective is to modify the environment of the hapten to create an immunological response *in vivo*. A hapten is usually a small molecule that is not able to generate an immune response on its own, but can react with the products of such a response once generated. Most often these products are antibodies having binding specificity for the hapten.

The complexities involved in achieving a successful conjugation strategy are best illustrated in the problems and concerns dealing with hapten–carrier conjugation. In order to produce the initial immune response to a small molecule, the hapten is typically coupled to a larger protein that can generate a response on its own. In simple terms, the larger carrier protein confers immunogenicity to the smaller hapten. The native presentation of the hapten is altered toward the immune system, thus creating the immune response.

The site of attachment of the hapten to the carrier and the nature of the crosslinker are both important to the specificity of the resultant antibodies generated against it. For proper recognition, the hapten must be coupled to the carrier with the appropriate orientation. For an antibody subsequently to recognize the free hapten without the attached carrier, the hapten–carrier conjugate must present the hapten in an exposed and

accessible form. Optimal orientation is often achieved by directing the crosslinking reaction to specific sites on the hapten molecule. With peptide haptens, this is typically carried out by attaching a terminal cysteine residue during synthesis. This provides a free thiol group on one end of the peptide for conjugation to the carrier. Crosslinking through this group provides hapten attachment only at one end, therefore ensuring consistent orientation.

In hapten–carrier conjugation, the goal is not to maintain the native state or stability of the carrier, but to present the hapten in the best possible way to the immune system. In reaching this goal, the choice of conjugation chemistry may control the resultant titer, affinity, and specificity of the antibodies generated against the hapten. It may be important in some cases to choose a crosslinking agent containing a spacer arm long enough to present the antigen in an unrestricted fashion. It may also be important to control the density of the hapten on the surface of the carrier. Too little hapten substitution may result in little or no response. A hapten density that is too high may actually cause immunological suppression and decrease the response. In addition, the crosslinker itself may generate an undesired immune response. Fortunately, for the majority of hapten–carrier conjugation problems, a few main crosslinking techniques provide a workable compromise to solving all these concerns and ultimately generating an effective immune response (Chapter 19).

Oxidation of Amino Acids in Proteins and Peptides

The modification of amino acids in proteins and peptides by oxidative processes plays a major role in the development of disease and in aging (Kim *et al*., 1985; Tabor and Richardson, 1987; Halliwell and Gutteridge, 1989, 1990; Stadtman, 1992). Tissue damage through free-radical oxidation is known to cause various cancers, neurological degenerative conditions, pulmonary problems, inflammation, cardiovascular disease, and a host of other problems. Oxidation of protein structures can alter activity, inhibit normal protein interactions, modify amino acid side chains, cleave peptide bonds, and even cause crosslinks to form between proteins.

Due to their abundance in cells relative to other biological molecules, proteins are one of the primary targets of oxidation *in vivo*. However, sometimes oxidation reactions involving proteins and peptides are thought of solely as the creation of disulfides from thiols on cysteine residues. This is certainly an important form of oxidation that can affect protein structure and function or even cause problems relevant to bioconjugation reactions. The presence of an accessible free thiol on a protein in an aqueous solution can be highly unstable to rapid oxidation unless precautions are taken to prevent disulfide formation. Dissolved oxygen and other potentially catalytic components, such as certain metal salts, can quickly result in disulfides being formed within a protein or between different protein molecules.

From a broader perspective, protein oxidation can result in covalent modification at many sites other than just at cysteine thiols. The earliest reports on protein oxidation date from the first decade of the 20th century, but it took many more years to characterize these reactions and their products (Dakin, 1906).

The significance of protein oxidation became paramount with the advent of recombinant protein biologics used as human therapeutics. Careful characterization of protein stability is essential to maintaining the efficacy of protein pharmaceuticals. If even a single side-chain amino acid residue becomes oxidized, then a protein therapeutic may not have the same activity *in vivo* as the unmodified protein.

Oxidation of proteins can result from exposure to oxidative species from many sources: reactive oxygen intermediates caused by metabolic reactions within cells (mitochondrial electron transport function and certain enzymes, such as oxidases, peroxidases, and P-450 enzymes), from the byproducts of oxidative stress reactions in cells (Sayre *et al*., 2001), or through the presence of strongly oxidizing compounds within a solution—all of these can contribute to selective damage or modification to protein structures. Some examples of chemical agents that can oxidatively modify proteins include hydrogen peroxide (H_2O_2) and other peroxy compounds, such as perborate and peroxycarbonate; hydroperoxyl radical ($HO_2\cdot$); superoxide anion ($O_2^{-}\cdot$); singlet oxygen ($^1O_2$); hydroxyl radical ($\cdot OH$), periodate (IO_4^-); metal salts in the presence of oxygen species, such as those of iron (Fe^{3+} and Fe^{2+}) and copper (Cu^{2+}); ozone (O_3); peroxynitrite ($ONOO^-$); hypobromous acid (HOBr); hypochlorous acid (HOCl); performic acid (HC(O)OOH); trichloromethylperoxyl radical ($CCl_3OO\cdot$); under the right conditions, metal-chelating compounds, such as porphyrins, texaphyrins, and FeBABE; and gamma radiation and ultraviolet light. For additional information, see Winterbourn and Kettle, 2000; Baynes and Thorpe, 2000; Greenacre and Ischiropoulos, 2001; Halliwell and Gutteridge, 1989, 1990; and Stadtman, 1992.

Singlet oxygen ($^1O_2$) differs from the predominant oxygen molecule in that O_2 is in the ground state or triplet state and its outer two unshared electrons have parallel spins (sometimes designated $^3O_2$), which is nearly unreactive toward other molecules, while singlet oxygen has increased energy and has its outer electrons transformed into an opposite spin orientation, which is highly reactive. Superoxide ($O_2^{-}\cdot$) is different from singlet oxygen in that it is a reduced form of oxygen having an extra unpaired electron, called a radical. The presence of the radical makes superoxide extremely

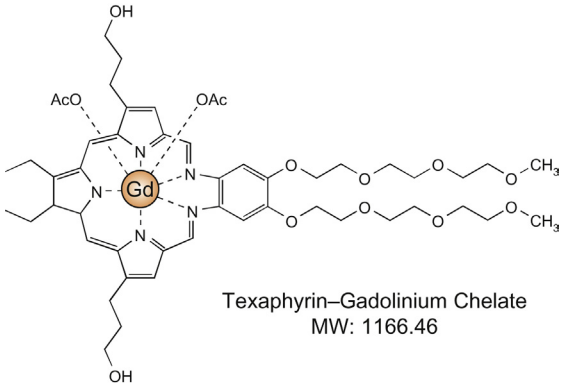

FIGURE 2.17 The texaphyrin–gadolinium chelate structure used as a photosensitizer and MRI contrast agent in the detection and treatment of cancer.

reactive and highly damaging to proteins and other biological molecules.

Singlet oxygen and superoxide, in addition to their modifying effects on proteins, are also important reactive oxygen species in biological applications, as they are intermediates used in some detection methods and in photodynamic therapy (PDT) for the treatment of cancer. One of the more common compounds used in PDT is Photofrin, which is a mixture of oligomers consisting of ether and ester linkages that combine up to eight porphyrin groups (Misawa *et al.*, 2005). The generation of reactive oxygen species takes place by irradiation with 630-nm wavelength laser light, which also penetrates the skin effectively during therapy. Photoactivation of the Photofrin molecule causes radical initiation to form porphyrin-excited states. Transfer of electrons from the porphyrin groups to molecular oxygen then generates the highly reactive singlet oxygen species. Subsequent radical reactions can also form superoxide and hydroxyl radicals, all of which severely damage tissue in the region of the tumor and ultimately cause cancer cell death.

Another compound used to generate reactive oxygen species for PDT is texaphyrin, which contains a metal-chelating ring structure resembling a porphyrin group (Figure 2.17). Typically, a gadolinium atom is chelated in the texaphyrin center and this complex becomes both a photosensitizing agent and an MRI contrast agent to better visualize tumor locations for irradiation therapy (Donnelly *et al.*, 2004).

The reactive oxygen species involved with protein oxidation can be generally categorized according to their relative reactivity as follows:

$$HO\cdot,\ HO_2\cdot > O_2^{-}\cdot > ROOH,\ H_2O_2 > {}^1O_2,$$
$$ClO^{-},\ BrO^{-} > O_2$$

Thus, radicals are the most reactive and destructive of protein structure, followed by peroxy derivatives, singlet oxygen, and other oxygen compounds. The oxidative reactivity of some of these oxygen species is so high that just contact of the pure compound with paper or cotton fabrics can cause combustion (e.g., superoxide).

In vitro studies of protein oxidation indicate that virtually all proteins and peptides are susceptible to damage by the radicals ·OH and $O_2^{-}\cdot$. Analysis of protein modification products after oxidation indicates the presence of altered molecular weight (either fragmentation or oligomerization), altered net charge, tryptophan destruction, and the formation of tyrosine dimers (Davies, 1987). Even in the presence of very low concentrations of oxidants (nM), SDS polyacrylamide gel electrophoresis of proteins can indicate multiple bands of higher and lower molecular weight due to oxidative damage.

Transition metals in solution can catalyze the formation of reactive oxygen species that are particularly damaging to proteins and other biomolecules. In a series of reactions, reduced transition metals, such as Fe^{2+} and Cu^{1+}, can be oxidized by oxygen to produce superoxide and ultimately undergo a Fenton reaction to create hydroxyl radicals (Kim *et al.*, 1985). Transition metal-chelating groups can accelerate this reaction, as demonstrated in the process of hydroxyl radical footprinting of protein interactions using EDTA chelates of iron (see discussion on the reagent FeBABE in Chapter 24, Section 4).

Production of superoxide: $Fe^{2+} + O_2 \rightarrow Fe^{3+} + O_2^{-}\cdot$

Production of hydrogen peroxide:
$$2O_2^{-}\cdot + 2H^{+} \rightarrow H_2O_2 + O_2$$

Production of hydroxyl radical:
$$Fe^{2+} + H_2O_2 \rightarrow Fe^{3+} + OH\cdot + OH^{-}$$

The potential sites of oxidation within a protein molecule include the peptide backbone and the side-chain amino acid groups. Hydrogen atom abstraction at the alpha carbon of an amino acid chain can occur upon reaction with an oxidative species to form a radical intermediate. Subsequent reaction can result in peptide bond cleavage and fragmentation of the protein structure, often forming carboxylic acids or carbonyls (aldehydes or ketones). This is the basic mechanism of fragmentation caused by the bifunctional chelating reagent FeBABE. When used in the presence of H_2O_2 and ascorbic acid, polypeptides will fragment in the neighborhood of interacting proteins.

Amino acid side chains can undergo oxidation through hydrogen abstraction, elimination, or by addition reactions. In the presence of oxygen, aliphatic

amino acids usually experience oxidation to a peroxy intermediate, which causes either hydrogen atom abstraction or an elimination reaction resulting in the formation of carbonyls, hydroxyls, or other peroxides (Requena *et al*., 2001) (Figure 2.18). Aromatic amino acids typically undergo addition reactions following exposure to strong oxidants. An example of this type of reaction is the nitrosation of tyrosine groups in the presence of a peroxynitrite ($ONOO^-$) to create *o*-nitrotyrosine (see Figure 2.19).

After exposure to an oxidant, the potential types of oxidation products in proteins and peptides can be extensive (Stadtman and Levine, 2000). Cysteine and methionine undergo a variety of sulfur oxidation reactions to yield cysteine disulfides, methionine sulfoxide, methionine sulfone, and sulfonate products (e.g., cysteic acid) (Ghesquiere *et al*., 2011) (Figure 2.20). Oxidation with performic acid can be used purposely to convert methionine and cysteine in peptides and proteins to more stable products prior to acid hydrolysis and amino acid analysis. Cysteine and methionine are perhaps the most sensitive amino acids to oxidation, and for this reason they are an early indicator of oxidative damage to proteins.

Tyrosine is also easily modified through addition reactions due to the ring activating nature of its phenolic group. Using oxidants, tyrosine's ring can be chlorinated or iodinated, undergo nitrosation or hydroxylation, and even form tyrosine–tyrosine crosslinks. The last product can be formed purposely by use of a peroxidase in the presence of hydrogen peroxide, and this type of reaction has been studied extensively in the manufacture of phenolic polymer resins (Dordick, 1991). In addition, Fancy *et al*. (1996) as well as Fancy and Kodadek (1997, 1998) have applied the oxidation of tyrosine to form dityrosine to the study of protein–protein interactions using nickel-chelated 6xHis-tagged fusion proteins in oxidative environments.

Nitrogen-containing side chains in amino acids can be altered by oxidation forming chloramines or even become deaminated. The result is often the formation of carbonyls (e.g., aldehydes) and hydroxyls. Lee *et al*. (2006)

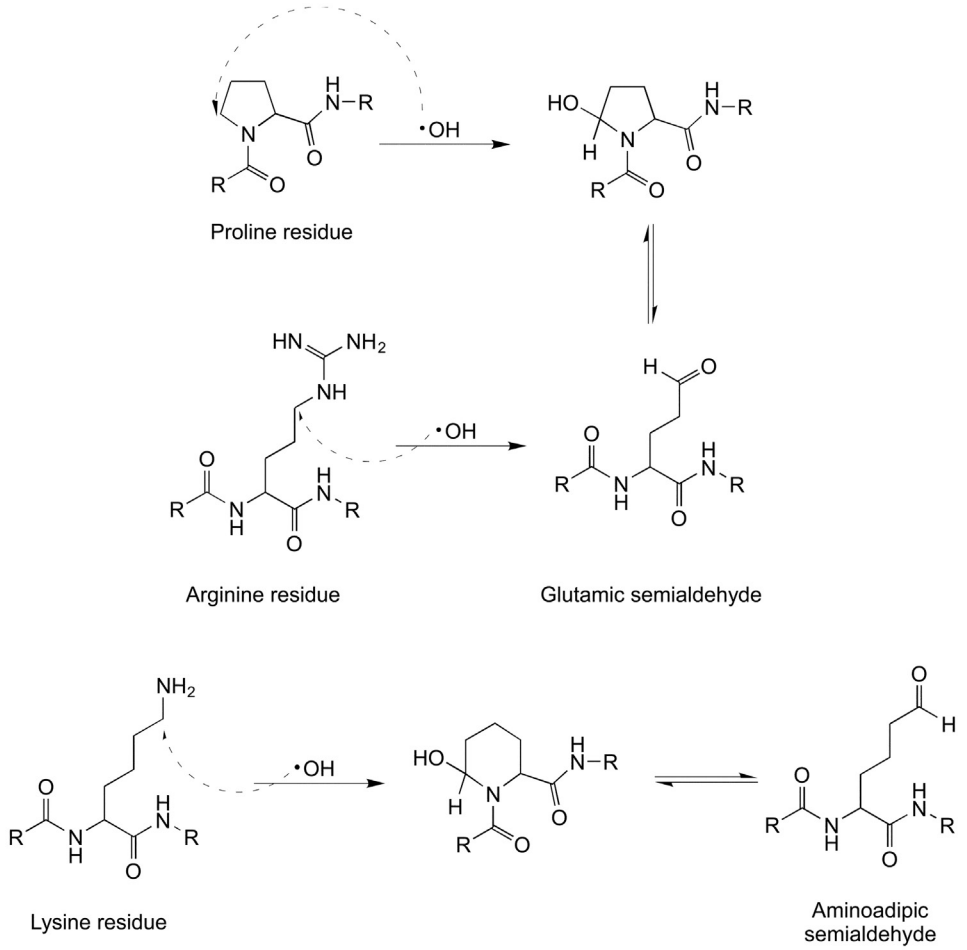

FIGURE 2.18 Reaction of proline, arginine, and lysine residues with hydroxyl radical results in oxidation of side-chain structures that form carbonyls. Both arginine and proline oxidation will result in the same product being formed.

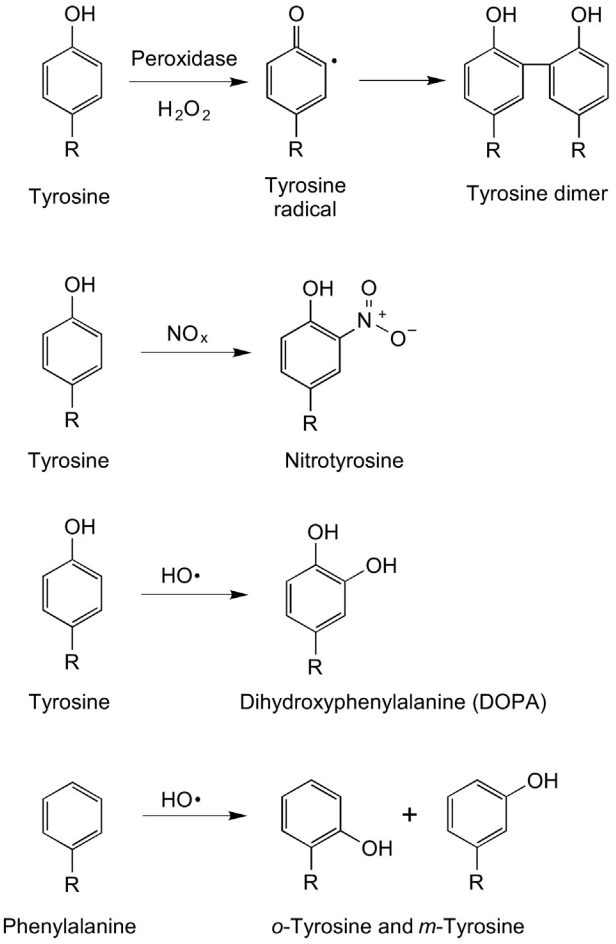

FIGURE 2.19 Tyrosine and phenylalanine residues can undergo oxidation to modify their phenyl side chain groups. Tyrosine can form covalent dimers that link two side chains together *via* a radical reaction. Both tyrosine and phenylalanine can be modified by oxidation to add oxygen-containing groups directly to their aromatic ring.

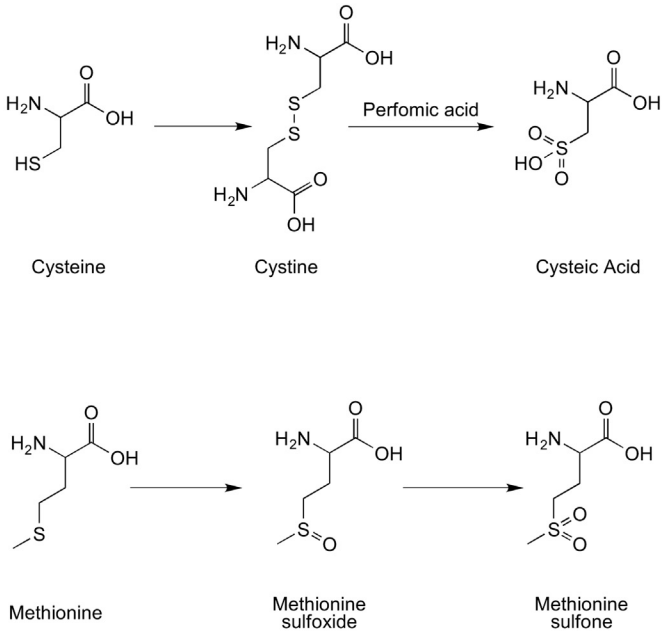

FIGURE 2.20 Cysteine and methionine are highly susceptible to oxidation reactions. Cysteine thiols can forms disulfide linkages with other cysteine groups or be oxidized to cysteic acid. Methionine is oxidized very easily to the sulfoxide or sulfone products.

found that Fe-EDTA-mediated oxidation of human serum albumin resulted in extensive aldehyde and ketone formation from modification of lysine, arginine, histidine, proline, threonine, and aspartic and glutamic acids. Some groups will oxidize and convert to another amino acid altogether. For instance, histidine can be converted to asparagine and proline to hydroxyproline, and tyrosine can be changed to dihydroxyphenylalanine (DOPA) through oxidation reactions.

It is obvious that the oxidation of protein molecules can have detrimental effects on protein structure and function. However, there are some unique methods in bioconjugation wherein controlled and purposeful oxidation is carried out to study protein–protein interactions (Chapter 24, Section 4).

Unfortunately, there are no universal methods to detect all types of protein oxidation, because the products formed can be so diverse in nature. However, some forms of protein oxidation can be assayed using chemical modification (Davies *et al.*, 1999; Shacter, 2000). In particular, the formation of carbonyl groups on proteins can be targeted using the reagent 2,4-dinitrophenylhydrazine (DNPH). This compound reacts with aldehydes to form 2,4-dinitrophenylhydrazone derivatives, which create chromogenic modifications that can be detected at high sensitivity in microplate assays or western blot analysis (Buss *et al.*, 1997; Winterbourn *et al.*, 1999).

In addition, a method involving mass spec analysis to determine carbonyl formation as a result of protein oxidation was developed using a novel mass tag. The carbonyl-specific Element-Coded Affinity Mass Tag (O-ECAT) can covalently couple to aldehyde or ketone oxidation sites using an aminoxy group to form an oxime (Lee *et al.*, 2006; see also Chapter 12, Section 3). The ECAT mass tag consists of a bifunctional metal-chelating group that coordinates a lanthanide metal ion of specific mass. Proteins that have been oxidized to contain carbonyls can be labeled with this reagent and the exact sites of modification determined by analyzing the mass spec signature of the labeled peptides after proteolysis.

Solvent Accessibility of Functional Targets in Proteins

Proteins are highly complex, folded polypeptide chains consisting of at least 20 different amino acids that are strung together in unique sequences, which relate to structure and function. Particular amino acids

in proteins may be further modified post-translationally to contain a wide variety of covalent modifications normally found in native proteins. The way in which a peptide chain is wrapped and folded governs each amino acid's relative exposure to the outside environment, but post-translational modifications can also obscure the protein surface from easy access to the solvent environment.

Amino acid side chains are the primary effectors of the three-dimensional structure of a protein, because their properties vary depending on the presence of charged groups, uncharged polar components, aliphatic chains, aromatic rings, and groups able to form hydrogen bonds with other amino acid residues. The relative hydrophilicity or hydrophobicity of an amino acid side chain is a major factor in determining whether the group will be found on the surface of a globular protein or buried within its globular structure.

However, just considering the individual properties of each amino acid type is not enough to determine its accessibility to the surrounding aqueous environment. There have been many attempts at developing analytical models with predictive value for determining buried or surface accessible amino acids in a folded polypeptide chain (Vasicek *et al.*, 2012). These studies have concluded fractional assignments for each residue that relate to its accessible surface area (ASA) or its solvent exposed area (SEA).

In most cases, there are general trends that emerge from theoretical studies in which hydrophilic amino acids are more likely to be found on the surface of a protein and hydrophobic amino acids are more likely to be inside its three-dimensional structure, but we already knew this intuitively so this conclusion is not surprising. However, a real-life study of the positions of amino acids in proteins whose structures are known is more revealing. The data for Figure 2.21 were calculated from 55 proteins in the Brookhaven database by Bordo and Argos (1991), and the graph was derived from the analysis as presented by the Jena Image Library of Biological Macromolecules (http://www.imb-jena.de/IMAGE_AA.html). Although most of these structures were determined using crystallographic means and thus the proteins are "frozen" in a single structural state, the results are revealing as to how often particular amino acids are accessible to the surrounding solvent.

Three levels of SEA are presented in the graph for each amino acid, which corresponds to areas in $Å^2$ accessible to the solvent environment: greater than $30 Å^2$ for highly accessible amino acids, between $10 Å^2$ and $30 Å^2$ for medium accessibility, and less than $10 Å^2$ for those residues that are relatively not accessible to the solvent. Only the SEA for each amino acid of $>30 Å^2$ is shown in the plotted data. The graph shows that the polar amino acids such as serine, threonine, asparagine, glutamine, and tyrosine often have large areas accessible to the solvent, as do the charged amino acids aspartic acid, glutamic acid, lysine, histidine, and arginine. Surprisingly, proline also falls in the highly accessible

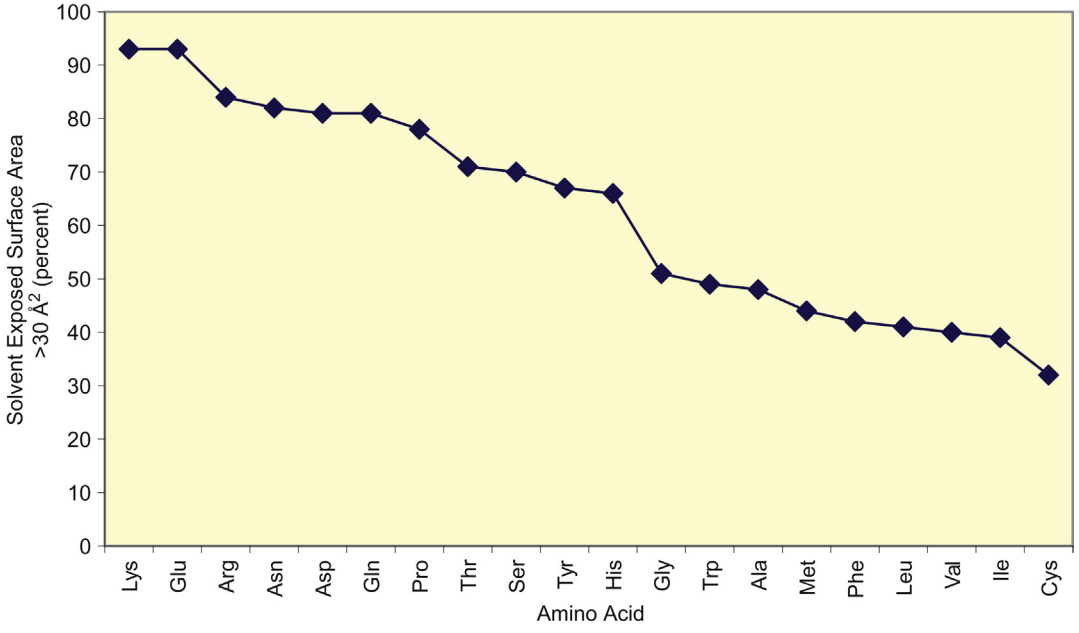

FIGURE 2.21 Comparison of the solvent exposed surface area of amino acids in proteins. Data are plotted as a percentage of each amino acid in a protein having greater than a 30-$Å^2$ exposure to the aqueous environment. Charged and polar amino acids are seen to have the most solvent exposure, while uncharged, aromatic, or aliphatic amino acids have the least exposure.

group, which is not as expected, because it does not carry a charge, nor is it a highly polar amino acid. However, proline does have a unique characteristic that may explain its appearance on the surface of proteins: it cannot freely rotate about its imino group as other amino acids in a peptide chain can do at amide bonds. This effect results in a kink in the polymer (called a beta-turn), and these sharp turns in a peptide backbone probably occur most often near the surface. Thus, proline is found to be frequently accessible to the solvent environment despite its hydrophobic nature.

The nonpolar amino acids glycine, alanine, valine, leucine, isoleucine, methionine, phenylalanine, and cysteine have lower exposure to the solvent environment than charged or polar residues. However, the frequency at which these groups are found to have an SEA of greater than 30 $Å^2$ is much higher than one would expect based solely upon consideration of their hydrophobicity. In fact, nearly 30 to 50% of the time nonpolar amino acids in a protein can be found at the surface.

At the two extremes, lysine is observed as the amino acid most accessible on the surface of proteins while cysteine is the least exposed amino acid. The inaccessibility of cysteine probably stems from the fact that disulfides are typically buried within the polypeptide structure of proteins, whether they are intrachain or in nature, and proteins rarely contain many reduced cysteine thiols.

It is clear from these data that proteins have complex hydrophilic and hydrophobic regions on their surfaces that determine their potential interactions, binding sites, and active centers. For bioconjugation purposes, targeting of an amino acid even with a high SEA for modification or crosslinking may not result in every residue being modified that is theoretically present in a protein based only on knowledge of its amino acid composition. Even when coupling to very polar or charged groups, such as lysine, there are varying degrees of accessibility to a given reagent, because of the complex folding of the polypeptide chains at the protein surface.

Figure 2.22 shows the globular structure of an immunoglobulin (IgG) Fc region to illustrate this point. In this space-filling model, the lysine residues are highlighted in yellow to easily show their locations within the two polypeptides of the heavy chains. Notice that some of the ε-amino groups at the ends of the side chains are protruding far out into the solvent and are therefore highly accessible for modification. Some of these groups, however, are less exposed even though they are still near the surface, and a few lysines are seen to be between the heavy chain regions where it would be difficult to modify them due to crowding.

Figure 2.64 in this chapter provides data to validate this effect. The reaction of the thiolating reagent SATA with IgG resulted in only a percentage of the available

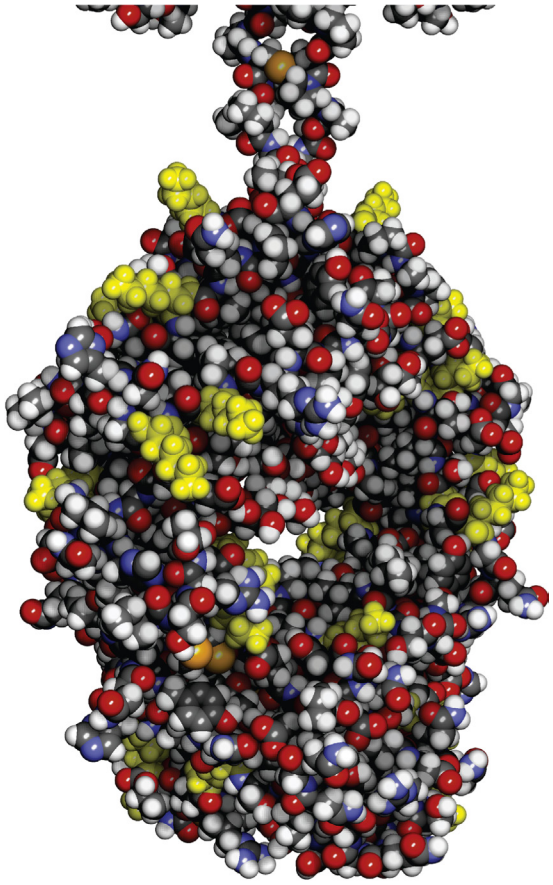

FIGURE 2.22 The solvent accessibility of lysine residues in the Fc region of an antibody is illustrated by highlighting the lysine groups in yellow. Some lysine ε-amine groups are extremely accessible to conjugation, while others are only partially exposed, thus making it difficult to modify all of them in bioconjugation reactions.

lysines being modified. As the molar ratio of SATA to IgG was increased, the yield of lysine modification actually became lower. This result can be explained by the relative accessibility of each lysine in the immunoglobulin structure. Some residues are easily accessible and they get modified with high yield even with low molar ratios of SATA-to-IgG. As the molar ratio is increased, it gets more difficult to modify those lysines that are less accessible to the solvent environment or are partially obscured by another polypeptide chain. Thus, the solvent accessibility of particular amino acids is a major factor in whether they can be effectively targeted and modified with a given bioconjugate reagent.

1.2. Protein Crosslinking Methods

The crosslinking of two proteins using a simple homobifunctional reagent (Section 2.2) can potentially result in a broad range of conjugates being produced (Avramease, 1969). The reagent may initially react with either one of the proteins, forming an active

intermediate. This activated protein may then form crosslinks with the other protein or with another molecule of the same protein. The activated protein may also react intramolecularly with other functionalities on part of its own polypeptide chain. Other crosslinking molecules may continue to react with these conjugated species to form various mixed products, including severely polymerized proteins that may fall out of solution (Figure 2.23).

The problems of indeterminate conjugation products are amplified in single-step reaction procedures using homobifunctional reagents (Chapter 5). Single-step procedures involve the addition of all reagents at the same time to the reaction mixture. This technique provides the least control over the crosslinking process and invariably leads to a multitude of products, only a small percentage of which represent the desired or optimal conjugate. Excessive conjugation may cause the formation of insoluble complexes that consist of very high-molecular-weight polymers. For example, one-step glutaraldehyde conjugation of antibodies and enzymes (Chapter 20, Section 1.2) often results in significant oligomers and precipitated conjugates. To overcome this shortcoming, multi-step reaction procedures have been developed using both homobifunctional and heterobifunctional reagents (Chapters 5 and 6). Controlled, multi-step conjugation protocols alleviate the polymerization problem and form relatively low-molecular-weight, soluble antibody–enzyme complexes (Chapter 20, Section 1.1).

In two-step protocols, one of the proteins to be conjugated is reacted or "activated" with a crosslinking agent and excess reagent and byproducts are removed. In the second stage, the activated protein is mixed with the other protein or molecule to be conjugated, and the final conjugation process occurs (Figure 2.24).

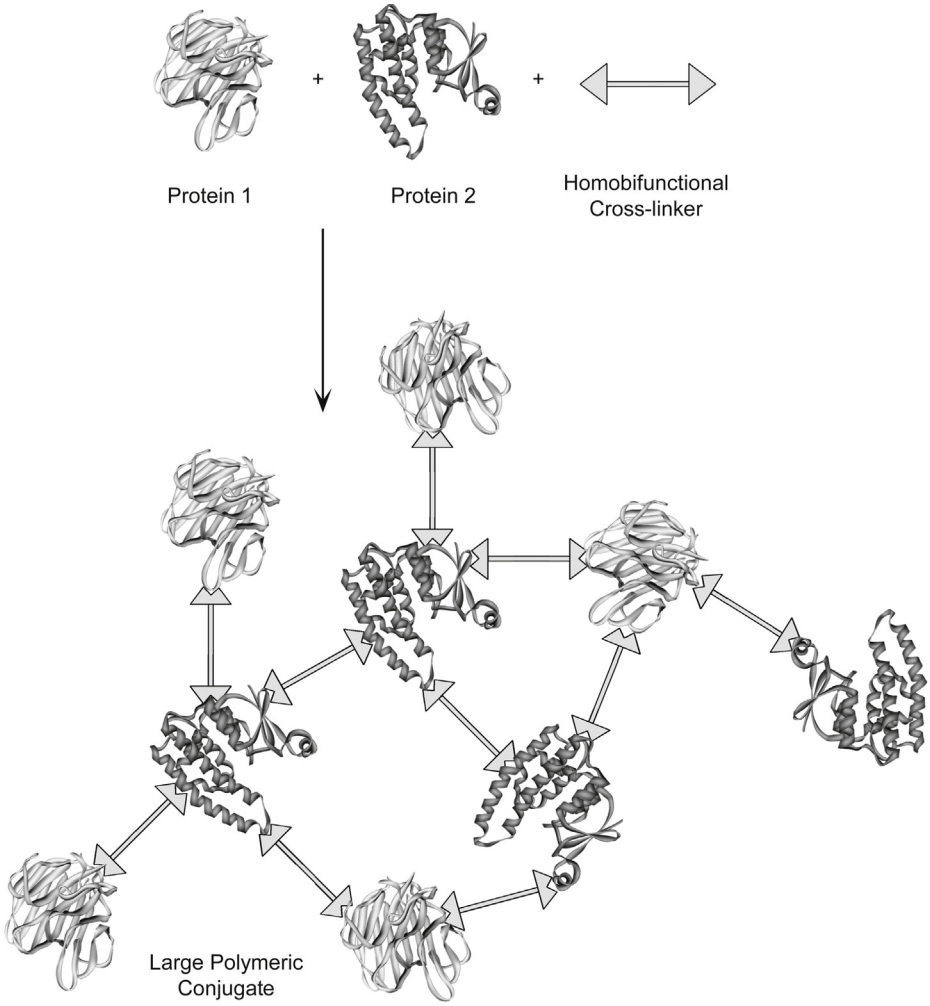

FIGURE 2.23 Protein crosslinking reactions carried out using homobifunctional reagents can result in large polymeric complexes of multiple sizes and indefinite structure.

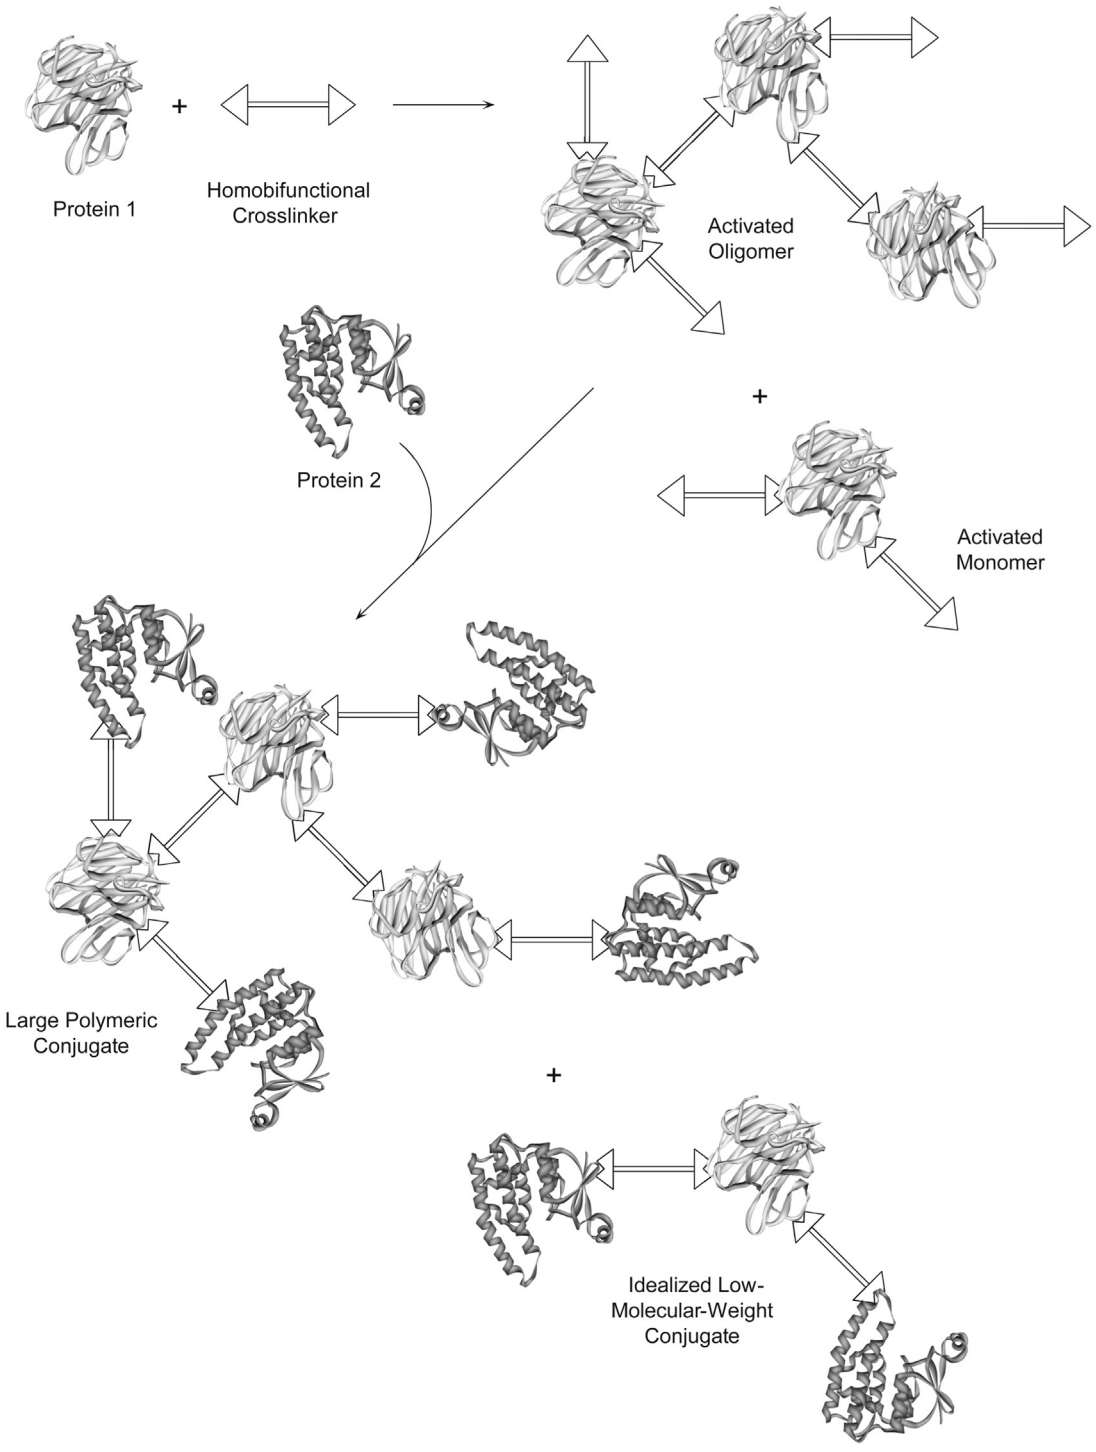

FIGURE 2.24 A two-step protocol using a homobifunctional crosslinking agent offers more control than single-step methods, but still may result in oligomer formation.

The use of homobifunctional reagents in two-step protocols still creates many of the problems associated with single-step procedures, because the first protein can crosslink and polymerize with itself long before the second protein is added. Homobifunctional reagents by definition have the same reactive group on both ends of the crosslinking molecule. Since the protein to be activated has target functionalities on every molecule that can couple with the reactive groups on the crosslinker, both ends of the reagent can potentially react.

This inherent potential to uncontrollably polymerize is unfortunately characteristic of all homobifunctional reagents, even in multi-step protocols.

The greatest degree of control in crosslinking procedures is afforded using heterobifunctional reagents (Section 2.3). Since a heterobifunctional crosslinker has different reactive groups on either end of the molecule, each side can be directed specifically toward different functional groups on proteins. Using a multi-step conjugation protocol with a heterobifunctional reagent can allow one macromolecule to be activated, excess crosslinker removed, and then a second macromolecule added to induce the final linkage. Directed conjugation will occur as long as the first protein that is activated does not have groups able to couple with the second end of the crosslinker, whereas the second molecule does possess the correct functionalities.

Occasionally, the second protein does not naturally have the target groups necessary to couple with the second end of the crosslinker. In such cases, a specific functionality can usually be created to make the conjugation successful (Chapter 2, Section 4). In such three-step systems, the first protein is activated with the heterobifunctional reagent and purified away from excess crosslinker. The second protein is then modified to contain the specific target groups required for the second stage of the conjugation. Finally, in step three, the two modified proteins are mixed to cause the coupling reaction to take place (Figure 2.25).

Two- and three-step protocols using heterobifunctional crosslinkers are often designed around amine-reactive and sulfhydryl-reactive chemical reactions. Many of these reagents utilize NHS esters on one end for coupling to amine groups on the first protein and

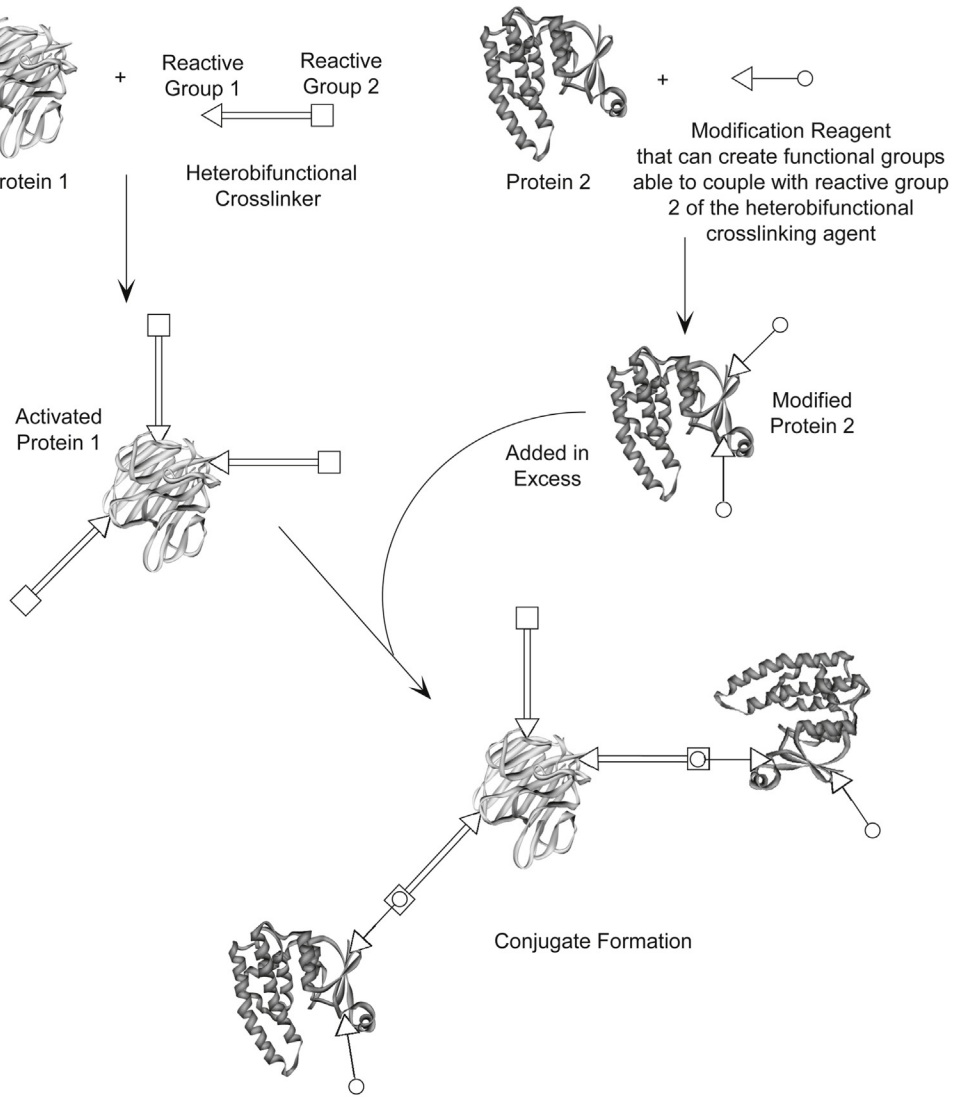

FIGURE 2.25 Heterobifunctional crosslinking agents used in multi-step protocols result in the best control over the products formed.

maleimide groups on the other end that can react with sulfhydryls on the second protein. The NHS ester end is reacted with the first protein to be conjugated, forming an activated intermediate containing reactive maleimide groups. Fortunately, the maleimide end of such crosslinkers is relatively stable to degradation, thus the activated protein can be isolated without loss of sulfhydryl coupling ability. Additionally, if the second protein does not contain indigenous sulfhydryls, these can be created by an abundance of methods (Chapter 2, Section 4.1). After mixing the maleimide-activated protein with the sulfhydryl-containing protein, conjugation can only occur in one direction.

Control of the products of conjugation will generally increase as the protocols progress from single-step to multi-step reactions. Likewise, control of the chemistry of conjugation increases as the reagent systems evolve from simple homobifunctional to site-directed heterobifunctional. It may appear to be a paradox, but often as the method of conjugation gets more complex the result is less potential for side reactions and therefore fewer products being formed. Therefore, multi-step processes using advanced heterobifunctional reagents are the best combination to ensure that the protein conjugate formed is indeed the one desired.

2. MODIFICATION OF SUGARS, POLYSACCHARIDES, AND GLYCOCONJUGATES

The basic units of food energy for cells and living organisms consist of polysaccharides or simple sugars, principally glucose and its derivatives. Biological molecules themselves often contain carbohydrate or are made exclusively of such components. Complex carbohydrate "trees" frequently project off the surface of cells, providing specific points of attachment or sites of recognition. Lipids and proteins that contain these components may possess them to give identity or partial hydrophilicity to their parent structures.

Many of the macromolecules that are the subject of modification or conjugation reactions contain significant proportions of carbohydrate. Reactions can be designed to directly target these polysaccharide portions, either selectively modifying them with small, detectable compounds or using them as conjugation bridges to couple with other macromolecules. The reactivity of carbohydrate molecules in such derivatizations is an important factor in the success of many bioconjugate techniques.

This section describes the basic chemical attributes of carbohydrate molecules. Principal sites of reactivity on carbohydrates are discussed with the aim of developing a rational approach to using them in modification and conjugation procedures.

2.1. Carbohydrate Structure and Functionality

Carbohydrates are characterized by the presence of polyhydroxylic aldehyde or polyhydroxylic ketone structures or polymers made of such units. Sugars and polysaccharides have definite three-dimensional structures that are important for many biological functions. They are hydrophilic and thus easily accessible to aqueous reaction mediums. The chemistry of bioconjugation using carbohydrate molecules begins with an understanding of the building blocks of polysaccharide molecules.

Basic Sugar Structure

The simplest carbohydrate, called a monosaccharide, is composed of a structure that cannot be hydrolyzed to simpler polyhydroxylic compounds. A disaccharide is a carbohydrate that contains two of these basic units, and a polysaccharide contains many polyhydroxylic monomers.

A monosaccharide that contains an aldehyde group is called an aldose, and one that contains a ketone group is a ketose. Monosaccharides are further classified by the number of carbon atoms they contain. Thus, a five-carbon sugar is known as a pentose and a six-carbon sugar, a hexose. All monosaccharides containing accessible aldehyde or ketone functionalities are reducing sugars—that is, they are able to reduce Fehling's or Tollen's reagent.

The aldehyde or ketone group of monosaccharides can undergo an intramolecular reaction with one of its own hydroxyl groups to form a cyclic, hemiacetal, or hemiketal structure, respectively (Figure 2.26). In aqueous solutions, this cyclic structure actually predominates. The open-chain aldehyde or ketone form of monosaccharides is in equilibrium with the cyclic form, but the open structure exists less than 0.5% of

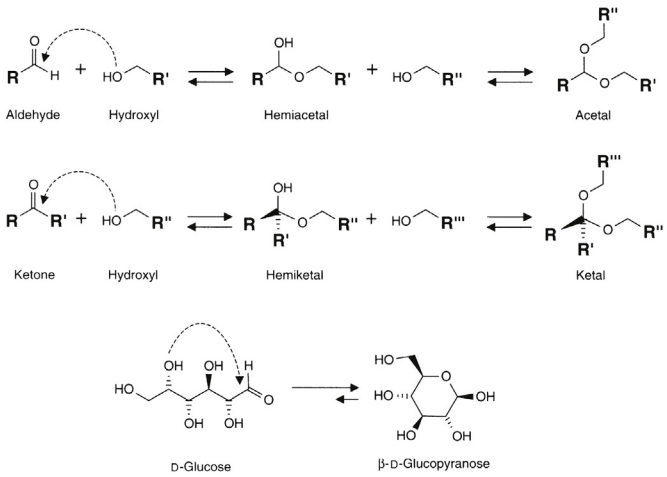

FIGURE 2.26 Carbonyl groups and hydroxyls may react to form acetal or ketal products. Sugars naturally undergo these reactions to form ring structures in aqueous solution.

the time in aqueous environments. It is the open form that reduces Fehling's or Tollen's reagent. However, due to this predominance of the cyclic structure of monosaccharides, they do not have the capability of reacting with bisulfite or Schiff's reagent, as do normal unblocked aldehydes and ketones. Thus, the carbonyl functionalities of sugars have reduced reactivity, because of hemiacetal and hemiketal formation.

Figure 2.27 shows the structures of some of the most common monosaccharide molecules: D-glyceraldehyde, D-erythrose, D-ribose, D-arabinose, D-xylose, D-glucose, D-glucosamine, *N*-acetyl-D-glucosamine, D-mannose, D-galactose, D-galactosamine, and *N*-acetyl-D-galactosamine of the aldose family and dihydroxyacetone, D-ribulose, D-fructose, and D-*N*-acetylneuraminic acid of the ketose family. Formation of the cyclic structure of each of these sugars can result in one of two stereoisomers, designated α and β, depending on the orientation of the aldehyde group or ketone group during hemiacetal formation. For aldoses, the α form is drawn in the standard Haworth projection with the number 1 carbon hydroxyl pointing down. For ketoses, the α form consists of the number 2 carbon hydroxyl pointing down. All the common monosaccharide structures shown in Figure 2.27 are in the β-stereoisomer form.

Since in aqueous solutions the cyclic form of monosaccharides is in equilibrium with their corresponding open forms, the α and β structures continually interconvert. At equilibrium, one form usually predominates. For instance, glucose dissolved in water consists of about a 2:1 ratio of β-D-glucose to α-D-glucose. Although their chemical constituents are identical, the biochemical properties between the α and β forms can be quite different. Monosaccharides linked together to form disaccharides and polysaccharides cannot continue to interconvert and are therefore frozen in the α or β forms. Changing one monosaccharide in a complex carbohydrate to its opposite stereoisomer form can produce radical structural changes in the polysaccharide chain and significantly alter its biochemical properties.

Sugar Functional Groups

Monosaccharide functional groups consist of either a ketone or an aldehyde, several hydroxyls, and the possibility of amine, carboxylate, sulfate, or phosphate groups as additional constituents. Amine-containing sugars may possess a free primary amine, but often are modified to the *N*-acetyl derivative, such as the *N*-acetylglucosamine residue of chitin. Sulfate-containing monosaccharides frequently are found in certain mucopolysaccharides, including chondroitin

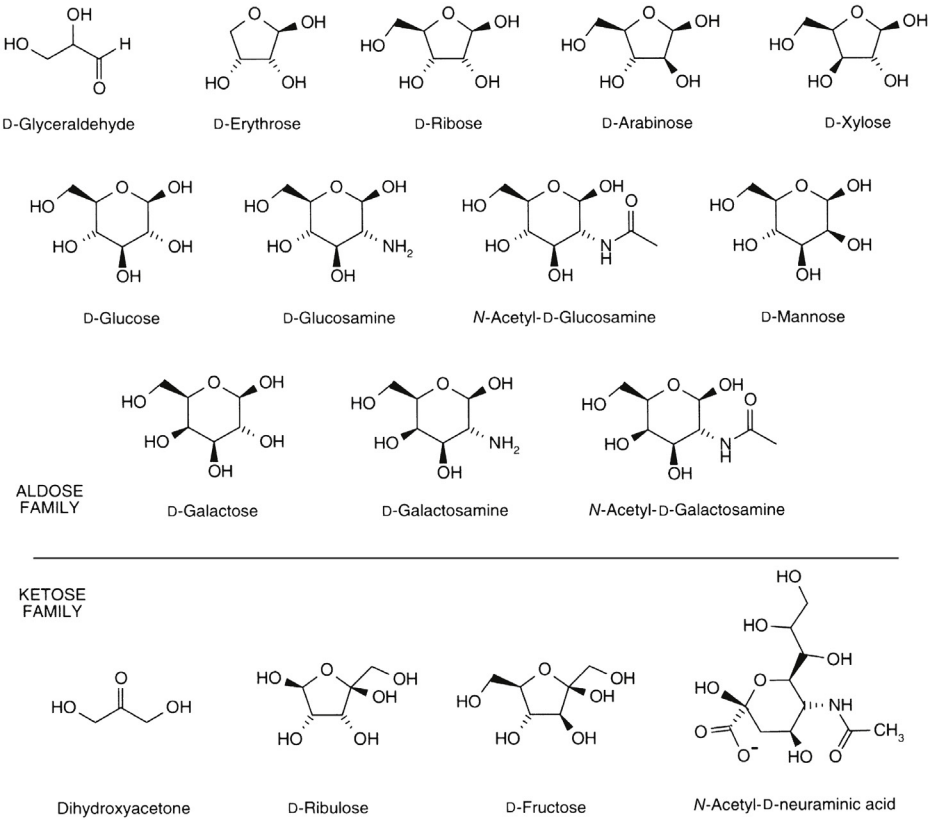

FIGURE 2.27 Common monosaccharides of the aldose and ketose families found in biological molecules.

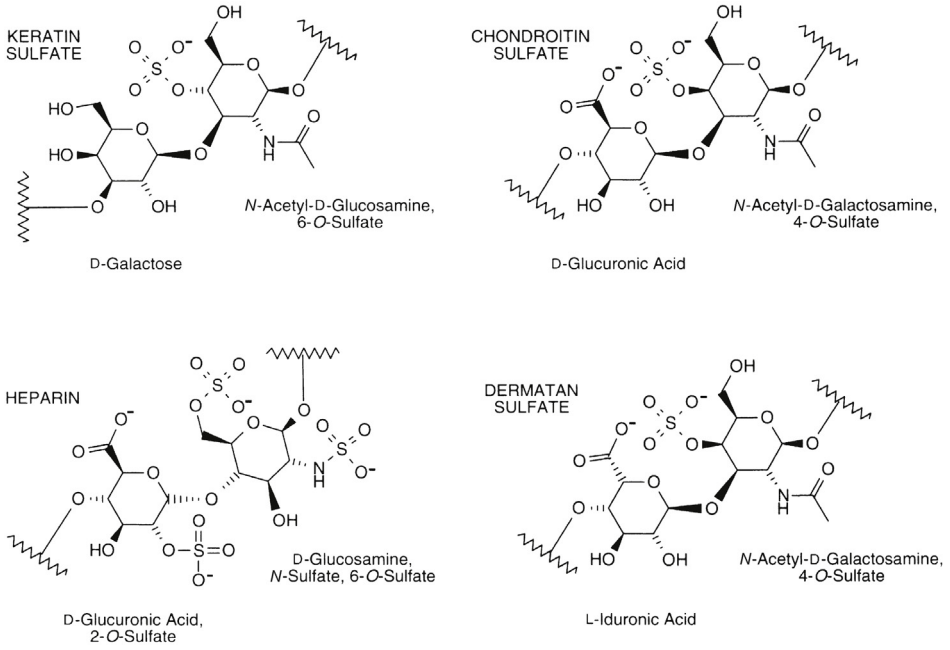

FIGURE 2.28 Common sulfonated polysaccharides of biological origin.

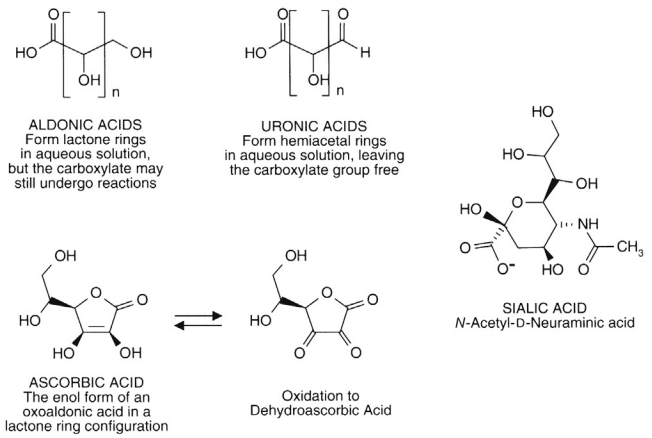

FIGURE 2.29 Monosaccharides containing carboxylate groups. Sialic acid is often found at the terminal residues of polysaccharides within glycoproteins.

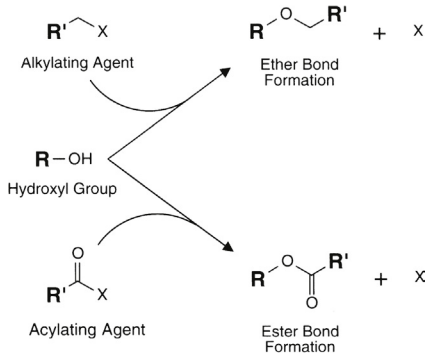

FIGURE 2.30 Hydroxyl groups within sugar residues may undergo alkylation or acylation reactions, forming ether or ester linkages.

sulfate, dermatan sulfate, heparin sulfate, and keratin sulfate (Figure 2.28). Carboxylate-containing sugars include sialic acid as well as many aldonic, uronic, oxoaldonic, and ascorbic acid derivatives (Figure 2.29). Phosphate-containing monosaccharides are almost exclusively created in metabolic processes involving energy utilization, such as in the production of glucose-1-phosphate formed during glycogen breakdown and glucose-6-phosphate produced during glycolysis. Perhaps the most common phosphate sugar derivative, however, is the 5′-phosphate of D-ribose or D-2-deoxyribose found as a repeating component of RNA and DNA, respectively.

Modification and conjugation reactions can be designed to target many of these functionalities. Sugar hydroxyl groups, for example, may be derivatized by acylating or alkylating reagents, similar to the principal reactions of primary amines (Section 1). However, acylation of a hydroxyl group usually creates an unstable ester derivative that is subject to hydrolysis in aqueous solution. An exception to this is acylation by a carbonylating reagent such as carbonyldiimidazole (CDI) (Chapter 3, Section 4.2) or *N,N′*-disuccinimidyl carbonate (DSC) (Chapter 3, Section 4.3), which can produce stable carbamate linkages after subsequent conjugation with an amine-containing molecule. By contrast, alkylating reagents, such as alkyl halogen compounds (Chapter 3, Section 4.6), typically form more stable ether bonds after reaction with hydroxyls. Figure 2.30

shows the reactions associated with alkylation and acylation of hydroxyl residues.

Carbohydrates containing hydroxyl groups on adjacent carbon atoms may be treated with sodium periodate (Section 4.4, this chapter) to cleave the associated diol carbon–carbon bond and oxidize the hydroxyls to reactive formyl groups (Bobbitt, 1956). Modulating the concentration of sodium periodate can direct this oxidation to exclusively modify sialic acid groups (using 1-m*M* concentration at temperatures <4°C) or to convert all available diols to aldehydes (using 10-m*M* or greater concentrations at room temperature). Specific monosaccharide residues may be targeted with selective sugar oxidases to generate similar aldehyde functions only at discrete points within a complex polysaccharide structure (Section 4.4, this chapter) (Avigad, 1962; Gahmberg, 1978). The creation of formyl groups in this manner may be carried out on purified polysaccharide molecules, as in the case of soluble dextrans (Chapter 18, Section 2.2), or may be selectively performed on carbohydrate constituents of glycoproteins and other glycoconjugates. Once formed, aldehyde groups may be covalently coupled with amine-containing molecules by reductive amination using sodium cyanoborohydride (Chapter 4, Section 4) (Dottavio-Martin and Ravel, 1978; Cabacungan *et al*., 1982).

The native reducing ends of carbohydrates may also be conjugated to amine-containing molecules by reductive amination. The reaction, however, is typically less efficient than using periodate-created aldehydes, since the open structure is in low concentration in aqueous solutions compared to the cyclic hemiacetal form. The reaction is usually allowed to continue for a week or more to reach good yields of coupling. Proteins may be modified to contain carbohydrate using this procedure (Gray, 1974, 1978; Baues and Gray, 1977; Schwartz and Gray, 1977). See Section 4.6 of this chapter for a more complete discussion of methods for the introduction of saccharide or glycan groups into proteins or other molecules.

The reducing ends of oligosaccharides can be modified with β-(*p*-aminophenyl)ethylamine to yield terminal arylamine derivatives (Jeffrey *et al*., 1975; Zopf *et al*., 1975). The aromatic amines can then be diazotized for coupling to active hydrogen-containing molecules, such as the tyrosine phenolic residues in proteins (Zopf *et al*., 1978a,b). Alternatively, the arylamines may be transformed into isothiocyanate derivatives for coupling to amine-containing molecules, such as proteins (Smith *et al*., 1978). The aromatic amine may also be used to conjugate the modified oligosaccharide directly with amine-reactive crosslinking agents or probes.

Another potential reaction of created or native aldehyde groups on carbohydrates is with hydrazide functionalities to form hydrazone linkages. Hydrazide-containing probes or crosslinking reagents may be conjugated with periodate-oxidized polysaccharides or with the reducing ends of sugars. The hydrazone bonds may be reduced with sodium cyanoborohydride to more stable linkages (Chapter 3, Section 5.1). The reduction step is recommended for long-term stability of crosslinked molecules. An example of this modification strategy is the use of biotin-hydrazide (Chapter 11, Section 6.4) or hydrazide-PEG_4-biotin (Chapter 18, Section 1.3) to label specifically glycoproteins at their carbohydrate locations.

Reducing sugars can be detected by reaction with phenylhydrazine to yield a hydrazone product, except the result of the reaction is not what one might imagine given the structure of aldoses and ketoses. Glucose, for example, can react with phenylhydrazine to yield the anticipated 1-phenylhydrazone derivative. In an excess of phenylhydrazine, however, the reaction continues to yield a 1,2-phenylhydrazone product, called an osazone, with concomitant production of aniline and ammonia (Figure 2.31). Exactly how the number 2 hydroxyl group gets oxidized to react with another molecule of phenylhydrazine is not entirely clear, but probably proceeds through an enol intermediate. This reaction is typical of all α-hydroxy aldehydes and α-hydroxy ketones, not just those occurring in carbohydrate molecules. Thus, glucose, mannose, and fructose all yield the same osazone product upon reaction with phenylhydrazine, since the stereochemical differences about carbons 1 and 2 are eliminated. Reversal of the phenylhydrazone linkage with an excess of benzaldehyde yields an osone, a 1-aldehyde-2-keto-derivative of the sugar. Many simple hydrazide-containing reagents probably are capable of forming similar 1,2-hydrazone

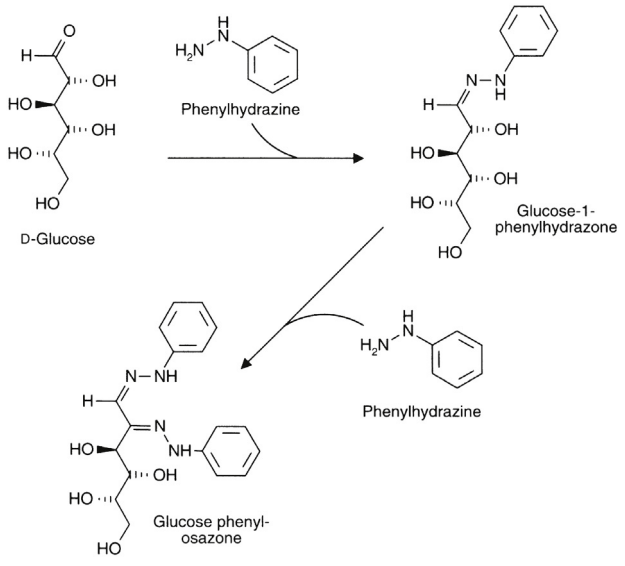

FIGURE 2.31 Phenylhydrazine can react with aldehyde or ketone groups within carbohydrates to give detectable products.

derivatives with reducing sugars, provided their size does not cause steric difficulties.

Polysaccharides, glycoproteins, and other glycoconjugates therefore may be specifically labeled on their carbohydrate portions by creating aldehyde functionalities and subsequently derivatizing them with another molecule containing an amine or a hydrazide group. This route of derivatization is probably the most common way of modifying carbohydrates.

The hydroxyl residues of polysaccharides may also be activated by certain compounds that form intermediate reactive derivatives containing good leaving groups for nucleophilic substitution. Reaction of these activated hydroxyls with nucleophiles such as amines results in stable covalent bonds between the carbohydrate and the amine-containing molecule. Activating agents that can be employed for this purpose include carbonyl diimidazole (Chapter 3, Section 4.2, and Chapter 3, Section 3), certain chloroformate derivatives (Chapter 3, Section 4.3), tresyl- and tosyl-chloride, cyanogen bromide, divinylsulfone, cyanuric chloride (Chapter 18, Section 2.1), disuccinimidyl carbonate (Chapter 5, Section 1.7), and various *bis*-epoxide compounds (Chapter 3, Section 1.8). Refer also to Chapters 14 and 15 for the use of many of these activators in the coupling of affinity ligands to particles or chromatography supports. Such activation procedures are typically carried out in nonaqueous solutions (i.e., dry dioxane, acetone, DMF, or DMSO) to prevent hydrolysis of the active species. While many pure polysaccharides can tolerate these organic environments, many biological glycoconjugates cannot. Thus, these methods are suitable for activating pure polysaccharides such as dextran, cellulose, agarose, and other carbohydrates, but are not appropriate for modifying sugar residues on glycoproteins. Many of these hydroxyl-activating reagents can also be used to activate polysaccharide chromatography supports and other hydroxyl-containing synthetic polymers such as polyethylene glycol or hydroxylic particles (Chapters 14, 15, and 18). For a complete treatment of polysaccharide chromatographic support activation through hydroxyl groups, see Chapter 15 and Hermanson *et al*. (1992). For a description of the activation of soluble polysaccharides and synthetic polymers, see Chapter 18.

While the hydroxyl groups on carbohydrate molecules are nucleophilic in aqueous solution, they are approximately equal to water in relative nucleophilicity. Since the majority of reactive functionalities on bioconjugation reagents are dependent upon nucleophilic reactions to initiate covalent bond formation, specific hydroxyl group modification is usually not possible in aqueous solution—especially with other biomolecules displaying stronger nucleophilic groups as well (e.g., amines and thiols). In many instances, hydrolysis of the active groups on crosslinking reagents occurs faster than hydroxyl group modification, due to the relative high abundance of water molecules compared to the amount of carbohydrate hydroxyls present. In some cases, even if modification does occur, the resultant bond may be unstable. For instance, NHS esters (Chapter 3, Section 1.4) can react with hydroxyls to form ester linkages, which are themselves unstable to hydrolysis.

Anhydrides, such as acetic anhydride (Sections 4.2 and 5.1, this chapter), may react with carbohydrate hydroxyls even in aqueous environments to form acyl derivatives. The reaction, however, is reversible by incubation with hydroxylamine at pH 10 to 11.

Epoxide-containing reagents, such as the homobifunctional 1,4-(butanediol) diglycidyl ether (Chapter 5, Section 7.1), can react with polysaccharide hydroxyl groups to form stable ether bonds. *bis*-Epoxy compounds have been used to couple sugars and polysaccharides to insoluble matrices for affinity chromatography (Sundberg and Porath, 1974; see also Chapter 15, Section 2.3). The reaction of epoxides, however, is not specific for hydroxyl groups and they will cross-react with amines and sulfhydryls if these functionalities are present.

Hydroxyl groups on carbohydrates may be modified with chloroacetic acid to produce a carboxylate functionality for further conjugation purposes (Plotz and Rifai, 1982). In addition, endogenous carboxylate groups, such as those in sialic acid residues and aldonic-or uronic-acid-containing polysaccharides, may be targeted for modification using typical carboxylate modification reactions (Chapter 3, Section 3). However, when these polysaccharides are part of macromolecules containing other carboxylic acid groups such as glycoproteins, the targeting will not be specific for the carbohydrate alone. Pure polysaccharides containing carboxylate groups may be coupled to amine-containing molecules by use of the carbodiimide reaction (Chapter 4, Section 1). The carboxylate is activated to an *O*-acylisourea intermediate, which is in turn attacked by the amine compound. The result is the formation of a stable amide linkage with loss of one molecule of isourea.

Carbohydrate molecules containing amine groups, such as D-glucosamine, may easily be conjugated to other macromolecules using a number of amine-reactive chemical reactions and crosslinkers (Chapters 3 to 6). Some polysaccharides containing acetylated amine residues, such as chitin which contains *N*-acetyl-glucosamine, may be deacetylated under alkaline conditions (Jeanloz, 1963) to free the amines (forming chitosan in this case).

Amine functionalities may also be created on polysaccharides (Section 4.3, this chapter). The reducing ends of carbohydrate molecules (or generated aldehydes) may be reacted with small diamine compounds to yield short alkylamine spacers that can be used for

subsequent conjugation reactions. Hydrazide groups may be similarly created using *bis*-hydrazide compounds (Sections 4.5 and 4.6, this chapter).

Phosphate-containing carbohydrates that are stable, such as the 5′-phosphate of the ribose derivatives of oligonucleotides, may be targeted for modification using a carbodiimide-facilitated reaction (Section 4.3, this chapter). The water soluble carbodiimide EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide) can react with the phosphate groups to form highly reactive phosphoester intermediates. These intermediates can react with amine-or hydrazide-containing molecules to form stable phosphoramidate bonds.

Polysaccharide and Glycoconjugate Structure

Aldose monosaccharide units are frequently bound together through the number 1 carbon hydroxyl group of one sugar to another sugar's number 4 or 6 hydroxyl group, forming a complete acetal linkage. Two monosaccharides coupled in this fashion are termed a disaccharide. Numerous monosaccharides bound together to form a chain are called a polysaccharide. The most abundant polysaccharides in nature, starch and cellulose, consist of glucose bound together in α-1,4, β-1,4, and, to a lesser extent, α-1,6 acetal linkages (Figure 2.32). While the hemiacetal, cyclic structure of individual sugars shows some reversibility under equilibrium conditions, the acetal linkage between two monosaccharides is quite stable, only hydrolyzing under severe pH extremes.

Similarly, ketose sugars participate in polysaccharide formation by reaction of their anomeric carbon with a hydroxyl of another monosaccharide to create a ketal linkage. The acetal and ketal bonds within polysaccharides are termed *O*-glycosidic linkages.

Hemiacetal hydroxyl groups of carbohydrate molecules may also be coupled to amine-containing molecules to form *N*-glycosidic linkages, such as those in nucleic acids and oligonucleotides.

Polysaccharides may or may not have reducing power, depending on the way they are linked together and whether the terminal, potentially reducing end is available. The structure of simple disaccharides can illustrate this point. Of the most common disaccharides, sucrose and lactose, sucrose is a non-reducing sugar since β-D-fructose is linked through its reducing C-2 hydroxyl, and lactose remains a reducing sugar, since the terminal glucose is linked to β-D-galactose through its C-4 hydroxyl, leaving its reducing end free (Figure 2.33).

Polysaccharide synthesis is under enzymatic control, but does not occur from a template as in protein synthesis. For this reason, each molecule of a particular polysaccharide will have its own unique molecular weight. The molecular weight of a carbohydrate polymer is usually expressed as an average. Starch

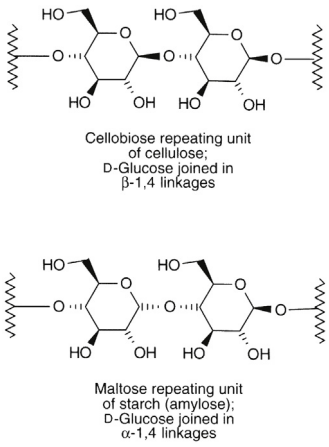

FIGURE 2.32 The repeating units of cellulose and starch, two of the most common polysaccharides in nature.

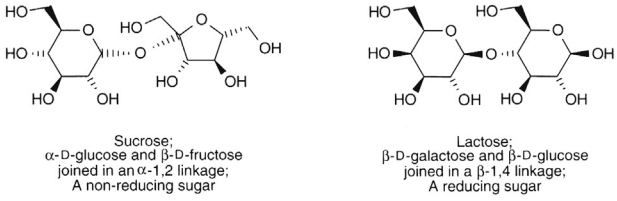

FIGURE 2.33 Comparison of a reducing and a nonreducing disaccharide.

or cellulose chains, for example, may vary by several hundred thousand in their molecular weights between individual molecules. For an excellent review of carbohydrate chemistry, see Binkley (1988).

Due to their polyhydroxylic structures, all carbohydrates are polar and will possess associated water molecules in aqueous solution, but they may not be fully water soluble. Large polysaccharides such as cellulose form intricate matrices created from extensive hydrogen bonding. Neighboring monosaccharide units hydrogen bond within the same chain, while neighboring polymers form interchain hydrogen bonds between hydroxyls. The three-dimensional structure of a carbohydrate to a large extent is determined by these hydrogen bonds—sometimes resulting in sheeted or helical structures, as in the triple helix of agarose polysaccharide chains. Water will be intimately associated in this internal arrangement, but the overall multi-polymer structure is often too large to allow for complete water solubility. For a review, see Preis (1980).

Polysaccharide solubility in aqueous solutions is usually dependent on polymer size and its allied three-dimensional structure. Even water-insoluble carbohydrates may be solubilized by controlled hydrolysis of *O*-glycosidic linkages to create smaller polysaccharide molecules. Thus, cellulose may be solubilized by

heating in an alkaline solution until the polymers are broken up sufficiently to reduce their average molecular weight. Many such soluble forms of common polysaccharides are available commercially.

Carbohydrate also is an important constituent of many biological molecules. Polysaccharides may be found covalently conjugated to proteins and lipids, forming glycoproteins, proteoglycans, glycolipids, and lipopolysaccharides. Such glycoconjugates (glycans) are produced in the cell through controlled, enzymatic processes. With proteins, the modification occurs after translational synthesis of the polypeptide chain at the ribosome.

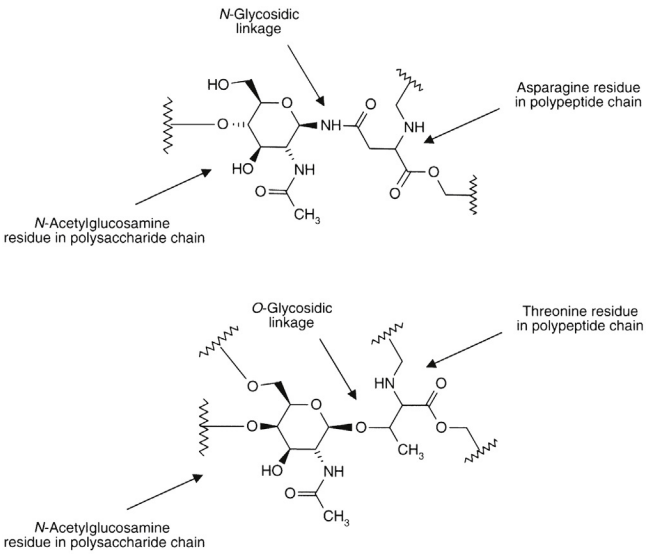

FIGURE 2.34 Common attachment points for polysaccharide chains on glycoproteins.

Proteins newly synthesized on ribosomes may be transported to the Golgi apparatus where specific glycosyl transferases catalyze the coupling of monosaccharides to the polypeptide chains. Glycoproteins and mucoproteins are formed by the coupling of polysaccharides through *O*-glycosidic linkages to serine, threonine, or hydroxylysine in addition to *N*-glycosidic linkages with the amide side-chain group of asparagine (Figure 2.34). For reviews of glycoconjugate structure and function, see Hynes (1987), Lennarz (1980), Jentoft (1990), Steer and Ashwell (1986), and the entire issue of *Science*, Vol. 291, March 23, 2001 (special edition on carbohydrates and glycobiology). The GlycomeDB also may be consulted to provide exact structures of known carbohydrates and glycans (Ranzinger *et al*., 2010).

The structure of most glycoprotein carbohydrate consists of a complex, branched heteropolysaccharide with the sugars mannose, *N*-acetyl glucosamine, sialic acid, galactose, and *L*-fucose being prevalent. Asparagine-linked polysaccharides are well characterized and are known to be constructed of a core unit consisting of three mannose residues and two *N*-acetyl-glucosamine (GlcNAc) residues. The GlcNAc residues are bound to the Asp side-chain amide nitrogen through a β1 linkage (Kornfield and Kornfield, 1985). The three mannose groups then usually form the first branch point in the oligosaccharide chain. Figures 2.35 and 2.36 illustrate

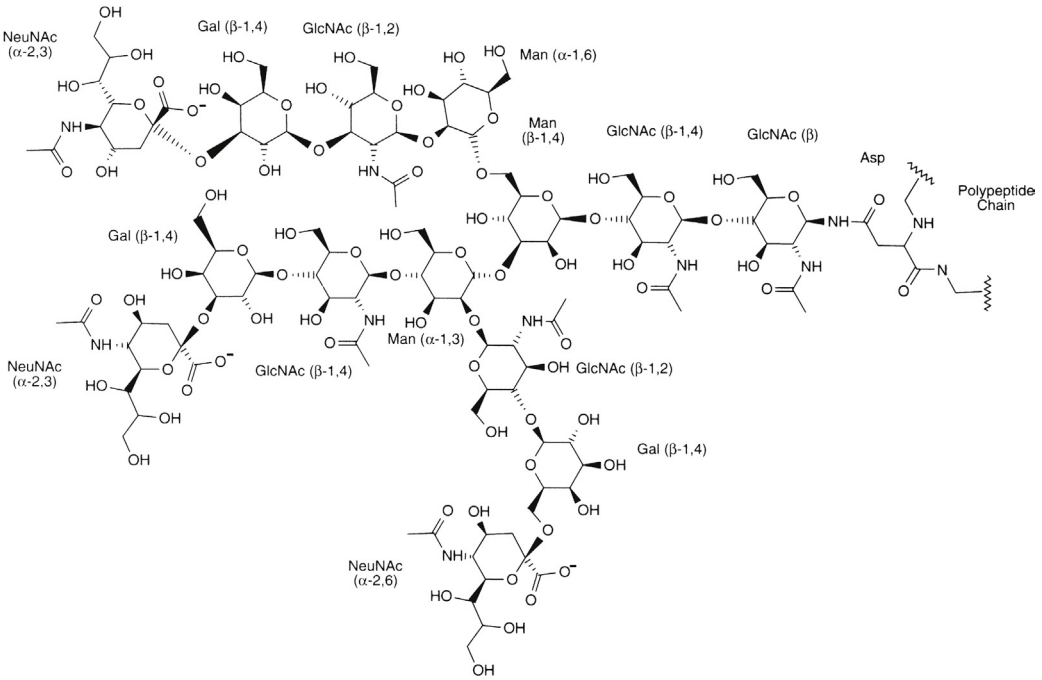

FIGURE 2.35 The complex structure of an asparagine-linked polysaccharide. Note the branched nature of the polymer with terminal sialic acid residues on each chain.

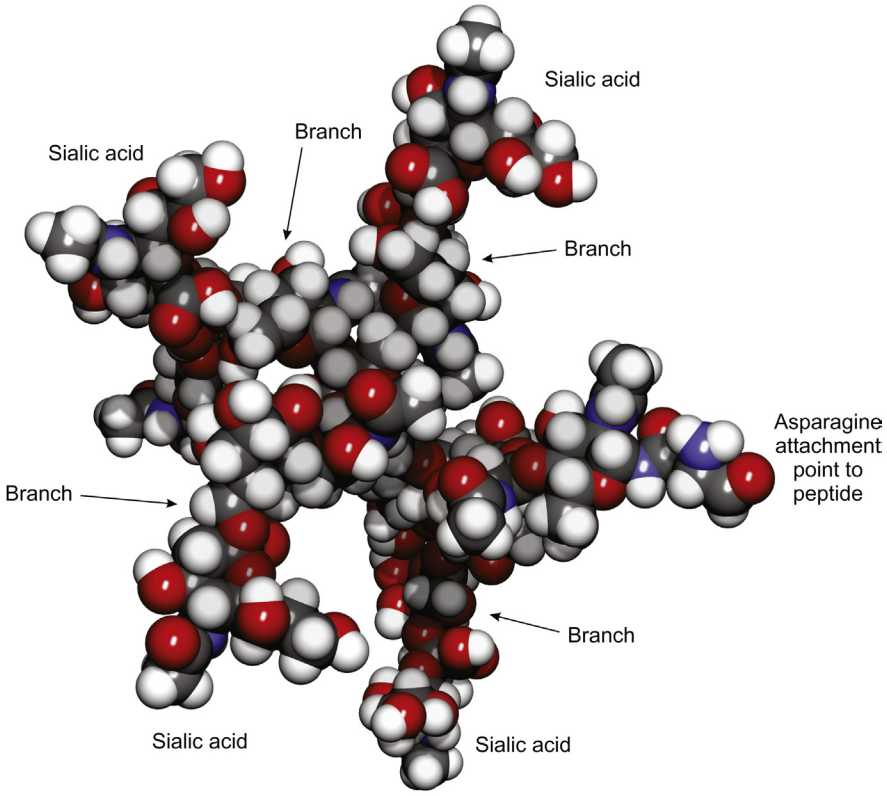

FIGURE 2.36 A space-filling model of an *N*-linked glycan showing four branch points.

the chemical makeup of a typical *N*-linked glycan and a space-filling model of a glycan's molecular structure. Much of the detailed structural knowledge of glycoconjugates is developed using controlled chemical or enzymatic degradation of the polysaccharides followed by analysis by gas chromatography and mass spectrometry (Vliegenthart *et al.*, 1983; Sweeley and Nunez, 1985; McCleary and Matheson, 1986; Biermann and McGinnis, 1989).

The content by weight of carbohydrate in glycoproteins may vary from only a few percent to as much as 70% in some proteins in mucous secretions. Although the exact function of the polysaccharide in most glycoproteins is unknown, in some cases it may provide hydrophilicity, recognition, and points of non-covalent interaction with other proteins through lectin affinity binding. Glycosylation also contributes to the correct folding of proteins after translation, probably by ensuring that certain amino acid regions end up at the surface of the protein structure. In addition, extensive polysaccharide modification is helpful in preventing proteolytic digestion of the underlying polypeptide chain.

Another form of post-translational modification that may add carbohydrate to a polypeptide is non-enzymatic glycation. This reaction occurs between the reducing ends of sugar molecules and the amino groups of proteins and peptides. The aldehyde group of a reducing sugar first forms a reversible Schiff base linkage with the α-amino or ε-amino groups of the protein. This bond can then undergo an Amadori rearrangement to form a stable ketoamine derivative (Figure 2.37). The result is a blocked amine containing a sugar derivative with available hydroxyl residues. This reaction commonly occurs with proteins continually exposed to reducing sugars, such as glucose in blood. The measurement of glycated hemoglobin is a clinically important parameter in the management of diabetes mellitus. Increases in the blood sugar level in diabetes are the cause of concomitant increases in the level of non-enzymatic glycation of blood proteins. Measuring the relative amount of glycated hemoglobin provides the physician with information concerning a diabetic patient's blood glucose control.

2.2. Carbohydrate and Glycan Conjugation Methods

The presence of carbohydrate on biomolecules provides important points of attachment for modification and conjugation reactions. Coupling only through polysaccharide chains often can direct the reaction away from active centers or critical points in protein

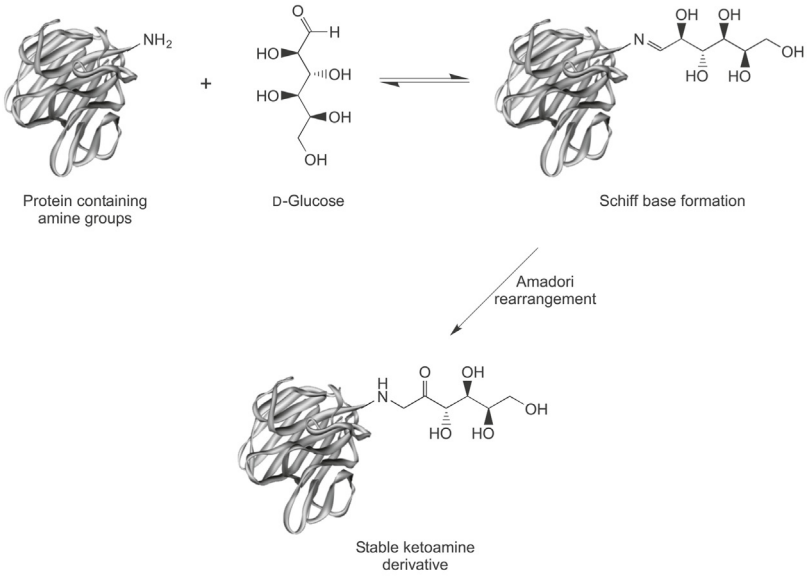

FIGURE 2.37 A reducing sugar may modify protein amine groups through Schiff base formation followed by an Amadori rearrangement to give a stable ketoamine product. Glucose is a common *in vivo* modifier of blood proteins through this process.

molecules, thus preserving activity. Crosslinking strategies involving polysaccharides or glycoconjugates usually involve a two- or three-step reaction sequence. If no reactive functionalities other than hydroxyl groups are present on the carbohydrate, then the first step is to create sufficiently reactive groups to couple with the functional groups of a second molecule.

Perhaps the easiest way specifically to target polysaccharides on glycoproteins is through mild sodium periodate oxidation. Periodate cleaves the carbon–carbon bond connecting adjacent hydroxyl groups in sugar residues to create highly reactive aldehyde functionalities (Section 4.4, this chapter). The level of oxidant addition can be adjusted to cleave selectively only certain sugars in the polysaccharide structure. A concentration of 1-m*M* sodium periodate at 0 to 4°C oxidizes sialic acid residues to aldehydes, leaving all other monosaccharides untouched. Increasing the concentration to 10-m*M* at room temperature, however, will cause oxidation of other sugars in the carbohydrate, including galactose and mannose residues in glycans. The generated aldehydes can then be used in coupling reactions with amine- or hydrazide-containing molecules to form covalent linkages. Amines react with formyl groups under reductive amination conditions when a suitable reducing agent is used, such as sodium cyanoborohydride. The result of this reaction is a stable secondary amine, linkage (Chapter 3, Section 5.3). Hydrazides spontaneously react with aldehydes to form hydrazone linkages, although the addition of a reducing agent greatly increases the efficiency of the reaction and the stability of the bond (Chapter 3, Section 5.1).

Oxidized glycoconjugates are usually stable enough to be stored in a freeze-dried state without loss of activity prior to a subsequent conjugation reaction, provided the protein itself is stable to lyophilization. Storage in solution, however, may cause slow polymerization if the molecule also contains amine groups, as in glycoproteins. Sometimes the protein can be treated to block its amines prior to periodate oxidation, as in the procedure often used with the enzyme horseradish peroxidase (HRP) (Chapter 22, Section 1.1), thus eliminating the potential for self-conjugation. Even in the absence of amines, periodate-oxidized HRP may polymerize due to the Mannich reaction (Chapter 3, Section 5.5).

If the second molecule to be coupled to the oxidized glycoconjugate already has the requisite amines or hydrazide groups, then directly mixing the two components together in the presence of a reductant is all that is needed to form the conjugate. This is an example of a two-step procedure. However, if the second molecule possesses none of the appropriate functionalities for coupling, then modifying it to contain amine or hydrazide groups must be carried out prior to the conjugation reaction (see Section 4.3 and 4.5), which results in a three-step protocol. The use of other functionalities (either indigenous or created) on polysaccharide molecules to effect a crosslinking reaction can be carried out in similar two- or three-step strategies.

Occasionally, it is important to conjugate a polysaccharide-containing molecule to another molecule while retaining, as much as possible, the carbohydrate's original chemical and three-dimensional structure. For instance, in the preparation of immunogen conjugates

by coupling a polysaccharide molecule to a carrier, care should be taken to preserve the structure of the carbohydrate to ensure antibody recognition of the native molecule. In this case, periodate oxidative techniques may not be the best choice to effect crosslinking due to the potential for extensive ring opening throughout the chain. Under controlled conditions, however, where periodate is carefully used in limiting quantities, this method has proved successful in creating oligosaccharide–carrier conjugates (Anderson *et al.*, 1989).

Retention of native carbohydrate structure is also important in applications that utilize the conjugated polysaccharide in binding studies with receptors or lectins. In these cases, the carbohydrate should be modified at limited sites, preferentially only at its reducing end. Section 4.6 of this chapter discusses glycan conjugation techniques in greater detail.

3. MODIFICATION OF NUCLEIC ACIDS AND OLIGONUCLEOTIDES

The nucleic acid polymers DNA and RNA form the most basic units of information storage within cells. The conversion of DNA's unique information code into RNA and proteins is the fundamental step in controlling all cellular processes. Targeting segments of this encoded data with labeled probes that are able to bind to specific genetic regions allows detection, localization, or quantification of discrete oligonucleotide sequences. This targeting capability is made possible by the predictable nature of nucleic acid interactions. Despite the complexity of the genetic code, the base-pairing process that causes one oligonucleotide to bind to its complementary sequence is rather simple to predict and decipher. Nucleic acids are the only type of complex biological molecule wherein their binding properties can be fully anticipated and incorporated into synthetic oligonucleotide probes. Thus, a short DNA segment can be synthetically designed and used to target and hybridize to a complementary DNA strand within much larger chromosomal material or extracted genomic DNA. If the small oligonucleotide is labeled with a detectable component that does not interfere in the base-pairing process, then the targeted DNA can be identified or assayed.

Bioconjugate techniques involving nucleic acids are becoming one of the most important application areas of crosslinking and modification chemistry. With the secrets of the genetic code now revealed by such mammoth efforts as the Human Genome Project, knowledge of the DNA sequence that governs specific protein expression is leading to diagnostic tests able to assess the presence of critical genetic markers associated with certain disease states. To test for particular target sequences, complementary oligonucleotide probes are used that possess conjugated enzymes, fluorophores, haptens, radiolabels, or other such groups which can be used to detect a hybridization signal. Such oligonucleotide conjugates can be used to discover target sequences in blots, electrophoresis gels, tissues, cells immobilized to surfaces, or in solution.

The power and advantages of assessing cellular processes at their most fundamental level is propelling the science of oligonucleotide probe detection into one of the most prominent positions in bioconjugate chemistry. Oligonucleotide arrays containing hundreds or thousands of tests are now carried out routinely to monitor different aspects of genetic information—all with the use of specific oligonucleotide probes.

In this section, the chemistry and structure of nucleic acids and oligonucleotides are discussed with a view to creating functional conjugates with detectable molecules. The corresponding strategies and protocols associated with DNA or RNA modification and conjugation can be found in Chapter 23.

3.1. Polynucleotide Structure and Functionality

Nucleic acid polymers are characterized by the types of base residues present and the structure of their sugar backbone. The bases are nitrogenous ring compounds consisting of either purine or pyrimidine derivatives. A purine is a fused-ring compound containing one six-membered ring attached to a five-membered ring, whereas a pyrimidine consists of a single six-membered ring structure (Figure 2.38).

Nucleic acids can contain of any one of three kinds of pyrimidine ring systems (uracil, cytosine, or thymine) or two types of purine derivatives (adenine or guanine). Adenine, guanine, thymine, and cytosine are the four main base constituents found in DNA. In RNA molecules, three of these four bases are present, but with thymine replaced by uracil to make up the fourth. Some additional minor derivatives are found in messenger RNA (mRNA), transfer RNA (tRNA), and ribosomal RNA (rRNA), particularly the N^4,N^4-dimethyladenine and N^7-methylguanine varieties.

Nucleic acid sugar residues are attached to the associated base units in an *N*-glycosidic bond, involving the

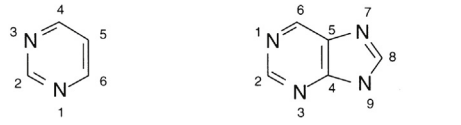

FIGURE 2.38 The pyrimidine and purine ring structures common to nucleic acids.

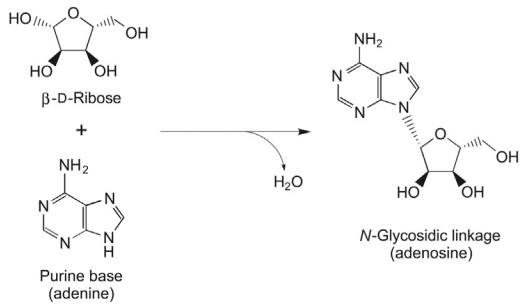

FIGURE 2.39 The formation of an *N*-glycosidic bond links the base unit of nucleic acids to the associated ribose derivative.

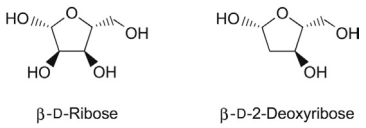

FIGURE 2.40 The two forms of sugar residues commonly found in nucleic acids. β-D-Ribose is the sugar constituent of RNA, while β-D-2-deoxyribose is a component of DNA.

number 1 nitrogen of pyrimidine bases or the number 9 nitrogen of purines directly linked to the number 1 carbon of the monosaccharide derivative (Figure 2.39). The sugar group consists of either a β-D-ribose unit (found in RNA) or a β-D-2-deoxyribose unit (in DNA) (Figure 2.40). In mRNA and rRNA, a minor sugar derivative, a 2′-*O*-methylribosyl group, also is found.

The nomenclature of nucleic acid chemistry further characterizes the structure of the associated groups. A *nucleoside* contains only a base group and an attached sugar. A *nucleotide* consists of a base and a sugar plus a phosphate group. At this point, the naming system gets somewhat confusing due to the fact that the nucleoside name is a derivative of the base name. Table 2.2 shows this relationship and their associated abbreviations (which are simpler to remember).

In each nucleotide monomer of DNA or RNA molecules, a phosphate group is attached to the C-5 hydroxyl of each sugar residue in an ester (anhydride) linkage. These phosphate groups in turn are linked in diester bonds to neighboring sugar groups of adjacent nucleotides through their 3′-ribosyl hydroxyl to create the oligonucleotide polymer backbone (Figure 2.41). Thus, the phosphate–sugar repeating unit produces the linear sequence within the DNA or RNA structure, while the four types of base units protrude out from this backbone, creating the unique code making up the genetic information.

Nucleotide Functional Groups

Chemical attachment of a detectable component to an oligonucleotide forms the basis for constructing a sensitive hybridization reagent. Unfortunately, the methods developed to crosslink or label other biological molecules such as proteins do not always apply to nucleic acids. The major reactive sites on proteins involve primary amines, sulfhydryls, carboxylates, or phenolates—groups that are relatively easy to derivatize. RNA and DNA contain none of these functionalities. They also are relatively unreactive directly with many of the common bioconjugate reagents discussed in Part II.

TABLE 2.2 Nucleic Acid Nomenclatures

Base Name	Nucleoside Name[a] (Base + Sugar)	Nucleotide Name[b] (Base + Sugar+Phosphate)
Adenine	Adenosine	Adenosine monophosphate (AMP)
Guanine	Guanosine	Guanosine monophosphate (GMP)
Cytosine	Cytidine	Cytidine monophosphate (CMP)
Thymine	Thymidine	Thymidine monophosphate (TMP)
Uracil	Uridine	Uridine monophosphate (UMP)

[a]*For deoxyribose nucleosides, add "deoxy" before the nucleoside name; for example, adenosine becomes deoxyadenosine.*
[b]*For the presence of two phosphate groups, the names are changed to diphosphate; for three phosphate groups, the terminology is triphosphate.*

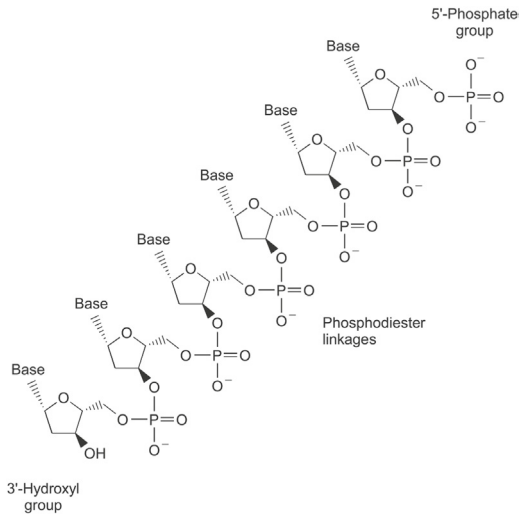

FIGURE 2.41 Polynucleotides are formed through phosphodiester bonds linking the associated sugar groups together. In DNA, the 3′-hydroxyl of one deoxyribose unit is bound to the 5′-hydroxyl of the next, creating direction in the polymer backbone.

However, there are particular sites that can be modified on the bases, sugars, or phosphate groups of nucleic acids to produce derivatives able to couple with a second molecule. The chemistry is almost entirely unique to DNA and RNA work, but once mastered the process of conjugation can be carried out with the same ease as with protein molecules.

The following sections discuss the major constituents of oligonucleotides with special emphasis on the chemical sites useful for bioconjugation.

Cytosine, Thymine, and Uracil Residues

The pyrimidine base units cytosine, thymine, and uracil contain six-membered nitrogenous ring structures with various points of unsaturation. Thymine and uracil are similar, containing the same double bond between carbons 5 and 6 and the same two ketone groups on C-2 and C-4 of the ring, but differ only in the presence of a methyl group on the number 5 carbon of thymine. Cytosine, by contrast, contains an additional site of unsaturation between carbons 3 and 4 as well as an amine group on C-4 instead of a ketone (Figure 2.42).

Figure 2.43 indicates major sites of reactivity within the ring structures for nucleophilic displacement reactions. Cytosine, thymine, and uracil all react toward nucleophilic attack at the same two sites, the C-4 and C-6 positions. The presence of powerful nucleophiles, even at neutral pH, can lead to significant base modification or cleavage with pyrimidine residues (Debye, 1947). For instance, hydrazine spontaneously adds to the 5,6-double bond, initiating further ring reactions, which eventually leads to oligonucleotide degradation. A similarly strong nucleophile, hydroxylamine is almost entirely specific for modifying pyrimidines. It too can add to the 5,6-double bond, creating a 6-hydroxylamino derivative. In general, the pyrimidines can undergo reactions at the 5,6-double bond leading to a stable modification at the C-5 position (Figure 2.44).

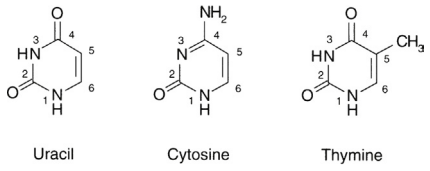

FIGURE 2.42 The three pyrimidine bases common to nucleic acid construction. Cytosine and thymine are found in DNA, while in RNA uracil residues replace thymine. The associated sugar groups are bound in *N*-glycosidic linkages to the N-1 nitrogen.

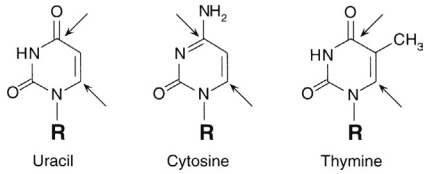

FIGURE 2.43 Pyrimidine bases ate subject to nucleophilic displacement reactions primarily at the C-4 and C-6 positions.

Addition of a nucleophile to the C-6 position of cytosine often results in fascile displacement reactions occurring at the N-4 location. With hydroxylamine attack, nucleophilic displacement causes the formation of an N^4-hydroxy derivative. A particularly important reaction for bioconjugate chemistry, however, is that of nucleophilic bisulfite addition to the C-6 position. Sulfonation of cytosine can lead to two distinct reaction products. At acid pH wherein the N-3 nitrogen is protonated, bisulfite reaction results in the 6-sulfonate product followed by spontaneous hydrolysis. Raising the pH to alkaline conditions causes effective formation of uracil. If bisulfite addition is carried out in the presence of a nucleophile, such as a primary amine or hydrazide compound, then transamination at the N-4 position can take place instead of hydrolysis (Figure 2.45). This is an important mechanism for adding spacer arm functionalities and other small molecules to cytosine-containing oligonucleotides (see Chapter 23, Section 2).

Electrophilic reagents can also modify the pyrimidine rings of nucleic acids. Alkylation and acylation reactions can take place at several sites on all three bases. Figure 2.46 illustrates the principal locations where electrophilic attack can occur. In particular, the heteroatoms (oxygen and nitrogen) are the best positions of high electron density, thus functioning as nucleophiles in reaction processes. Of the pyrimidine residues, however, it is the N-3 position of cytosine derivatives that is the most susceptible to alkylation. Reactions can occur with ethylenimine compounds (Section 4.3, this chapter), alkyl halogens (Chapter 3, Section 2.1), epoxides (Chapter 3, Section 1.8), and many other strong alkylating agents (for a review, see Brown, 1974).

Acylation reactions can be carried out at the nucleophilic sites on pyrimidines using activated forms of carboxylic acids. Acylation of functional groups in nucleotides is typically used for protection during synthesis (Reese, 1973). However, for bioconjugate

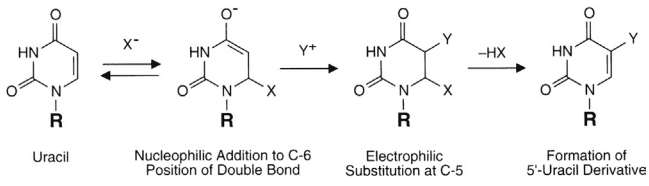

FIGURE 2.44 Nucleophilic addition at C-6 of the pyrimidine double bond can cause electrophilic substitution to occur at the C-5 position.

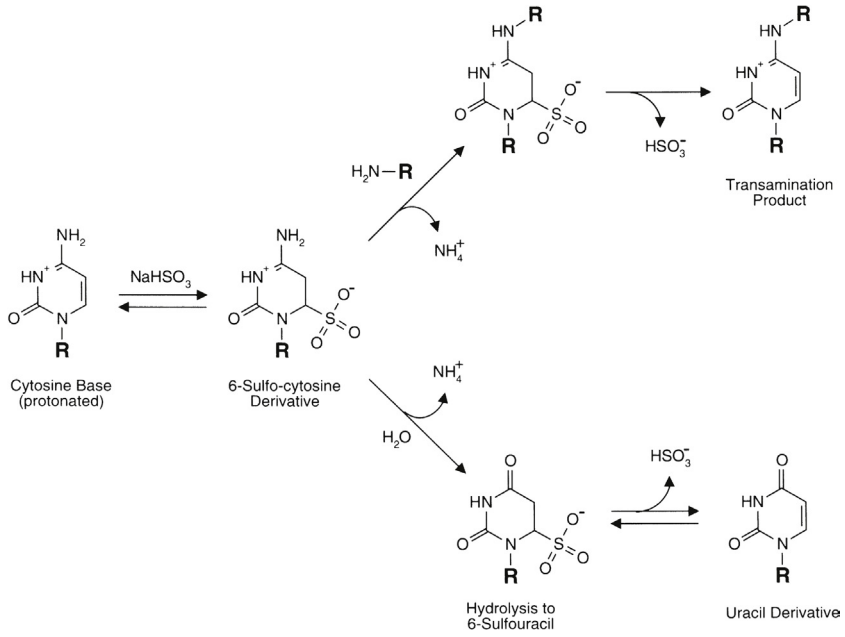

FIGURE 2.45 Reaction of bisulfite with cytosine bases is an important route of derivatization. It can lead to uracil formation or, in the presence of an amine- (or hydrazide)-containing compound, transamination can occur, resulting in covalent modification.

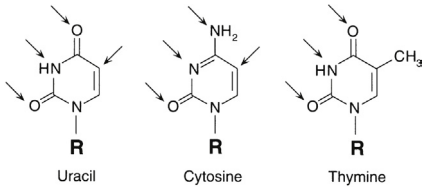

FIGURE 2.46 Potential sites of electrophilic attack on pyrimidine bases.

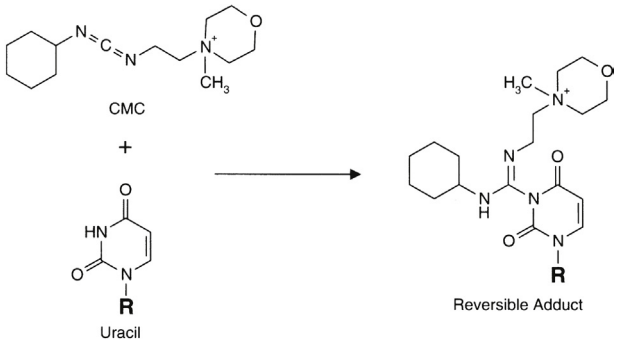

FIGURE 2.47 The carbodiimide CMC can react with the N-3 nitrogen to yield a reversible product.

applications, the reactivity of native groups on pyrimidines is not as great as that obtained using an amine-terminal spacer derivative, such as those described in Chapter 23, Section 2.1. Yields and reaction rates are typically low for direct acylation or alkylation of pyrimidine bases, especially in aqueous environments.

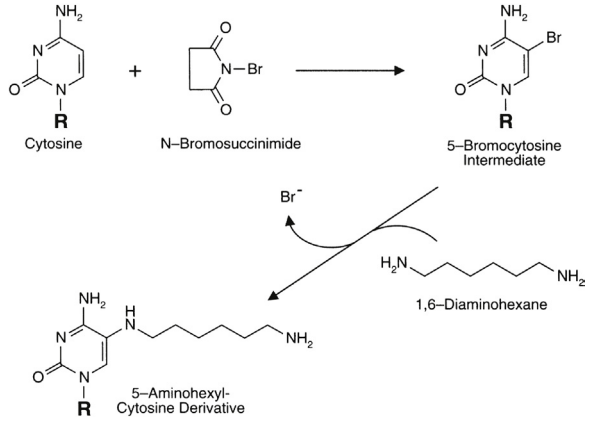

FIGURE 2.48 Cytosine bases are susceptible to bromination at the C-5 double bond position, resulting in active intermediates capable of reacting with amine nucleophiles.

The N-3 position of uracil can also be modified with carbodiimide reagents. In particular, the water soluble carbodiimide CMC (1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide, as the metho *p*-toluene sulfonate salt) can react with the N-3 nitrogen at pH 8 to give an unstable, charged adduct. The derivative is reversible at pH 10.5, regenerating the original nucleic acid base (Figure 2.47). Cytosine is unreactive in this process.

Halogenation of pyrimidine bases may be carried out with bromine or iodine. Bromination occurs at the C-5 of cytosine, yielding a reactive derivative, which can be used to couple diamine spacer molecules by nucleophilic substitution (Figure 2.48) (Traincard *et al.*, 1983; Sakamoto

et al., 1987; Keller *et al*., 1988). Other pyrimidine derivatives are also reactive to bromine compounds at the C-5 position. Either an aqueous solution of bromine or the compound *N*-bromosuccinimide can be used for this reaction. The brominated derivatives can then be used to couple amine-containing compounds to the pyrimidine ring structure (Chapter 23, Section 2.1).

Other reactions characterized for pyrimidine residues include mercuration at C-5 of cytosine or uracil (Hopman *et al*., 1986), cycloaddition to the 5,6-double bond of thymine and uracil (Cimino *et al*., 1985), and thiolation at the C-4 amino group of cytosine (Malcom and Nicolas, 1984).

Adenine and Guanine Residues

The purine bases of nucleic acids are constructed of a two-ring system made from a pyrimidine-type, six-membered ring fused with a five-membered imidazole ring. Adenine and guanine are present in both RNA and DNA. They differ in their six-membered ring structures by an additional point of unsaturation between C-6 and N-1 (in adenine) and by the presence of amine or ketone groups attached to C-2 or C-6 (Figure 2.49). Attachment to ribose or deoxyribose in nucleosides is made through an *N*-glycosidic linkage at N-9 of the imidazole ring on either purine.

As in the case of pyrimidine bases discussed previously, adenine and guanine are subject to nucleophilic displacement reactions at particular sites on their ring structures (Figure 2.50). Both compounds are reactive with nucleophiles at C-2, C-6, and C-8, with C-8 being the most common target for modification. However, the purines are much less reactive to nucleophiles than the pyrimidines. Hydrazine, hydroxylamine, and bisulfite—all important reactive species with cytosine, thymine, and uracil—are almost unreactive with guanine and adenine.

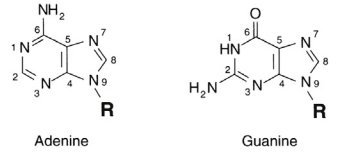

FIGURE 2.49 The structures of the common purine bases of RNA and DNA. The associated sugar groups are bound in *N*-glycosidic linkages to the N-9 position.

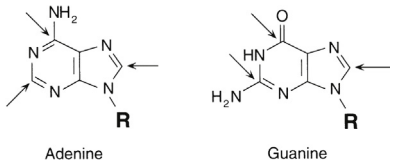

FIGURE 2.50 Primary nucleophilic displacement sites on purine bases.

With purines, reaction with electrophilic species is the most important route to derivatization. Figure 2.51 identifies the major sites of electrophilic attack on adenine and guanine. On both bases it is the heteroatoms that make up the majority of sites. Alkylation reactions thus can occur at N-1, N-3, and N-7 in adenine or N-3 and N-7 in guanine. However, the greatest location of electron density (nucleophilicity) occurs at N-7 on the imidazole ring of guanine, followed by N-1 of adenine. According to Brown (1974), the order of reactivity of nucleosides toward alkylation by esters of strong acids is guanine > adenosine > cytidine >> uridine (nearly unreactive).

As with pyrimidines, the water soluble carbodiimide CMC may react with guanine derivatives to give a reversible adduct at N-1 (Figure 2.52). Raising the pH to highly alkaline conditions regenerates the purine group. Adenine residues, however, display no reactivity in this process.

One of the most important reactions of purines is the bromination of guanine or adenine at the C-8 position. It is this site that is the most common point of modification for bioconjugate techniques using purine bases (Figure 2.53). Either an aqueous solution of bromine or the compound *N*-bromosuccinimide can be used for this reaction. The brominated derivatives can then be used to couple amine-containing compounds to the pyrimidine ring structure by nucleophilic substitution (Chapter 23, Section 2.1).

Adenine may also undergo an additional reaction at its C-6 amine group using a Fischer–Dimroth

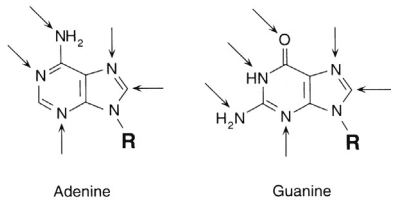

FIGURE 2.51 Electrophilic attack can occur at a number of sites on both purine bases.

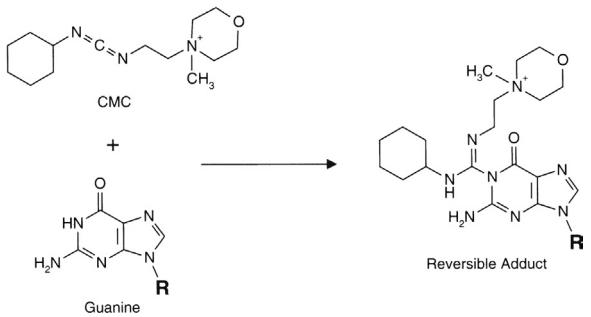

FIGURE 2.52 The carbodiimide CMC can react with guanine at the N-1 position to form a reversible complex.

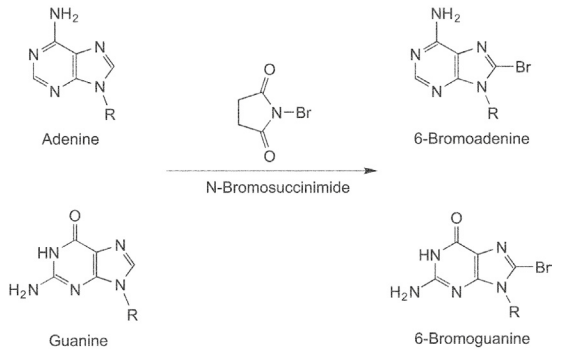

FIGURE 2.53 The purine bases are subject to bromination reactions at the C-8 position, forming an important reactive intermediate for derivatization purposes.

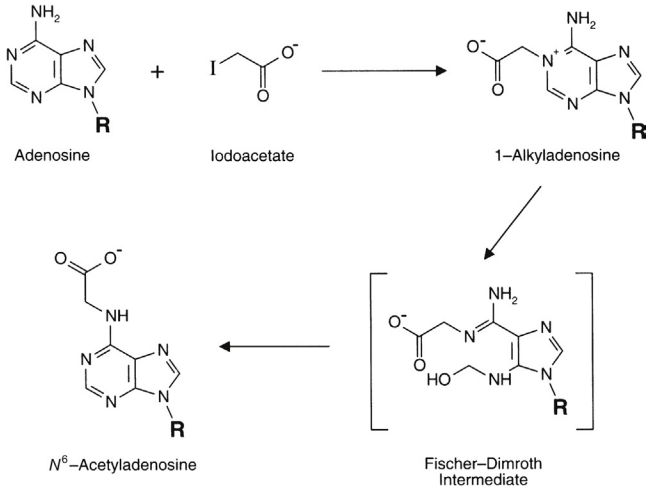

FIGURE 2.54 Alkylation reactions can occur at the N-1 position of adenosine, resulting in a Fischer–Dimroth rearrangement to yield an N^6 derivative.

rearrangement mechanism. Alkylation at N-1 can result in a rearrangement to give the C-6 alkylated product. The reaction at N-1 usually requires extended time to obtain good yields. For instance, alkylation with iodoacetic acid takes 5 to 10 days at pH 6.5. Under alkaline conditions and elevated temperatures, the six-membered ring is then broken and reformed, resulting in the 6-aminoalkylated product containing a terminal carboxylate group (Figure 2.54). The resultant acid can be used in further derivatization reactions to facilitate conjugate formation (Lowe, 1979).

An additional reaction reported for adenine involves the coupling of glutaraldehyde to the 6-amino group (Matthews and Kricka, 1988). However, reaction at this group with electrophilic reagents such as those discussed in Section 2 proceeds more slowly than that possible using a primary aliphatic amine. In general, bioconjugate chemistry carried out with nucleic acid bases involves the formation of an intermediate

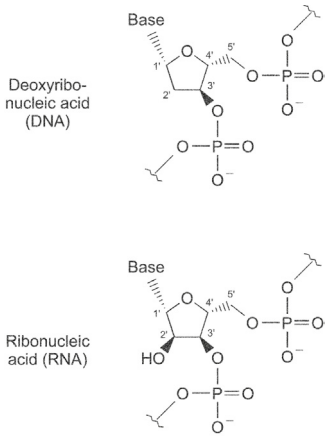

FIGURE 2.55 The similar structures of DNA and RNA basic units.

derivative containing a spacer arm terminating in an amine, sulfhydryl, or carboxylate to obtain acceptable reactivity and yields.

Sugar Groups

The sugar portion of oligonucleotides is a five-carbon pentose occurring in one of two forms. In RNA, it is β-D-ribose in a ring structure. In DNA, the monosaccharide is β-D-2-deoxyribose, wherein the number 2′ carbon of the ring lacks a hydroxyl group. An individual nucleotide will have its 1′ hydroxyl group of the ribose unit tied up in an *N*-glycosidic bond with the associated base and its C-5 hydroxyl group bound to phosphate in an ester linkage. If the nucleotide is of the deoxy form, then the only remaining hydroxyl is on the 3′ carbon of the sugar unit. Ribonucleic acids, by contrast, contain a diol group formed from the two hydroxyls on the 2′- and 3′-carbons of ribose (Figure 2.55). Polymers of nucleic acids are created through diester phosphate bonds, mainly connected between the 5′ hydroxyl of one sugar group and the 3′ hydroxyl of the next adjacent sugar. Thus, DNA contains no hydroxyl groups except the single one at the 3′ terminal of each strand. RNA has one hydroxyl at each nucleotide sugar unit and a diol group at the 3′ end.

Conjugation or modification reactions may be done through the 3′ hydroxyl group of deoxyribonucleic acids or the 2′,3′-diol of ribonucleic acids. Hydroxyls may be targeted for coupling using strong alkylating agents under alkaline conditions. Epoxide compounds (Chapter 5, Section 7) are particularly effective at modifying hydroxyl groups. The most common method of conjugation through nucleotide sugar units, however, is periodate oxidation of the adjacent hydroxyls of ribonucleic acids. Treatment with periodate breaks the carbon–carbon bond between the two hydroxyl residues and creates two aldehyde groups (Seela and Waldeck, 1975). A procedure for oxidizing carbohydrates with sodium

periodate can be found in Section 4.4, this chapter. This method can be used to create RNA conjugates through directed coupling only at the 3′ end or to immobilize ribonucleic acids such as ATP to insoluble supports for affinity chromatography (Lowe, 1979).

Phosphate Groups

The phosphate groups of nucleotides are joined to the 5′ hydroxyl group of the sugar component in an ester or anhydride linkage. Several forms of nucleoside phosphate compounds are possible, containing up to three esterified phosphate groups polymerized off the ribose or deoxyribose unit. The presence of these groups contributes an overall negative charge to the nucleotide—minus two for the terminal phosphate group and minus one for each internal phosphate under alkaline conditions. Multiple esterified phosphates contain considerable potential energy from their easily hydrolyzed anhydride bonds. This energy is the basis for many biochemical transformations in biological systems. It is the triphosphate form of nucleosides that is utilized in DNA and RNA synthesis *in vivo*. However, nucleoside triphosphates and diphosphates such as ATP and ADP have numerous contributions to cellular metabolism beyond just oligonucleotide construction. Controlled hydrolysis of their multiple phosphate ester bonds releases energy for many biological operations. Other derivatives of nucleoside phosphate compounds provide cofactors for enzymes (such as coenzyme A) or are involved in signal transduction processes (such as cyclic AMP [cAMP]). Figure 2.56 shows some of these common nucleoside phosphate derivatives.

The phosphate groups of nucleotides may be targeted for modification reactions using condensation agents such as carbodiimides. In aqueous environments, EDC (Chapter 4, Section 1.1) may be used to couple amine-containing compounds to the terminal phosphate group of an oligonucleotide, forming a phosphoramidate linkage. In DNA or RNA chains, the internal phosphate groups do not react under the pH conditions of the modification. In this way, the 5′-phosphate group may be specifically targeted for modification or conjugation, thus avoiding potential interference with hydrogen bonding interactions with complementary polynucleotide strands. Chapter 23, Sections 2.1 and 2.2 describe the use of this reaction in bioconjugate applications.

Another phosphate modification procedure that is effective at adding detectable components to oligonucleotide probes is to use a phosphoramidite derivative. The common method of automated oligonucleotide synthesis is to use phosphoramidite chemistry to add nucleotides to the growing sequence. A functionalized phosphoramidite nucleotide derivative can be added at particular points in the synthetic process to create labeled probes

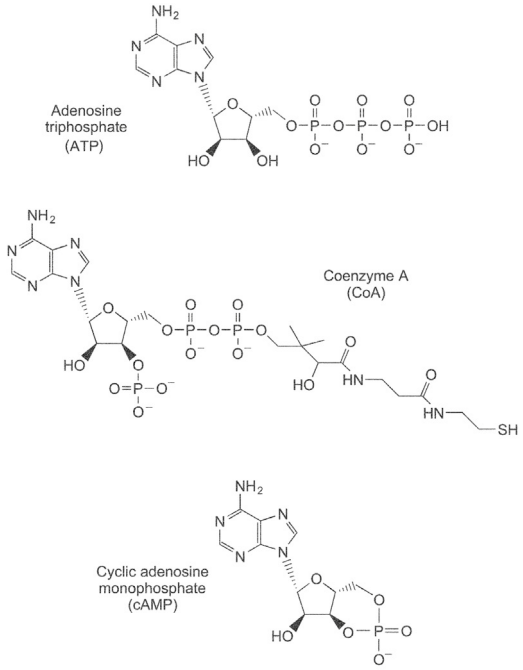

FIGURE 2.56 Nucleotide derivatives have additional functions *in vivo* beyond their role in oligonucleotide construction.

of known structure. Non-nucleotide phosphoramidites may also be used to produce modified probes containing fluorescent molecules, biotin, chelating groups, or spacer groups with amines for further derivatization. Most of these techniques require an automated DNA synthesizer. The methods of DNA modification during synthesis have been reviewed and are beyond the scope of this book (Beaucage and Iyer, 1993).

RNA and DNA Structure

The nucleotides forming RNA or DNA molecules are linked together in phosphodiester bonds with sugar–phosphate repeating units. The esters are directionally linked between the 3′ hydroxyl of one ribosyl group and the 5′ hydroxyl of the next. The fundamental step in cellular DNA synthesis involves the reaction of a deoxynucleoside triphosphate group with the 3′ end of an existing chain. The nucleotide sequence of a new strand is enzymatically controlled by use of a complementary chain as a template. Each new nucleotide addition is facilitated by the energy released through hydrolysis of two phosphates from the triphosphate group of the incoming nucleoside. The resulting succession of nucleotides encodes the message for protein synthesis, with each three-base code signaling a particular amino acid in a polypeptide sequence.

Nucleotide bases projecting from the sugar–phosphate backbone of a polynucleotide are able to interact with other strands through hydrogen bonding. Hydrogen bonding can occur between cytosine and guanine base

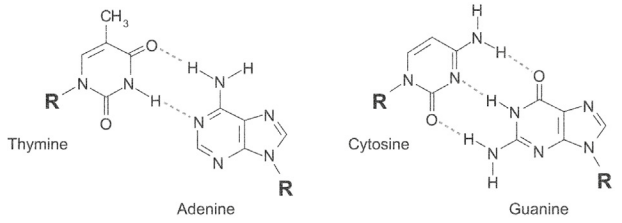

FIGURE 2.57 Base-pairing can occur between complementary bases in opposing oligonucleotide strands. These predictable interactions form the basis for using synthetic oligonucleotide probes to target particular DNA sequences.

units in different strands of DNA through interaction of the C-2 ketone oxygen, the N-3 nitrogen, and C-4 amine groups of cytosine with the C-2 amine, N-1 nitrogen, and the C-6 ketone oxygen of guanine. In a similar fashion, thymine (or uracil) residues can hydrogen bond with adenine groups through the N-3 nitrogen and C-4 ketone oxygen of thymine interacting with the N-1 nitrogen and C-6 amine of adenine (Figure 2.57).

This specific base-pairing capability of oligonucleotides defines the structure of complementary DNA molecules. In the classic Watson–Crick model, two complementary DNA strands interact in an antiparallel fashion to form a right-handed double helix. Thus, one chain runs in the 3′-to-5′ direction while the complementary chain runs in the 5′-to-3′ direction through the helical structure. This standard double helix, now called the B form, occurs often in aqueous solution and is the most stable structure under physiological conditions (Figure 2.58). However, there are several other forms that double-stranded DNA can take in solution. Another right-handed helical construction, the A form, can occur under nonaqueous conditions and is more compact than the B form. A completely different DNA structure, the Z form, is a left-handed helix that can occur in some segments containing an abundance of alternating pyrimidines and purines. Short segments of Z structure have been found in some cells. Finally, some rare DNA sequences can form triple-helical regions through normal and non-Watson–Crick base pairing.

Unlike the double-stranded nature of DNA, RNA molecules usually occur as single strands. This does not mean they are unable to base-pair as DNA can. Complementary regions within an RNA molecule often undergo base-pairing and form complex tertiary structures, even approaching the three-dimensional nature of proteins. Some RNA molecules, such as transfer RNA (tRNA), possess several helical areas and loops as the strand interacts with itself in complementary sections. Other hybrid molecules such as the enzyme RNase P contain protein and RNA portions. The RNA part is highly complex, with many circles, loops, and helical regions creating a convoluted structure.

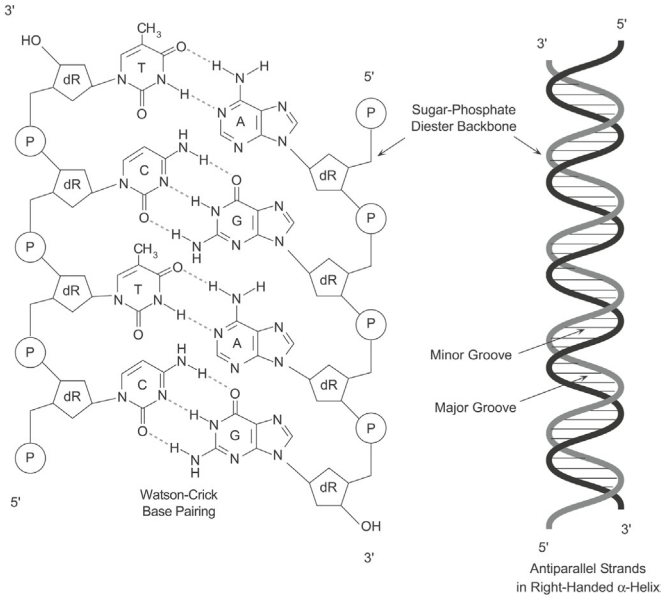

FIGURE 2.58 The classic Watson–Crick DNA double helix is formed through base-pairing interactions between two antiparallel strands. In physiological conditions, the two strands take on an α-helical shape with about 10 bp per turn of the helix. The phosphate–sugar backbone of the helix faces outward, while hydrogen bonding between opposing bases occurs in the middle of the wrapped strands. This configuration creates minor and major grooves between the phosphate–sugar backbones, potentially exposing the internal bases to interactions with other molecules.

The predictable nature of DNA and RNA base pairing make their interactions the most defined of any biological system. The specific affinity of one strand for its complementary sequence makes it possible to target genetic markers with extreme accuracy. Synthetic segments of RNA or DNA can be used to detect or quantify their complementary targets, even in highly dilute environments containing many other oligonucleotide molecules. If the oligonucleotide probe is labeled with a highly detectable component, then specific base-pairing interactions can be assayed. This ability has created an extensive utilization of labeled probes in molecular biology. Detection of target DNA or RNA can be carried out in cells, tissue sections, blots, and electrophoresis gels; after amplification by polymerase chain reaction (PCR techniques); or in solution. The ability to detect single-copy genes through the use of labeled oligonucleotide probes will make this field one of the leading application areas for bioconjugate techniques.

3.2. Polynucleotide Crosslinking Methods

The unique properties of oligonucleotides create crosslinking options that are far different from any other biological molecule. Nucleic acids are the only major class of macromolecule that can be specifically

duplicated *in vitro* by enzymatic means. The addition of modified nucleoside triphosphates to an existing DNA strand by the action of polymerases or transferases allows addition of spacer arms or detection components at random or discrete sites along the chain. Alternatively, chemical methods that modify nucleotides at selected functional groups can be used to produce spacer arm derivatives or activated intermediates for subsequent coupling to other molecules.

Thus, both chemical and enzymatic derivatization techniques can be used to form oligonucleotide probes of high activity in hybridization assays. The main consideration for successful polynucleotide crosslinking, as in other bioconjugate applications, is to avoid probe inactivation during the modification or conjugation process. Since the purpose in constructing a DNA or RNA probe is to hybridize to a complementary oligonucleotide through hydrogen bond interactions, any derivatization procedure that significantly interferes with Watson–Crick base pairing should be avoided. This means that a large amount of base derivatization along a polynucleotide chain has potential for causing obstructions in the hybridization process, sometimes dramatically reducing or eliminating base-pairing efficiency. In general, base modifications within an oligonucleotide probe should be limited to no more than about 30 to 40 sites per 1000 bases to maintain hybridization ability.

By contrast, derivatization at the ends of an oligo or at the sugar–phosphate backbone usually produces little interference in base pairing. Conjugates may be created by enzymatic polymerization of functionalized nucleoside triphosphates off the 3′ end or by chemical modification of the 5′ phosphate group with minimal to no interference in hybridization potential. The application of these strategies to creating labeled oligonucleotide probes is discussed in Chapter 23.

4. CREATING SPECIFIC FUNCTIONALITIES

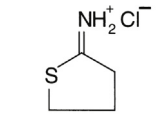
It is often desirable to alter the native structure of a macromolecule to provide functional targets for modification or conjugation. The use of most reagent systems requires the presence of particular chemical groups to effect coupling. For instance, heterobifunctional crosslinkers contain two different reactive species that are directed against different functionalities. One target molecule has to contain chemical groups able to react with one end of the crosslinker, while the other target molecule must contain groups able to react with the other end. Occasionally, the required chemical groups are not present on one of the target molecules and must be created. This can usually be done by reacting an existing chemical group with a modification reagent that contains or produces the desired functionality upon coupling. Thus, an amine can be "changed" into a sulfhydryl or a carboxylate can be altered to yield an amine simply by using the appropriate reagent.

This same type of modification strategy can also be used to create highly reactive groups from functionalities of rather low reactivity. For instance, carbohydrate chains on glycoproteins can be modified with sodium periodate to transform their rather unreactive hydroxyl groups into highly reactive aldehydes. Similarly, cystine or disulfide residues in proteins can be selectively reduced to form active sulfhydryls, or 5′ phosphate groups of DNA can be transformed to yield modifiable amines.

Alternatively, spacer arms can be introduced into a macromolecule to extend a reactive group away from its surface. The extra length of a spacer can provide less steric hindrance to conjugation and often yields more active complexes.

The use of modification reagents to create specific functionalities is an important technique to master. In one sense, the process is like using building blocks to construct on a target molecule any desired functional groups necessary for reactivity. The success of many conjugation schemes depends on the presence of the correct chemical groups. Care should be taken in choosing a modification strategy, however, since some chemical changes will radically affect the native structure and activity of a macromolecule. A protein may lose its capacity to bind a specific ligand. An enzyme may lose the ability to act upon its substrate. A DNA probe may no longer be able to hybridize to its complementary target. In many cases, the potential for inactivation relates to changing conformational structures, blocking active sites, or modifying critical functional groups. Trial and error and careful literature searches are often necessary to optimize any modification tactic.

4.1. Introduction of Sulfhydryl Residues (Thiolation)



The sulfhydryl group is a popular target in many modification strategies. Crosslinking agents that have more than one reactive group often employ a sulfhydryl-reactive functionality at one end to direct the conjugation reaction to a particular part of a target macromolecule. The frequency of sulfhydryl occurrence in proteins or other molecules is usually low (or nonexistent) compared to other groups such as amines or carboxylates. The use of sulfhydryl-reactive chemistries thus can restrict modification to only a limited number of sites within a target molecule. Limiting modification greatly increases the chances of retaining activity after conjugation, especially in sensitive proteins such as some

enzymes. Unfortunately, sulfhydryl groups often need to be generated (from reduction of indigenous disulfides) or created (from use of the appropriate thiolation reagent systems). The following sections describe the most popular techniques for creating these functionalities. Some of these reagent systems are specifically designed to form –SH groups, while others are crosslinkers that can also serve the dual purpose of sulfhydryl-generating agents.

Sulfhydryl groups are susceptible to oxidation and formation of disulfide crosslinks. To prevent disulfide bond formation, remove oxygen from all buffers by degassing under vacuum and bubbling an inert gas (e.g., nitrogen) through the solution. In addition, EDTA (0.01–0.1-*M*) may be added to buffers to chelate metal ions, preventing metal-catalyzed oxidation of sulfhydryls. Some proteins of serum origin (particularly BSA) contain so much contaminating metal ions (presumably iron from hemolyzed blood) that 0.1-*M* EDTA is required to prevent this type of oxidation.

Modification of Amines with 2-Iminothiolane (Traut's Reagent)

Perham and Thomas (1971) originally prepared an imidoester compound containing a thiol group, methyl 3-mercaptopropionimidate hydrochloride. The imidoester group can react with amines to form a stable, charged linkage (Chapter 3, section 1.11), while leaving a sulfhydryl group available for further coupling (Figure 2.59). Traut *et al*. (1973) subsequently synthesized an analogous reagent containing one additional carbon, methyl 4-mercaptobutyrimidate. Later, this compound was found to cyclize as a result of the sulfhydryl group reacting with the intrachain imidoester, forming 2-iminothiolane (Jue *et al*., 1978). The cyclic imidothioester can still react with primary amines in a ring-opening reaction that regenerates the free sulfhydryl (Figure 2.60).

Traut's Reagent;
2-Iminothiolane
MW 137.6
8.1 Å

Traut's reagent is fully water soluble and reacts with primary amines in the range of pH 7 to 10. The cyclic imidothioester is stable to hydrolysis at acid pH values, but its half-life in solution decreases as the pH increases beyond neutrality. However, even at pH 8.0 in 25-m*M* triethanolamine the rate of sulfhydryl formation without added primary amine was found to be negligible. Upon addition of dipeptide amine, the reagent reacted quickly as evidenced by the production of Ellman's reagent color. The rate of reaction can also be followed by 2-iminothiolane's absorbance at 248 nm (λ_{max}; $\varepsilon = 8840\,M^{-1}cm^{-1}$). As the cyclic imidate reacts with amines, its absorbance at this wavelength decreases. With addition of the dipeptide glycylglycine, the starting absorbance of a solution of Traut's reagent decreased over 80% within 20 minutes (Jue *et al*., 1978). Thus, protein modification with 2-iminothiolane is very efficient and proceeds rapidly at slightly basic pH.

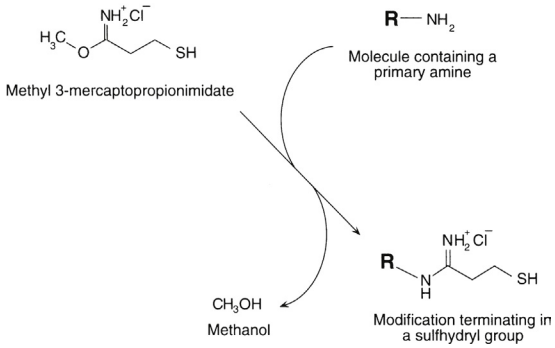


FIGURE 2.59 Thiolation of an amine-containing compound with methyl 3-mercaptopropionimidate. The modification preserves the positive charge on the primary amine.

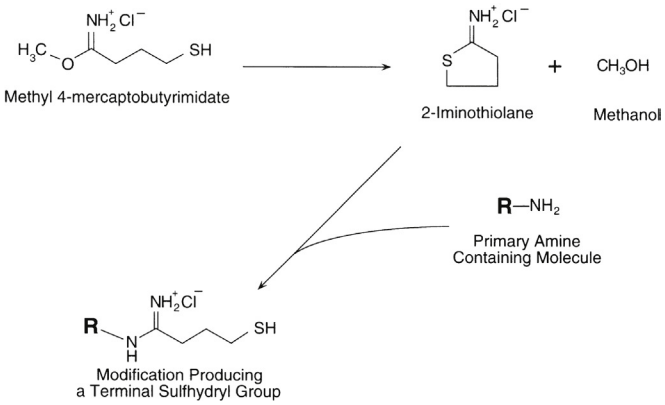

FIGURE 2.60 Methyl 4-mercaptobutyrimidate forms 2-iminothiolane, which can react with a primary amine to create a sulfhydryl group. The modification preserves the positive charge of the original amine.

At high pH (10.0), Traut's reagent is also reactive with aliphatic and aromatic hydroxyl groups, although the rate of reaction with these groups is only about 0.01 that of primary amines. In the absence of amines, however, carbohydrates such as agarose or cellulose membranes can be modified to contain sulfhydryl residues (Alagon and King, 1980). Polysaccharides modified in this manner are effective in covalently crosslinking antibodies for use in immunoassay procedures.

Proteins modified with 2-iminothiolane are subject to disulfide formation upon sulfhydryl oxidation. This can cause unwanted conjugation, potentially precipitating the protein. The addition of a metal-chelating

agent such as EDTA (0.01–0.1-*M*) will prevent metal-catalyzed oxidation and maintain sulfhydryl stability. In the presence of some serum proteins (e.g., BSA) a 0.1-*M* concentration of EDTA may be necessary to prevent metal-catalyzed oxidation, presumably due to the high contamination of iron from hemolyzed blood.

Traut's reagent has been used successfully in the investigation of ribosomal proteins (Sunn *et al.*, 1974; Jue *et al.*, 1978; Kenny *et al.*, 1979; Lambert *et al.*, 1983; Blattler *et al.*, 1985), RNA polymerase (Hillel and Wu, 1977), progesterone receptor subunits (Birnbaumer *et al.*, 1979), and in the synthesis of enzyme-labeled DNA hybridization probes (Ghosh *et al.*, 1990). It is an excellent thiolation reagent for use in the preparation of immunotoxins (Section 3.3). It also has been used to modify and introduce sulfhydryls into oligosaccharides from asparagine-linked glycans (Tarentino *et al.*, 1993).

Side reactions other than oxidation to disulfides can also occur using Traut's reagent. Once an amine on a protein is modified with 2-iminothiolane, the terminal thiol can recyclize by attacking the amidine carbon (Figure 2.61). This can then rearrange into an iminothiolane derivative, which effectively ties up the thiol (Singh *et al.*, 1996; Mokotoff *et al.*, 2001). Proteins and other molecules thiolated using Traut's reagent can lose substantial amounts of available thiol to recyclization in just hours. For this reason, the thiolated product of a Traut's reaction should be used immediately in a conjugation reaction to avoid significant loss of activity.

Protocol

1. Prepare the protein or macromolecule to be thiolated in a non-amine-containing buffer at pH 8.0. For the modification of ribosomal proteins (often cited in the literature) use 50-m*M* triethanolamine hydrochloride, 1-m*M* $MgCl_2$, 50-m*M* KCl, pH 8.0. The magnesium and potassium salts are for stabilization of some ribosomal proteins. If other proteins are to be thiolated, the same buffer may be used without added salts for stabilization. Alternatively, 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 8.0, or 0.1-*M* sodium borate, pH 8.0, may be used. For the modification of polysaccharides, use 20-m*M* sodium borax, pH 10, to produce reactivity towards carbohydrate hydroxyl residues. Dissolve the protein to be modified at a concentration of 10 mg/ml in the reaction buffer of choice. Lower concentrations may also be used with a proportional scaling back of added 2-iminothiolane.
2. Dissolve the Traut's reagent (Thermo Fisher) in water at a concentration of 2 mg/ml (makes a 14.5-m*M* stock solution). The solution should be used immediately. For the modification of IgG at a concentration of 10 mg/ml using a 10-fold molar excess of Traut's reagent, add 45.8 µl of the stock solution to each milliliter of the protein solution.
3. React for 1 h at room temperature (a 4°C reaction temperature may be used successfully as well).
4. Purify the thiolated protein from unreacted Traut's reagent by gel filtration using your buffer of choice (e.g., 20-m*M* sodium phosphate, 0.15-*M* NaCl, 1-m*M* EDTA, pH 7.2). The addition of EDTA to this buffer helps to prevent oxidation of the sulfhydryl groups and the resultant disulfide formation. After purification, use the thiolated protein immediately in a conjugation reaction to avoid the recyclization of the free thiol with concomitant decrease in thiol availability.
5. The degree of –SH modification may be determined using the Ellman's assay (Section 4.1, this chapter).

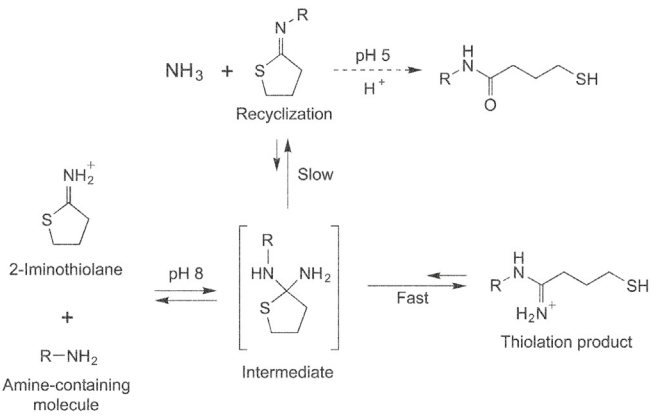

FIGURE 2.61 Traut's reagent can undergo side reactions after the modification of an amine-containing molecule. The terminal thiol group can recyclize to create another iminothiolane derivative that effectively ties up the thiol.

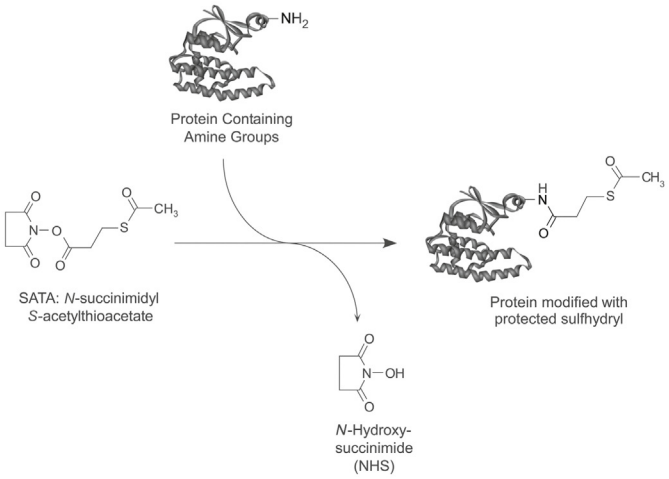
When 2-iminothiolane is used to modify proteins in tandem with 4,4′-dipyridyl disulfide, a protected sulfhydryl can be introduced in a single step (King *et al.*, 1978). The simultaneous reaction between a protein, 2-iminothiolane, and 4,4′-dipyridyl disulfide yields a modification containing pyridyl disulfide groups. The pyridyl disulfide subsequently may be reduced with DTT to yield a free sulfhydryl. Pyridyl disulfides are also highly reactive toward sulfhydryls through disulfide interchange (Chapter 3, Section 2.6). The protocol is a modification of the method of King *et al.* (1978). 2-Iminothiolane is used to modify proteins in tandem with 4,4′-dipyridyl disulfide, in which a protected sulfhydryl can be introduced in a single step (King *et al.*, 1978). The simultaneous reaction between a protein, 2-iminothiolane, and 4,4′-dipyridyl disulfide yields a modification containing pyridyl disulfide groups. The pyridyl disulfide subsequently may be reduced with DTT to yield a free sulfhydryl. Pyridyl disulfides are also highly reactive toward sulfhydryls through disulfide interchange (Chapter 6,

Section 1.1). The following protocol is a modification of the method of King *et al*. (1978).

Protocol

1. Dissolve 1–10 mg of a protein to be modified in 1.0 ml of 0.025-*M* sodium borate, pH 9.0.
2. Dissolve 2-iminothiolane in 0.025-*M* sodium borate to a concentration of 0.02-*M*.
3. Dissolve 4,4′-dipyridyl disulfide at a concentration of 2 mg/ml in acetonitrile.
4. Add 0.2 ml of (3) and 1.0 ml of (2) to the protein solution.
5. React for 2 h at room temperature.
6. Purify the modified protein by gel filtration or dialysis.



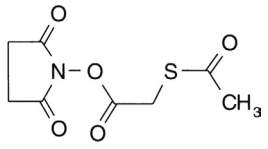


FIGURE 2.62 SATA can react with available amine groups in proteins and other molecules *via* its NHS ester end to form protected sulfhydryl derivatives. The illustrated protein is glutathione-*S*-transferase (E.C.2.5.1.18) (Ji *et al*., 1995).

Occasionally, a protein modified in this manner will begin to precipitate as the reaction proceeds. Stopping the reaction earlier or adding a smaller quantity of modifying reagents may limit this effect.

Modification of Amines with SATA

A versatile reagent for introducing sulfhydryl groups into proteins is SATA, *N*-succinimidyl *S*-acetylthioacetate (Duncan *et al*., 1983). The active NHS ester end of SATA reacts with amino groups in proteins and other molecules to form a stable amide linkage (Figure 2.62) (Chapter 3, Section 1.4). The modified protein then contains a protected sulfhydryl that can be stored without degradation and subsequently deprotected as needed with an excess of hydroxylamine (Figure 2.63). Since the protecting group can be removed without adding disulfide reducing agents like DTT, disulfides indigenous to the native protein will not be affected. This is an important consideration if disulfides are vital to activity, such as in the case of antibodies and some protein toxins.

SATA;
N-succinimidyl
S-acetylthioacetate
MW 231.2

SATA is often used to form antibody–enzyme conjugates utilizing maleimide-containing heterobifunctional crosslinking agents. Most polyclonal antibody molecules may be modified to contain up to about six SATA

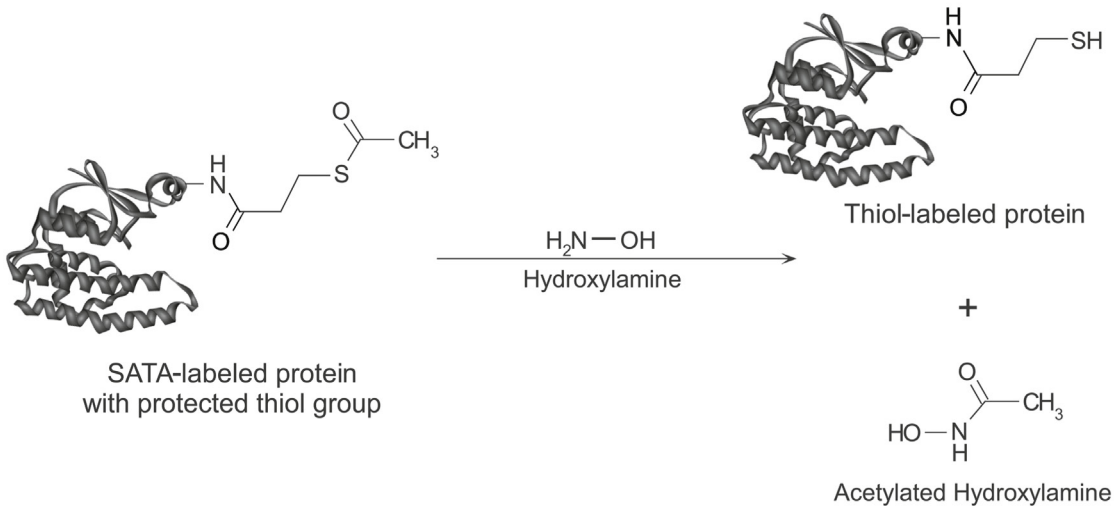

FIGURE 2.63 Deprotection with hydroxylamine of the acetylated thiol of SATA-modified proteins yields a free sulfhydryl group.

molecules per immunoglobulin with minimal effect on antigen binding activity. Some sensitive monoclonal antibodies, however, may be susceptible to modification and should be tested on a case-by-case basis. The modified antibody may then be deprotected and reacted with a maleimide-activated enzyme to form a conjugate useful in immunoassays (Chapter 20, Section 1.1). Conjugates formed using SATA are usually of low molecular weight with very few high-molecular-weight oligomers. They also maintain a bivalent antibody structure, ensuring a conjugate containing two antigen binding sites. This is an advantage over reduction schemes that break the antibody molecule into two heavy–light chain pairs to create sulfhydryls, since disulfide cleavage yields antibody fragments with only one antigen binding site.

SATA has been used to form conjugates with avidin or steptavidin with excellent retention of activity (Chapter 11, Section 3.1). It has also been used in the formation of a therapeutically useful toxin conjugate with recombinant CD4 (Ghetie *et al*., 1990), to study syntaxin proteins (Amessou *et al*., 2007), to prepare biospecific antibodies (Lenderfer *et al*., 2001), and to make a unique polylysine conjugate as a vehicle for drug delivery (Sakharov *et al*., 2001).

SATA is freely soluble in many organic solvents. In use, it is typically dissolved as a stock solution in DMSO, DMF, or methylene chloride, and then an aliquot of this solution is added to an aqueous reaction mixture containing the protein to be modified.

The thiolation method described below is generally applicable for the modification of proteins with SATA, particularly for subsequent conjugation with a maleimide-activated secondary protein. The degree of modification described usually yields 3 to 4 moles of –SH groups per mole protein when thiolating immunoglobulins. Other macromolecules containing primary amines may be modified using a similar procedure. The degree of modification observed with other molecules may vary depending on the number of available primary amines and their relative reactivity. The molar ratio of SATA to immunoglobulin added to a reaction for the modification of rabbit polyclonal IgG *versus* the degree of sulfhydryl incorporation is illustrated in Figure 2.64 (Sykaluk, 1994).

The following protocol represents a generalized method for protein thiolation using SATA. For comparison purposes, contrast the variation of this SATA modification method as outlined in Chapter 20, Section 1.1, for use in the preparation of antibody–enzyme conjugates.

Protocol

1. Dissolve the protein to be thiolated at a concentration of 1–5 mg/ml in 50-m*M* sodium phosphate, pH 7.5, containing 1–10-m*M* EDTA. Other non-amine-containing buffers such as borate, HEPES, and bicarbonate may also be used as the reaction medium. The effective pH for the NHS ester modification reaction is in the range of 7.0 to 9.0, but environments closer to neutrality will limit the hydrolysis of the ester.
2. Dissolve the SATA reagent (Thermo Fisher) in DMSO at a concentration of 65 m*M* (15 mg/ml). Note: DMSO should be handled in a fume hood.
3. Add 10 µl of the SATA solution to each milliliter of protein solution.
4. Mix and react for 30 min at room temperature.
5. Separate modified protein from unreacted SATA and reaction byproducts by dialysis against 50-m*M* sodium phosphate, pH 7.5, containing 1-m*M* EDTA or by gel filtration on a Sephadex G-25 column (Pharmacia) using the same buffer.
6. Deprotect the acetylated –SH groups as needed by adding 100 µl of 0.5-*M* hydroxylamine hydrochloride in 50-m*M* sodium phosphate, 25-m*M* EDTA, pH 7.5, to each milliliter of the SATA modified protein solution.
7. Mix and react for 2 h at room temperature.
8. Purify the sulfhydryl-modified protein by dialysis against 50-m*M* sodium phosphate, 1-m*M* EDTA, pH 7.5, or by gel filtration on a Sephadex G-25 column using the same buffer.

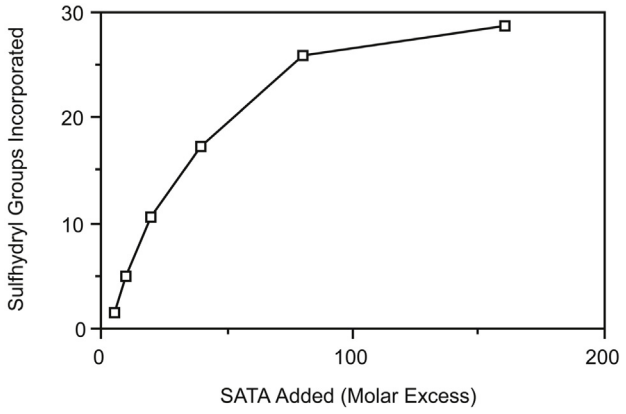

FIGURE 2.64 SATA modification of rabbit polyclonal IgG with the resultant sulfhydryl incorporation level.

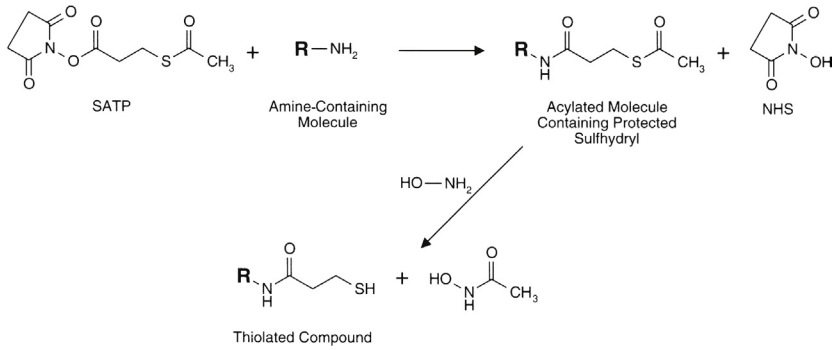
The deacetylated protein should be used immediately to prevent loss of sulfhydryl content through disulfide formation. The degree of –SH modification may be determined by performing an Ellman's assay (Section 4.1).

Modification of Amines with SATP

SATP, succinimidyl acetylthiopropionate, is an analog of SATA (Section 4.1) containing one additional carbon atom in length (Fuji *et al*., 1985). The compound retains all the advantages of a protected sulfhydryl, including stability of the modified protein and selective release of the protecting group with hydroxylamine to free the sulfhydryl as needed (Figure 2.65). SATP is soluble in DMF



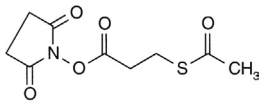


FIGURE 2.65 SATP reacts with amine-containing proteins or other molecules *via* its NHS ester end to create protected sulfhydryl derivatives in a manner similar to that of SATA. Deprotection can be done with hydroxylamine to free the thiol.

and methylene chloride. It is usually first solubilized in organic solvent and an aliquot added to an aqueous solution containing the macromolecule to be modified. It is particularly useful in adding an N-terminal –SH group at the completion of peptide synthesis.

SATP
Succinimidyl acetyl-thiopropionate
MW 245

Protocol

1. Dissolve the protein or peptide to be thiolated at a concentration of 10 mg/ml in 50-m*M* sodium phosphate, pH 7.5, containing 1-m*M* EDTA. Other non-amine-containing buffers such as borate, HEPES, and bicarbonate may also be used as the reaction medium. The effective pH for the NHS ester modification reaction is in the range of 7.0 to 9.0. Conditions closer to neutral pH will limit the degree of NHS ester hydrolysis during the reaction.
2. Dissolve the SATP reagent (Molecular Probes) in DMF at a concentration of 65 m*M* (16 mg/ml). Note: DMF should be handled in a fume hood.
3. Add 10 µl of the SATP solution to each milliliter of protein or peptide solution.
4. Mix and react for 30–60 min at room temperature (or 2–4 h at 4°C).
5. Separate modified protein from unreacted SATP and reaction byproducts by dialysis against 50-m*M* sodium phosphate, pH 7.5, containing 1-m*M* EDTA or by gel filtration using a desalting column with the same buffer. If a peptide of low molecular weight is being modified, careful gel filtration using a matrix having a low exclusion limit will separate the peptide from the reaction byproducts, but the separation should be carried out on an automated system to accurately capture the peaks. In this case, use either Sephadex G-25 or Sephadex G-10 for the chromatography.
6. Deprotect the acetylated –SH groups as needed by adding 100 µl of 0.5-*M* hydroxylamine hydrochloride in 50-m*M* sodium phosphate, 25-m*M* EDTA, pH 7.5, to each milliliter of the SATP-modified protein solution.
7. Mix and react for 2 h at room temperature.
8. Purify the sulfhydryl-modified protein by dialysis against 50-m*M* sodium phosphate, 1-m*M* EDTA, pH 7.5, or by gel filtration on a Sephadex G-25 column using the same buffer. Again, if a peptide of low molecular weight is being modified, use careful gel filtration for purification.

The deacetylated protein should be used immediately to prevent loss of sulfhydryl content through disulfide formation. The degree of –SH modification may be determined by performing an Ellman's assay (Section 4.1, this chapter).

Modification of Amines with SPDP

SPDP, *N*-succinimidyl 3-(2-pyridyldithio)propionate, is one of the most popular heterobifunctional crosslinking agents (Chapter 6, Section 1.1). The NHS ester end of SPDP reacts with amine groups to form an amide linkage, while the 2-pyridyldithiol group at the other end can react with sulfhydryl residues to form a disulfide linkage (Carlsson *et al.*, 1978). The crosslinker is used extensively to form immunotoxin conjugates for *in vivo* administration (Chapter 20, Section 3.2.1). The reagent is also useful in creating sulfhydryls in proteins and other molecules. Once modified with SPDP, a protein can be treated with DTT (or other disulfide reducing agents; see Section 4.1, this chapter) to release the pyridine-2-thione leaving group and form the free sulfhydryl (Figure 2.66). The terminal –SH group can then be used to conjugate with any crosslinking agents containing sulfhydryl-reactive groups, such as maleimide or iodoacetyl functionalities (for covalent conjugation) or 2-pyridyldithiol groups (for reversible conjugation).

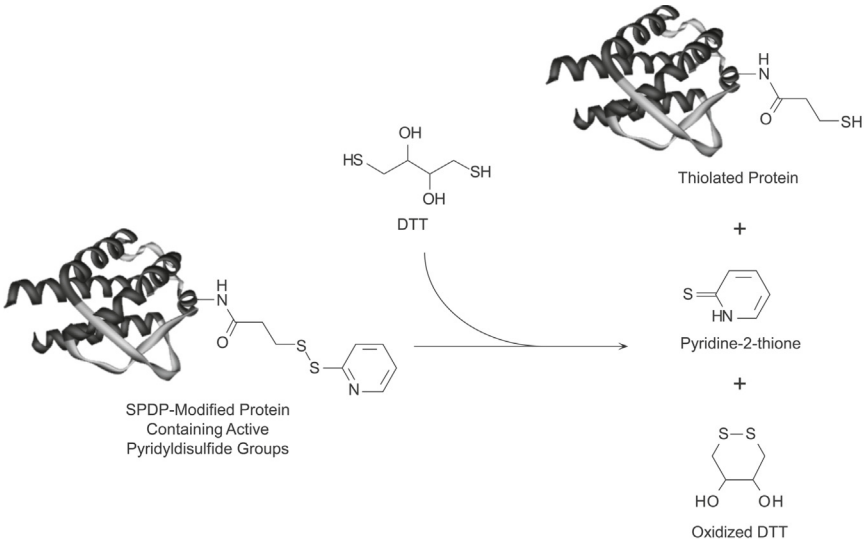

FIGURE 2.66 SPDP-modified proteins can be reduced with DTT to yield free sulfhydryl groups for conjugation.

There are three forms of SPDP analog currently available commercially (Thermo Fisher): the standard SPDP, a long-chain version designated LC-SPDP, and a water soluble, sulfo-NHS form also containing an extended chain, called Sulfo-LC-SPDP (Chapter 6, Section 1.1). The main disadvantage in using SPDP to create sulfhydryls is the necessity of using a reducing agent to remove the pyridine-2-thione group. Reducing agents will also affect indigenous disulfides within a protein molecule, cleaving and reducing them. This method therefore works well for proteins containing no sulfhydryls or no disulfides that are critical to function, but it may cause loss of activity or subunit breakdown in proteins containing essential disulfides.

The following procedure is similar to the method of Cumber *et al.* (1985), but with some modifications.

Protocol

1. Dissolve the protein or macromolecule to be thiolated at a concentration of 10 mg/ml in 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Other non-amine-containing buffers such as borate, HEPES, and bicarbonate may also be used in this reaction. The effective pH for the NHS ester modification reaction is in the range of 7.0 to 9.0, but environments closer to neutrality will limit ester hydrolysis.
2. Dissolve SPDP (Thermo Fisher) at a concentration of 6.2 mg/ml in DMSO (makes a 20-m*M* stock solution). Alternatively, LC-SPDP may be used and dissolved at a concentration of 8.5 mg/ml in DMSO (also makes a 20-m*M* solution). If the water soluble Sulfo-LC-SPDP is used for the reaction, a stock solution in water may be prepared just prior to adding an aliquot to the protein solution. In this case, prepare a 10-m*M* solution of Sulfo-LC-SPDP by dissolving 5.2 mg/ml in water. Since an aqueous solution of the crosslinker will degrade by hydrolysis of the sulfo-NHS ester, it should be used quickly to prevent significant loss of activity. If a sufficiently large amount of protein will be modified to allow accurate weighing of Sulfo-LC-SPDP, the solid may be added directly to the reaction mixture without preparing a stock solution in water.
3. Add 25 µl of the stock solution of either SPDP or LC-SPDP in DMSO to each milliliter of the protein to be modified. If Sulfo-LC-SPDP is used, add 50 µl of the stock solution in water to each milliliter of protein solution.
4. Mix and react for at least 30 min at room temperature. Longer reaction times, even overnight, will not adversely affect the modification.
5. Purify the modified protein from reaction byproducts by dialysis or gel filtration using 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
6. To release the pyridine-2-thione leaving group and form the free sulfhydryl, add DTT at a concentration of 0.5 mg DTT per mg of modified protein. A stock solution of DTT may be prepared to make it easier to add it to a small amount of protein solution. In this case, dissolve 20 mg of DTT per milliliter of 0.1-*M* sodium acetate, 0.1-*M* NaCl, pH 4.5. Add 25 µl of this solution per mg of modified protein. Release of pyridine-2-thione can be followed by its characteristic absorbance at 343 nm ($\varepsilon = 8.08 \times 10^3 M^{-1} cm^{-1}$).
7. Mix and react at room temperature for 30 min.

8. Purify the thiolated protein from excess DTT by dialysis or gel filtration using 50-m*M* sodium phosphate, 0.15-*M* NaCl, 1-m*M* EDTA, pH 7.2. The modified protein should be used immediately in a conjugation reaction to prevent sulfhydryl oxidation and formation of disulfide crosslinks.

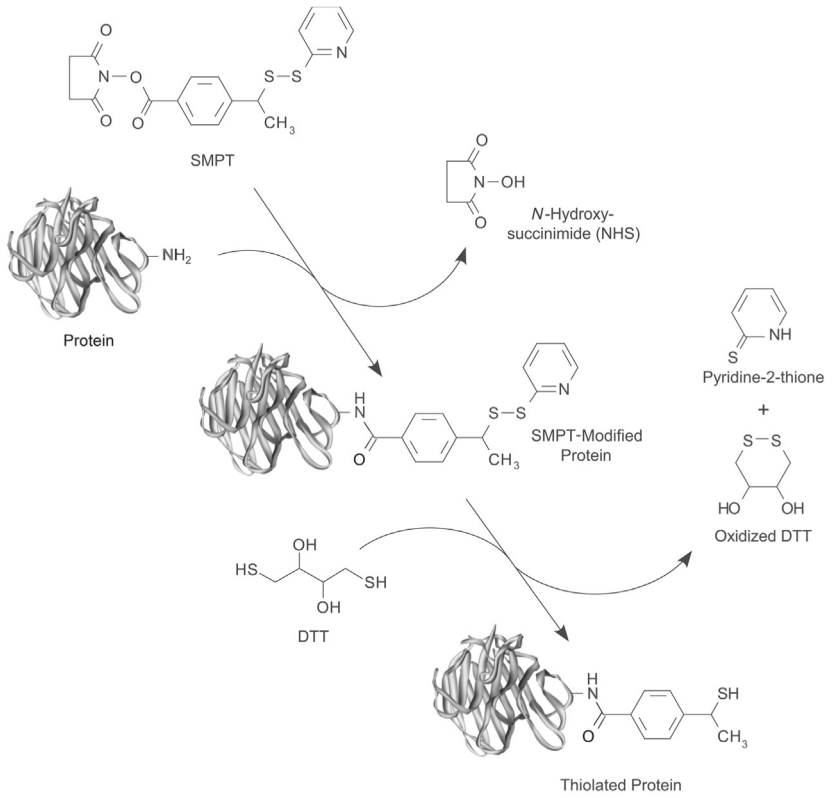
Modification of Amines with SMPT

SMPT, succinimidyloxycarbonyl-α-methyl-α-(2-pyridyldithio)toluene, contains an NHS ester end and a pyridyldisulfide end similar to SPDP, but its hindered disulfide makes conjugates formed with this reagent more stable (Thorpe *et al*., 1987) (Chapter 6, Section 1.2). The reagent is especially useful in forming immunotoxin conjugates for *in vivo* administration (Chapter 20, Section 3.2.1). A water soluble analog of this crosslinker containing an extended spacer arm is also commercially available as Sulfo-LC-SMPT (Thermo Fisher).

SMPT or Sulfo-LC-SMPT may be used as thiolation reagents by first reacting its NHS ester end with an amine-containing molecule and then releasing the pyridine-2-thione leaving group with DTT to free the sulfhydryl (Figure 2.67). The disadvantage of this approach is the necessity of using a reducing agent to create the –SH group modification. This method of thiolation should only be used if there are no disulfides in the target molecule that are critical to function. If a reductant cannot be used, choose a thiolation method that does not need DTT treatment, such as the use of Traut's reagent or SATA (Section 4.1, this chapter).

Since SMPT is not soluble in aqueous solutions it must first be dissolved in organic solvent and an aliquot of this stock solution transferred to the reaction solution. The reagent is soluble in DMF and DMSO, but is much more stable in solutions of acetonitrile. A stock solution of SMPT in acetonitrile may be kept frozen without loss of activity. The NHS ester of SMPT is also extraordinarily stable to hydrolysis in water. Even when an SMPT/acetonitrile aliquot is added to an aqueous solution and stored at room temperature, SMPT will only lose about 5% of its activity after 16 h. By contrast, other NHS esters usually have half-lives measured in minutes or hours in aqueous environments, depending on the pH.

Sulfo-LC-SMPT is not as stable as SMPT. The sulfo-NHS ester is more susceptible to hydrolysis in aqueous solutions and the pyridyl disulfide group is more easily reduced to the free sulfhydryl. Stock solutions of Sulfo-LC-SMPT may be prepared in water, but should be used immediately to prevent loss of amine coupling ability.



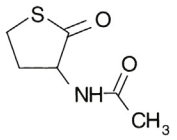


FIGURE 2.67 SMPT can be used to modify the amine groups of proteins to form disulfide intermediates. The disulfides can be reduced with DTT to create free thiols for subsequent conjugation purposes.

Protocol

1. Dissolve the protein or macromolecule to be thiolated at a concentration of 10 mg/ml in 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Other non-amine-containing buffers such as borate, HEPES, and bicarbonate may also be used as the reaction medium. The effective pH for the NHS ester modification reaction is in the range of 7.0 to 9.0, but conditions close to neutrality will limit ester hydrolysis.
2. Dissolve SMPT (Thermo Fisher) at a concentration of 7.7 mg/ml in acetonitrile (makes a 20-m*M* stock solution). Alternatively, the water soluble Sulfo-LC-SMPT may be used and dissolved at a concentration of 6.0 mg/ml in water (makes a 10-m*M* solution). This should be carried out just prior to adding an aliquot to the thiolation reaction. Since an aqueous solution of the crosslinker will degrade by hydrolysis of the sulfo-NHS ester, it should be used quickly to prevent significant loss of activity. If a sufficiently large amount of protein will be modified to allow accurate weighing of Sulfo-LC-SMPT, the solid may be added directly to the reaction mixture without preparing a stock solution in water, but this is not recommended with most reactions.
3. Add 25 µl of the stock solution of SMPT in acetonitrile to each milliliter of the protein to be modified. If Sulfo-LC-SMPT is used, add 50 µl of the stock solution in water to each milliliter of protein solution.
4. Mix and react for at least 30 min at room temperature. Longer reaction times, even overnight, will not adversely affect the modification.
5. Purify the modified protein from reaction byproducts bydialysis or gel filtration using 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
6. To release the pyridine-2-thione leaving group and form the free sulfhydryl, add DTT at a concentration of 0.5 mg DTT per mg of modified protein. A stock solution of DTT may be prepared to make it easier to add it to a small amount of protein solution. In this case, dissolve 20 mg of DTT per milliliter of 0.1-*M* sodium acetate, 0.1-*M* NaCl, pH 4.5. Add 25 µl of this solution per mg of modified protein. Release of pyridine-2-thione can be followed by its characteristic absorbance at 343 nm ($\varepsilon = 8.08 \times 10^3\,M^{-1}\,cm^{-1}$).
7. Mix and react at room temperature for 30 min.
8. Purify the thiolated protein from excess DTT by dialysis or gel filtration using 50-m*M* sodium phosphate, 0.15-*M* NaCl, 1-m*M* EDTA, pH 7.2. The modified protein should be used immediately in a conjugation reaction to prevent sulfhydryl oxidation and formation of disulfide crosslinks.

Modification of Amines with N-Acetyl Homocysteine Thiolactone

N-Acetyl homocysteine thiolactone (also called citiolone or 2-acetamido-4-mercaptobutyric acid) is a cyclic derivative of homocysteine containing a blocked α-amino group. The compound can react with primary amines in a ring opening reaction to create free sulfhydryl modifications (Figure 2.68). It was originally used as a reagent for insolubilizing antibodies. Later, it was immobilized on an amine-containing matrix to form a disulfide reducing support for cleaving cystine residues in peptides and proteins (Eldjarn and Jellum, 1963; Jellum, 1964) (see *Use of Disulfide Reductants*, this section). The thiolation reaction of amine-containing macromolecules proceeds much like the reaction for 2-iminothiolane. Nucleophilic attack occurs at the carbonyl, cleaving the thiolactone and producing an amide linkage with the target molecule, while at the same time creating the free sulfhydryl (Benesch and Benesch, 1956, 1958). *N*-Acetyl homocysteine is soluble in aqueous buffers.

N-Acetyl Homocysteine
Thiolactione
MW 159

Thiolation of peptides and other small molecules containing amines proceeds easily with *N*-acetyl

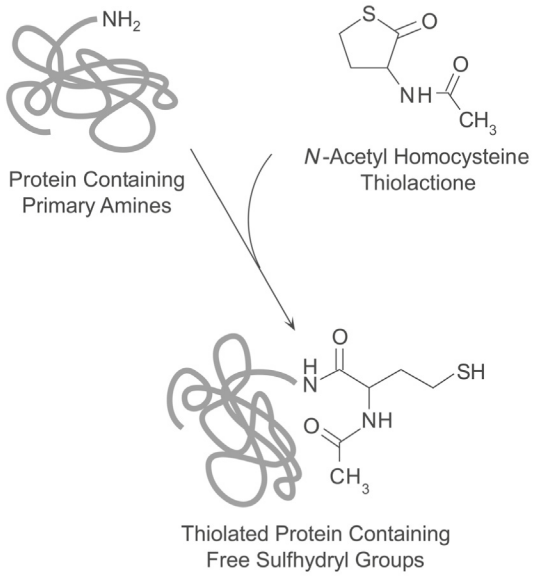

FIGURE 2.68 *N*-Acetyl homocysteine thiolactone spontaneously reacts with amine groups on proteins to create sulfhydryl groups.

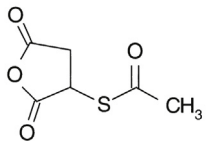
homocysteine thiolactone. However, protein modification often results in much lower yields unless the reaction is carried out for extended periods at pH 10 to 11.

It has been found that silver ions catalyze the thiolation process with proteins, allowing the reaction to be completed rapidly at physiological pH (Benesch and Benesch, 1958). The addition of an equal molar concentration of $AgNO_3$ forms an insoluble complex with the thiolactone, and this in turn reacts with protein amines.



Protocol

1. Dissolve the amine-containing molecule to be thiolated at a concentration of 10 mg/ml in cold (4°C) 1-*M* sodium bicarbonate (reaction buffer). For proteins, dissolve them in deionized water at a pH of 7.0 to 7.5, at room temperature. Note: The presence of some buffer salts, such as phosphate or carbonate, is incompatible with silver nitrate.
2. Add *N*-acetyl homocysteine thiolactone (Aldrich) to the bicarbonate reaction mixture to obtain a concentration representing a 10- to 20-fold excess over the amount of amines present. For protein thiolation, add the same molar excess of thiolactone reagent to the water reaction medium, and then slowly add an equivalent molar quantity of silver nitrate ($AgNO_3$). Maintain the pH at 7.0 to 7.5 with periodic addition of NaOH.
3. For the bicarbonate reaction, gently mix for 20 h at 4°C. For the silver-catalyzed reaction, continue the reaction for 1 h or until the silver complex has fully dissolved.
4. To remove the silver mercaptide formed from the facilitated protein thiolation reaction, add an excess of thiourea to convert all the silver into a soluble $Ag(thiourea)_2^+$ complex and free the sulfhydryl modifications.
5. Remove unreacted *N*-acetyl homocysteine thiolactone and reaction byproducts by gel filtration or dialysis against 10-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2. Other buffers suitable for individual protein stability may be used as desired. For the silver nitrate-containing reaction, removal of the silver–thiourea complex may be carried out by adsorption onto Dowex 50, and the protein subsequently eluted from the resin by 1-*M* thiourea. Removal of the thiourea may then be carried out by gel filtration or dialysis.

Including EDTA in the final preparation inhibits metal-catalyzed oxidation of the sulfhydryl groups to disulfides. The modified peptide or protein should be used immediately to assure full sulfhydryl reactivity.

Modification of Amines with SAMSA

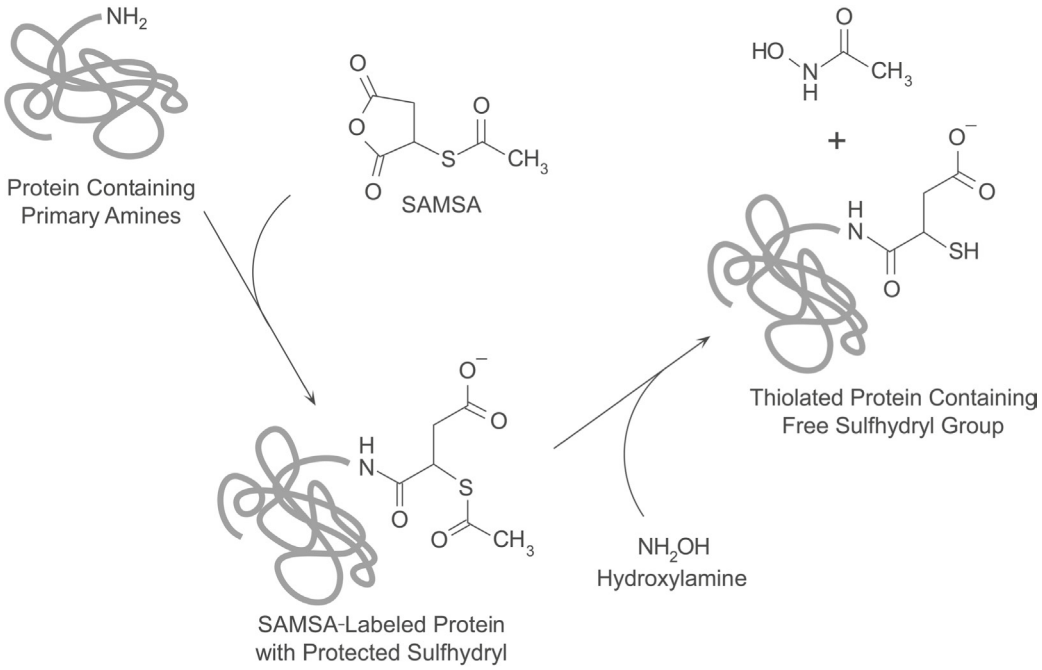
S-Acetylmercaptosuccinic anhydride, or SAMSA, is an amine-reactive reagent containing a protected sulfhydryl much like SATA, described previously. The anhydride portion opens in response to the attack of an amine nucleophile, yielding an amide linkage (Klotz *et al.*, 1962; Weston *et al.*, 1980). The ring opening reaction, however, does produce a free carboxylate group that lends a negative charge to the modified molecule where once there may have been a positive charge (Figure 2.69). This charge reversal may affect the conformation and activity of some sensitive proteins. After the initial modification step, releasing the acetylated sulfhydryl-protecting group with hydroxylamine forms the thiolated derivative.

SAMSA;
S-Acetylmercaptosuccinic
Anhydride
MW 174

Protocol

1. Dissolve the protein or other amine-containing macromolecule in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of 5 mg/ml.
2. Dissolve SAMSA in DMF at a concentration of 25 mg/ml.
3. Add 20 µl of the stock SAMSA solution to each milliliter of the protein solution, with mixing.
4. React at room temperature for 30 min.
5. Remove excess reagent and reaction byproducts by dialysis or gel filtration using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5. For chromatographic separation, use a desalting gel filtration support such as the Zeba desalting spin columns (Thermo Fisher) or the equivalent. The SAMSA-modified protein may be stored at −20°C until needed.
6. To deprotect the acetylated sulfhydryl group of SAMSA-modified proteins, add 100 µl of 0.5-*M* hydroxylamine hydrochloride in 50-m*M* sodium phosphate, 25-m*M* EDTA, pH 7.5, to each milliliter of protein solution.
7. Mix and react for 2 h at room temperature.
8. Purify the sulfhydryl-modified protein by dialysis against 50-m*M* sodium phosphate, 1-m*M* EDTA, pH 7.5, or by gel filtration on a Sephadex G-25 column using the same buffer.

The deacetylated protein should be used immediately to prevent loss of sulfhydryl content through disulfide formation. The degree of –SH modification may be



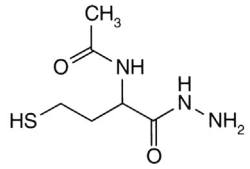


FIGURE 2.69 SAMSA is an anhydride compound containing a protected thiol. Reaction with protein amine groups yields amide bond linkages. Deprotection of the acetylated thiol produces free sulfhydryl groups for conjugation.

determined by performing an Ellman's assay (see *Ellman's Assay for the Determination of Sulfhydryls*, this chapter).

Modification of Aldehydes or Ketones with AMBH

AMBH (2-acetamido-4-mercaptobutyric acid hydrazide) is a unique hydrazide derivative that can thiolate aldehydes and ketones to form reactive sulfhydryl groups (Taylor and Wu, 1980). It is particularly useful in converting oxidized carbohydrates to contain a thiol. In this respect, glycoproteins or other carbohydrate and diol-containing molecules may be treated with sodium periodate under relatively mild conditions to form aldehyde residues (Section 4.4, this chapter). The aldehydes readily react with the hydrazide groups of AMBH to form hydrazone linkages, leaving a free terminal sulfhydryl residue to use in further conjugation reactions (Figure 2.70).

AMBH
2-Acetamido-4-mercaptobutyric
acid hydrazide
MW 191

Protocol

1. Dissolve an aldehyde-containing macromolecule to be modified (e.g., a periodate oxidized glycoprotein) in 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, containing 1-m*M* EDTA. A suitable concentration range for a protein is 1–10 mg/ml.
2. Add a 10-fold molar excess of AMBH (pre-dissolved in ethanol) (Molecular Probes) over the expected amounts of aldehydes to be modified.
3. React for 2 h at room temperature.
4. Purify the modified protein by gel filtration.

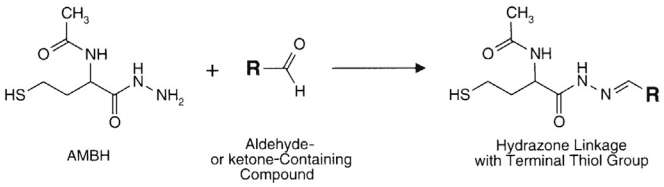

FIGURE 2.70 AMBH is a hydrazide-containing compound that reacts with carbonyl groups to form hydrazone bonds. The free thiol can be used for subsequent conjugation reactions.

Modification of Carboxylates or Phosphates with Cystamine

Cystamine is decarboxylated cystine [or 2,2′-dithiobis(ethylamine)], a small disulfide-containing molecule with primary amines at both ends. This versatile reagent can be used in several conjugation techniques. Cystamine may be used to introduce sulfhydryl residues in proteins, nucleic acids and other molecules, or as the active species in disulfide exchange crosslinking reactions, or in reversible conjugation

procedures. The reagent can be used to create sulfhydryl groups in proteins or other molecules by first conjugating one of its terminal amino groups with the carboxylates on a target molecule using a carbodiimide reaction (Chapter 3, Section 1.12 and Chapter 4, Section 1). Subsequent reduction of the disulfide group liberates the free sulfhydryl (see *Ellman's Assay for the Determination of Sulfhydryls*, this section) (Figure 2.71). This same modification procedure can also be used to introduce sulfhydryl residues at the 5′ phosphate group of DNA (Chu *et al*., 1986; Ghosh *et al*., 1990). The carbodiimide activates the phosphate and the amines of cystamine may then react with this active species to form a phosphoramidate bond (Chapter 23, Section 2.2) (Figure 2.72). Specific labeling of DNA probes only at the 5′ end is possible using this technique.

Cystamine;
2,2'-dithiobis(ethylamine)
MW 152

The carbodiimide of choice used to couple cystamine to carboxylate- or phosphate-containing molecules is most often the water soluble carbodiimide, EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride; Chapter 4, Section 1.1). This reagent rapidly reacts with carboxylates or phosphates to form an active ester intermediate, which is highly reactive toward primary amines. The reaction is efficient from pH 4.7 to 7.5, and a variety of buffers may be used, providing they do not contain competing groups.

Cystamine is also used as an activating reagent for disulfide exchange reactions. In this procedure, the reagent is used to modify one of two proteins to be conjugated. The cystamine-modified protein is then mixed with the other protein that contains, or is thiolated to contain, a sulfhydryl group. By disulfide exchange, the sulfhydryl-containing molecule cleaves the disulfide of the cystamine-modified protein, releasing 2-mercaptoethylamine and forming a disulfide crosslink (Figure 2.73).

Using this approach, EGF has been successfully conjugated by disulfide exchange to the A chain of diphtheria toxin (Shimisu *et al*., 1980). A cystaminyl derivative of insulin could also be conjugated to the A chain of diphtheria toxin by this method (Miskimins and Shimizu, 1979). Other references to disulfide exchange using cystamine include Oeltmann and Forbes (1981) and Bacha *et al*. (1983), who prepared antibody–toxin and peptide–toxin conjugates, respectively.

Finally, cystamine may be used to conjugate two macromolecules through its terminal amine groups. In this case, the internal disulfide bridge remains intact, forming a reversible conjugate of the two molecules through reduction of the disulfide bond. Using this approach, the first molecule is modified with cystamine by use of the EDC reaction. A second molecule is then reacted with the free amines of cystamine on the

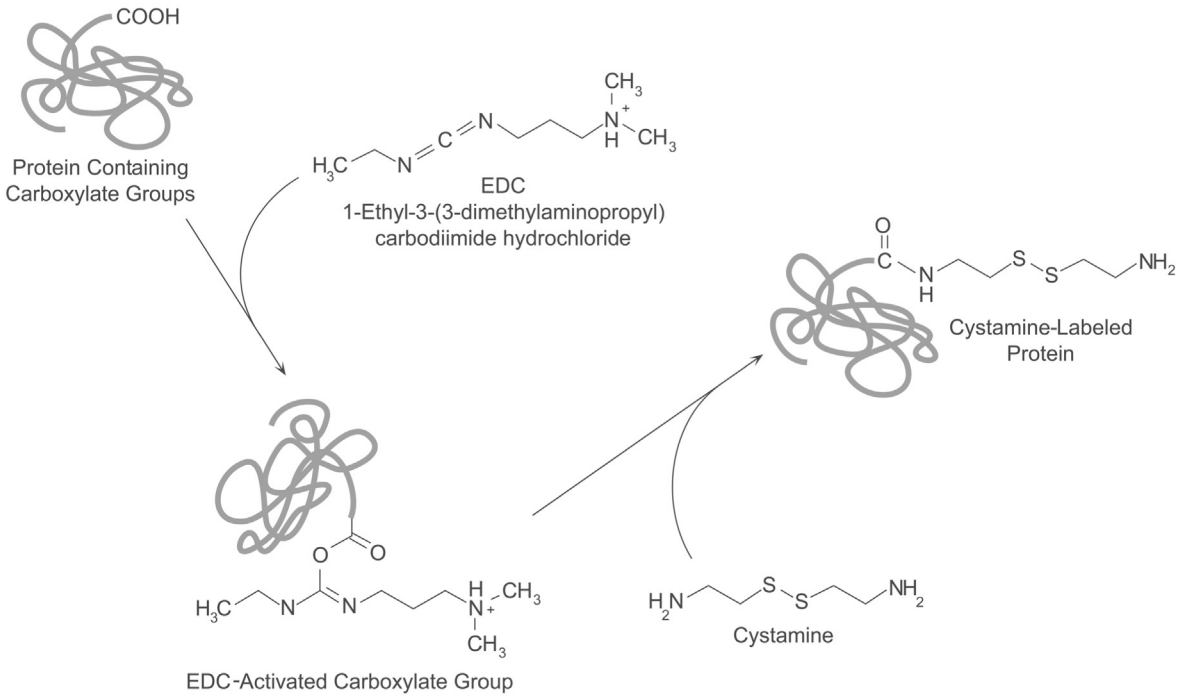

FIGURE 2.71 Cystamine may be used to label protein carboxylate groups using the water soluble carbodiimide EDC.

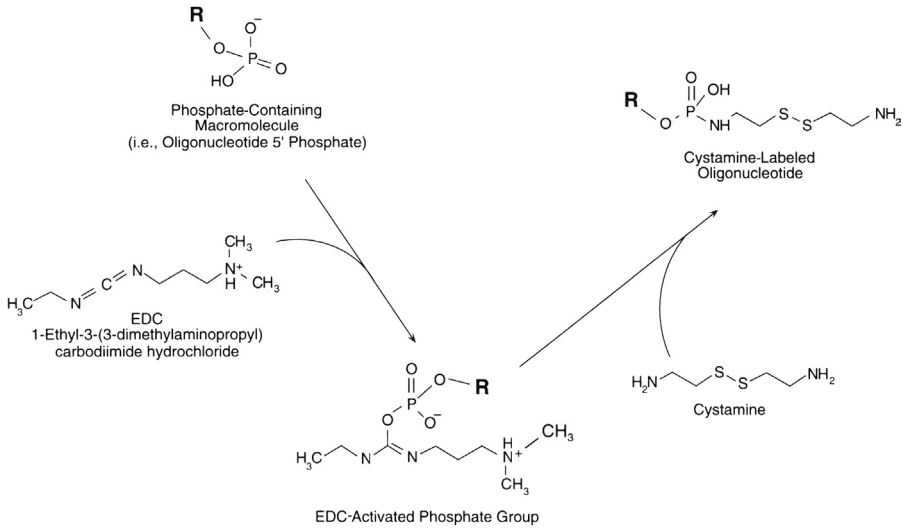

FIGURE 2.72 Cystamine may be used to label phosphate groups, such as at the 5′ end of oligonucleotides, *via* a carbodiimide reaction using EDC. The resultant phosphoramidate linkage is a common way to modify oligonucleotides at the 5′ end.

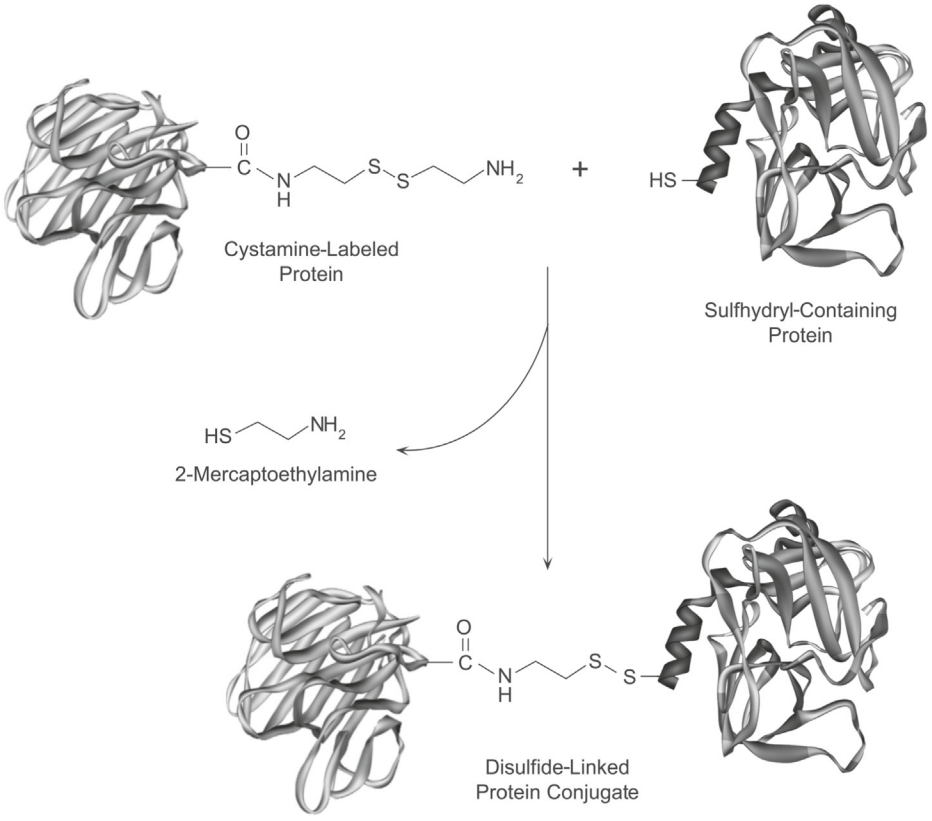

FIGURE 2.73 The disulfide group of a cystamine-modified protein may undergo disulfide interchange reactions with another sulfhydryl-containing protein to yield a disulfide-linked conjugate.

first molecule by use of an amine-reactive chemistry. Typically, this reaction scheme is used if the first molecule initially contains no reactive amines and the second molecule is often an amine-reactive fluorescent tag or other probe. For instance, DNA probes may be cystamine-modified through their 5′ phosphate group using this method and amine-reactive biotin labels subsequently attached. The biotin label is then reversible by virtue of the cystamine cross-bridge through simple disulfide reduction (Chapter 23, Section 2.2).

Modification of Proteins with Cystamine

The following protocol is useful for the modification of proteins with cystamine with subsequent reduction to create the free sulfhydryl.

Protocol

1. Dissolve the protein to be modified at a concentration of 10 mg/ml in a buffer having a pH between 4.7 and 7.5. Avoid buffers or other components containing competing groups to the carbodiimide reaction (i.e., carboxylates or amines). For the lower pH conditions, 0.1-*M* MES, pH 4.7 works best. For a physiological pH environment, 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, will also give good incorporation of cystamine. For other concentrations of protein in solution, proportionally adjust the amount of reagents added.
2. Dissolve cystamine (Aldrich) in the reaction buffer at a concentration of 2.25 mg/ml (10-m*M*). Add an aliquot of this solution to the protein solution to be modified. Use about a 10- to 20-fold molar excess of cystamine over the amount of protein present. For a protein of MW 100,000 at a concentration of 10 mg/ml, add 10 µl of the stock cystamine solution to each milliliter of protein solution to obtain a 10-fold molar excess.
3. Add EDC (Thermo Fisher) to the solution prepared in (2) to obtain at least a 5-fold molar excess over the amount of cystamine present. React for 2 h at room temperature.
4. Separate excess cystamine and EDC (and reaction byproducts) from the modified protein by dialysis or gel filtration using 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. A desalting column may be used for the gel filtration procedure (e.g., Zeba spin columns from Thermo Fisher).
5. To reduce the disulfide groups, add DTT at a concentration of 0.5 mg DTT per mg of modified protein. A stock solution of DTT may be prepared to make it easier to add it to a small amount of protein solution. In this case, dissolve 20 mg of DTT per milliliter of 0.1-*M* sodium acetate, 0.1-*M* NaCl, pH 4.5. Add 25 µl of this solution per mg of modified protein.
6. Mix and react at room temperature for 30 min.
7. Purify the thiolated protein from excess DTT by dialysis or gel filtration using 50-m*M* sodium phosphate, 0.15-*M* NaCl, 1-m*M* EDTA, pH 7.2. The modified protein should be used immediately in a conjugation reaction to prevent sulfhydryl oxidation and formation of disulfide crosslinks.

Modification of Nucleic Acids and Oligonuleotides with Cystamine

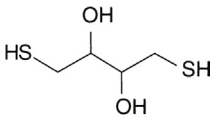
DNA or RNA also may be modified with cystamine at the 5′ phosphate group using a carbodiimide reaction. See Chapter 23, Section 2.2, for a complete discussion of the labeling protocol.

Use of Disulfide Reductants

One of the most convenient ways of generating sulfhydryl groups is by reduction of indigenous disulfides. Many proteins contain cystine disulfides that are not critical to structure or activity. In some cases, mild reducing conditions can free one or more –SH groups for conjugation or modification purposes. The creation of free sulfhydryls in this manner allows for site-directed modification at a limited number of locations within the protein molecule.

This method of creating sulfhydryls for conjugation purposes should be avoided, however, if the indigenous disulfides are important for maintaining native structure and activity. Disulfides are often the point of attachment for subunits within a protein molecule. The cystine bonds may be crucial for maintaining quaternary integrity. Reduction may cause a protein to break up into two or more subunits with little or no remaining activity. Disulfides may also be critical for retention of ligand binding activity. Deformation of an active site may occur if important disulfides are reduced. In these cases, the best mode of thiolation is through the use of a reagent system that does not require a disulfide reducing agent, such as 2-iminothiolane or SATA (see previous discussion, this section).

Occasionally, even a protein containing critical disulfides can be partially reduced to yield a useful thiolated derivative. IgG molecules contain disulfide groups that hold together the two heavy chains as well as disulfides holding the light chain–heavy chain pairs together. Selective reduction of some or all of the hinge region disulfides between the heavy chains can result in a divalent or even a monovalent antibody molecule that still maintains its antigen binding capability. Reductants such as DTT, 2-mercaptoethylamine, 2-mercaptoethanol, or tris(2-carboxyethyl)phosphine (TCEP) in a non-denaturing environment can be used at low concentrations to perform this type of partial cleavage. The thiol-containing antibody that is generated can then be successfully conjugated with enzymes or other molecules through the sulfhydryl residue(s) in the exposed hinge region (Chapter 20, Section 1.1).



Disulfide reductants are also used to investigate protein structural properties. In this case, retention of activity is not the critical issue, but complete reduction of all disulfides is paramount. The standard method of carrying out protein subunit molecular weight determinations by SDS polyacrylamide gel electrophoresis often depends on complete disulfide reduction. When total reduction is necessary, the reductants must also contain a deforming agent to unfold protein tertiary structure. This is typically done by including high concentrations

of denaturants such as 8-*M* urea or guanidine or detergents such as SDS. Under severely deforming conditions, proteins unfold, exposing internal disulfides to the reducing agent. Without these added reagents to deform native protein structure, many buried disulfides would remain unaffected by the reductants.

The following reducing agents represent the most popular options for cleaving disulfide bonds. Their properties and use vary widely. The decision as to which reagent is best is often governed by the molecule being reduced and the potential application. Careful review of these properties may sway the success or failure of a conjugation protocol.

CLELAND'S REAGENT: DTT AND DTE

Dithiothreitol (DTT) and dithioerythritol (DTE) are the *trans* and *cis* isomers of the compound 2,3-dihydroxy-1,4-dithiolbutane. The reducing potential of these versatile reagents was first described by Cleland in 1964. Due to their low redox potential (−0.33 V) they are able to reduce virtually all accessible biological disulfides and maintain free thiols in solution despite the presence of oxygen. The compounds are fully water soluble with very little of the offensive odor of the 2-mercaptoethanol they were meant to replace. Since Cleland's original report, literally thousands of references have cited the use of mainly DTT for the reduction of cystine and other forms of disulfides.

DTT;
Dithiothreitol
MW 154.25

The unique characteristics of DTT and DTE are mainly reflected in their ability to form intramolecular ring structures upon oxidation. Disulfide reductants such as 2-mercaptoethanol, 2-mercaptoethylamine, glutathione, thioglycolate, and 2,3-dimercaptopropanol cleave disulfide bonds in a two-step reaction that involves the formation of a mixed disulfide (Figure 2.74). In the second stage of the reducing process, the mixed disulfide is cleaved by another molecule of reductant, freeing the sulfhydryl and forming a dimer of the reducing agent through the formation of an intermolecular disulfide bond. For simple reductants containing only one thiol, the equilibrium for disulfide exchange is nearly equivalent for the reductant and target protein. Thus, monothiol compounds are usually required in extreme excess to drive the reaction to completion.

The presence of two sulfhydryl groups in DTT and DTE, however, allows the formation of a favored cyclic disulfide during the course of target protein reduction (Figure 2.75). This drives the equilibrium toward the reduction of target disulfides. Therefore, complete reduction is possible with much lower concentrations of DTT or DTE than when using monothiol systems.

As with all reductants, DTT and DTE will reduce disulfides only if they are accessible. The three-dimensional structure of a protein molecule often contains disulfides buried deep in the inner structure of

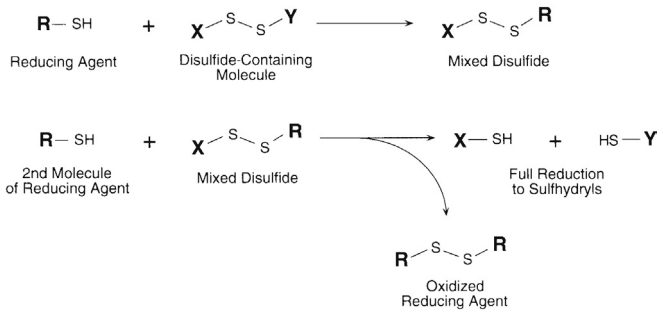


FIGURE 2.74 Thiol-containing disulfide reductants reduce disulfide groups through a multi-step process producing a mixed disulfide intermediate.

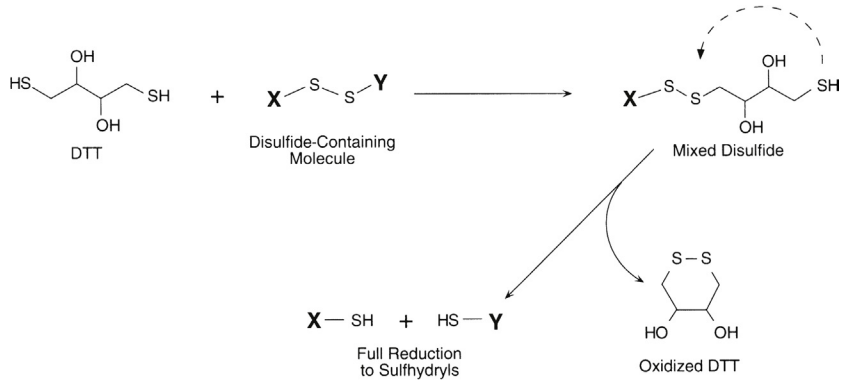

FIGURE 2.75 DTT is highly efficient at reducing disulfides, since a single molecule can reduce the intermediate mixed disulfide by forming a ring structure.

the polypeptide chains. A protein retaining its native conformation is frequently protected from complete reduction. In the absence of denaturants such as urea, guanidine, or SDS, DTT is not capable of reducing all available disulfides within some proteins (Bewley *et al*., 1968; Bewley and Li, 1969). For instance, at moderate concentrations of DTT and no denaturants, limited cleavage of disulfides in antibody molecules can result in reducing mainly the bonds between the heavy chains of the immunoglobulin. This produces two half-antibody molecules, each containing one antigen binding site and free sulfhydryls in the hinge region. This limited reduction process can be used to site-direct sulfhydryl-reactive conjugation reagents away from the antigen binding sites, thus preserving activity (de Rosario *et al*., 1990). However, using an appropriate concentration of deforming agents, DTT efficiently reduces all protein disulfides in the antibody and allows subunit separation for analysis (Konigsberg, 1972).

In a comparative study of disulfide reducing agents, it was determined that use of the relatively strong reductants DTT and TCEP required only 3.25 and 2.75 mole equivalents per mole equivalent of antibody molecule to achieve the reduction of two interchain disulfide bonds between the heavy chains of a monoclonal IgG (Sun *et al*., 2005). This limited reduction strategy retains intact bispecific antibody molecules while providing discrete sites for conjugation to thiols.

DTT may also be used to cleave disulfide containing modification and crosslinking reagents. For thiolation procedures, DTT may be used to remove a dithiopyridyl group or cleave other disulfides to produce a free sulfhydryl. In this case, the presence of a denaturant is usually not required to access and reduce the disulfide of the modification reagent. Similarly, disulfides of crosslinking agents may be reduced after two macromolecules have been conjugated to release them as desired. This technique is often used to analyze receptor–ligand interactions or to discover how two proteins associate *in vivo*.

COMPLETE REDUCTION OF DISULFIDES IN PROTEIN MOLECULES USING DTT

Protocol

1. Dissolve a disulfide-containing protein or peptide at a concentration of 1–10 mg/ml in 6-*M* guanidine hydrochloride, 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4. Alternative denaturant conditions may be used (e.g., 8-*M* urea or 2.3% (w/w) SDS) along with any other buffer salts and pH values desired. A pH between 7.0 and 8.1 usually works best.
2. Add DTT to a final concentration of 10–100-mm.
3. Incubate for 2 h at room temperature. For some buried disulfides to become exposed and fully reduced, it may be necessary to heat the solution (in a capped test tube) at 50°C for 30 min. Some procedures use a 2-min incubation in a boiling water bath to completely denature the protein.
4. For removal of excess DTT, a protein of molecular weight greater than 5000 may be isolated by gel filtration using a desalting column. To maintain the stability of the exposed sulfhydryl groups, include 1–10-m*M* EDTA in the chromatography buffer. The presence of oxidized DTT can be monitored during elution by measuring the absorbance at 280 nm. The protein should elute in the first peak and the DTT reaction products in the second peak.

USE OF DTT TO CLEAVE DISULFIDE-CONTAINING CROSSLINKING AGENTS

The following method may be used to reduce the disulfide bonds of some crosslinking agents, thus cleaving conjugated proteins. This procedure will reduce the pyridyl disulfide group of SPDP to create a thiolated species (see previous discussion in this section and Chapter 6, Section 1.1). It may also be used to partially reduce the indigenous disulfides in some protein molecules. In this regard, low concentrations of DTT under non-denaturing conditions have been used to selectively reduce the disulfides between the heavy chains of immunoglobulin G (Edelman *et al*., 1968; Sun *et al*., 2005). Without an added denaturant to open up the polypeptide chain, internally buried disulfides will typically remain unreduced.

Protocol

1. Dissolve a crosslinked protein or peptide that has been conjugated with the use of a disulfide-containing crosslinker at a concentration of 1–10 mg/ml in 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4. Alternative buffer conditions and pH values may be used; however, a pH between 7.0 and 8.1 usually works best.
2. Add DTT to a final concentration of 1–10-mm.
3. Incubate for 2 h at room temperature.
4. For removal of excess DTT, a protein of molecular weight greater than 5000 may be isolated by gel filtration using a desalting resin. To maintain the stability of the exposed sulfhydryl groups, include 10-m*M* EDTA in the chromatography buffer. The presence of oxidized DTT can be monitored during elution by measuring the absorbance at 280 nm. The protein should elute in the first peak and the DTT reaction products in the second peak.

2-MERCAPTOETHANOL

2-Mercaptoethanol is one of the most common agents used for disulfide reduction. Sometimes referred to as β-mercaptoethanol, it is a clear, colorless liquid with an extremely strong odor. All operations with this chemical should be performed in a well-ventilated

fume hood. The reduction of protein disulfides with 2-mercaptoethanol proceeds rapidly *via* a two-step process involving an intermediate mixed disulfide (Figure 2.76). Due to its strong reducing properties, the reagent is used most often when complete disulfide reduction is required. It can also be used to cleave disulfide-containing crosslinking agents. Usually a concentration of 0.1-*M* 2-mercaptoethanol will cleave a disulfide-containing crosslinker and liberate conjugated proteins (Chapter 9, Section 1).

2-ME;
2-Mercaptoethanol
MW 78.13

2-Mercaptoethanol is used as a reducing additive in a number of biochemical reagents. It is used as a reductant for a Gram-negative bacteria lysis buffer (Schwinghamer, 1980; Scopes, 1982), as the second dimensional equilibration buffer for 2-D electrophoresis (Dunbar, 1987), as the sample reducing buffer for SDS polyacrylamide gel electrophoresis (Laemmli, 1970), and as a participant in the *o*-phthalaldehyde (OPA) reaction for the detection of primary amines (Jones and Gilligan, 1983).

PROTOCOL FOR PREPARATION AND USE OF A GRAM-NEGATIVE BACTERIA LYSIS BUFFER

1. Prepare a solution consisting of 2.5 ml glycerol, 100 µl of 10% Triton X-100 (Thermo Fisher Surfact-Amps X-100), and 10 µl 2-mercaptoethanol.
2. Add 10 g of wet packed cells to the lysis buffer and stir vigorously for 30 min.
3. Add 30 ml of an extraction buffer consisting of 20-m*M* potassium phosphate, pH 7.0, 1-m*M* EDTA, 0.2 mg/ml lysozyme, and 10 µg/ml DNase I.
4. Add 5 mg PMSF dissolved in 0.5 ml acetone and 0.1 mg pepstatin A.
5. Centrifuge for 20 min at 15,000 *g*. Recover the extracted, solubilized material in the supernatant.

PROTOCOL FOR PREPARATION AND USE OF THE SECOND-DIMENSION EQUILIBRATION BUFFER FOR 2-D GELS The following procedure relates to electrophoretic protocols where the first dimension is developed by isoelectric focusing (in tube gels) and the second dimension is a size-exclusion separation by SDS polyacrylamide electrophoresis in a slab gel.

1. Add 4.0 g SDS and 20 ml of 10% glycerol to 150 ml of 0.125-*M* Tris, pH 6.8, and adjust the final volume to 200 ml. Once dissolved, add a few crystals of bromophenol blue, mix, and pass the solution through a 0.2-µm filter. For storage, freeze in 10- to 15-ml aliquots.
2. Immediately before use, add 2-mercaptoethanol to a final concentration of 0.5–0.8%.
3. Incubate the first dimensional electrophoresis tube gel in this reducing buffer for 15 min. Drain off excess buffer and electrophorese in the second dimension.

SDS SAMPLE BUFFER FOR RUNNING ELECTROPHORESIS SIZE SEPARATIONS UNDER REDUCING CONDITIONS

1. Dissolve 2.0 g of SDS, 0.75 g Tris base, and 10 ml of glycerol in 90 ml of water. Adjust the pH to 6.8 and bring the final volume to 100 ml.
2. To a small aliquot of the above buffer, add 2-mercaptoethanol to obtain a final concentration of 2–5%. Only 200 µl of this buffer typically is required to treat and reduce about 10–500 µg of protein. Solubilize the protein sample in this buffer.
3. Incubate in a sealed tube at 95°C for 5–10 min or in a boiling water bath for 1–2 min. Electrophorese immediately.

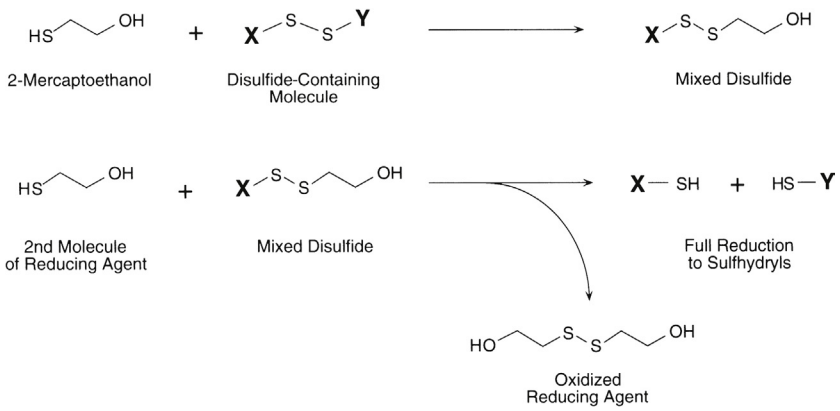

FIGURE 2.76 The reduction of disulfides by 2-mercaptoethanol proceeds through a mixed disulfide intermediate.

O-PHTHALALDEHYDE SOLUTION FOR THE FLUORESCENT DETECTION OF PRIMARY AMINES (SEE SECTION 4.3, OPA)

1. Add 3 ml of the detergent Brij-35 (as a 30% solution) and 2 ml of 2-mercaptoethanol to 950 ml of Fluoraldehyde Reagent Diluent (all reagents from Thermo Fisher).
2. Dissolve 0.5–0.8 g of *o*-phthalaldehyde (OPA) crystals in about 10 ml of methanol.
3. Mix the OPA solution with the solution from (1) and store under nitrogen in sealed glass bottles at 4°C. The addition of an aliquot of this solution to a sample containing primary amines will yield an intense blue fluorescence.

2-MERCAPTOETHYLAMINE

2-Mercaptoethylamine (also called aminoethanethiol) is a disulfide reducing agent that has found widespread application in the partial reduction of immunoglobulin molecules. The reagent is supplied as a solid in the hydrochloride form (Thermo Fisher) and possesses very little of the sulfhydryl odor of 2-mercaptoethanol. When used under non-denaturing conditions, 2-mercaptoethylamine can cleave the disulfide bonds between the heavy chains of IgG. This directed reduction is important for generating sulfhydryls while preserving antigen binding activity.

2-MEA;
2-Mercaptoethylamine
Hydrochloride
MW 113.62

The complex structure of an antibody molecule creates two antigen binding sites from the interaction of the hypervariable regions on both the heavy and light chains. For this reason, heavy–light chain pairing must remain intact during any modification procedure to ensure that antigen binding activity is retained. In addition, it is important that any chemistry take place away from the antigen binding sites so they are not sterically blocked by modification reagents or by subsequent conjugation steps. 2-Mercaptoethylamine can be used to cleave disulfides primarily in the hinge region of IgG—away from the antigen binding sites—thus preserving the disulfides that hold the heavy and light chains together (Yoshitake *et al.*, 1979). It can also be used to reduce $F(ab')_2$ fragments, because they still retain the hinge region disulfides of intact IgG (Figure 2.77).

Once reduced with 2-mercaptoethylamine, immunoglobulins will often be cleaved in half, forming two heavy chain–light chain molecules of MW 75–80,000 and each containing one antigen binding site. These half molecules of IgG will possess reactive sulfhydryls in the hinge region that can be used in conjugation protocols with sulfhydryl-reactive crosslinking reagents. For instance, a reduced antibody may be used to make a conjugate with a maleimide-activated enzyme, forming a reagent useful in immunoassays (Chapter 20, Section 1.1). Similarly, $F(ab')_2$ fragments may be reduced to yield two molecules, each containing an antigen binding site. Making conjugates with this low molecular weight fragment can dramatically

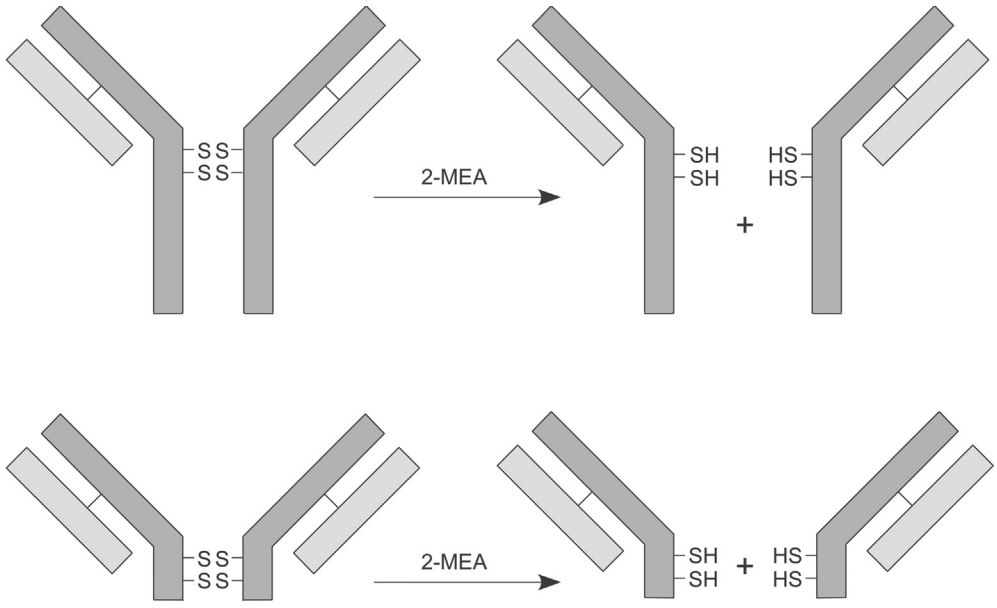

FIGURE 2.77 Disulfide reducing agents such as 2-mercaptoethylamine can be used to cleave the disulfide bonds in the hinge region of antibody molecules. Either intact IgG molecules or $F(ab')_2$ fragments may be reduced in this manner to yield monofunctional antigen binding fragments.

reduce background in assay systems or provide access to antigens restricted to higher molecular weight conjugates made with intact antibody (such as in immunohistochemical staining techniques).

The use of a 500-fold molar excess of 2-mercaptoethylamine over the concentration of antibody presence was found to result in a partially reduced antibody in which two disulfides were reduced to yield four thiols (Sun *et al.*, 2005). This strategy can be used to retain a biospecific antibody construct for subsequent discrete conjugation at the hinge region between the heavy chains.

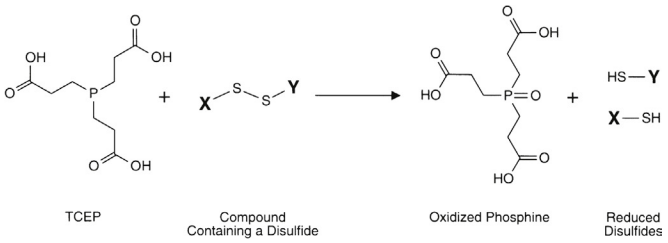

FIGURE 2.78 TCEP reduction of disulfides proceeds without the use of thiol compounds.

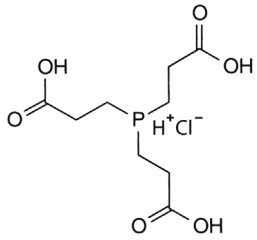
Protocol

1. Dissolve the antibody to be reduced at a concentration of 10 mg/ml in 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, containing 1–10-m*M* EDTA.
2. To each milliliter of the antibody solution, add 6 mg of 2-mercaptoethylamine hydrochloride (final concentration is 50-m*M*). Mix to dissolve. Alternatively, to limit the degree of disulfide reduction, add a 500-fold molar excess of 2-mercaptoethylamine over the concentration of antibody present.
3. Incubate the solution in a sealed tube for 90 min at 37°C.
4. Purify the reduced IgG from excess 2-mercaptoethylamine and reaction byproducts by dialysis or gel filtration using a desalting resin. All buffers should contain 1–10-m*M* EDTA to preserve the free sulfhydryls from metal-catalyzed oxidation. The sulfhydryl-containing antibody may now be used in conjugation protocols that use –SH-reactive heterobifunctional crosslinkers (Chapter 6, Section 1).



TCEP

The reduction of disulfide bonds with trivalent phosphines has been known for some time (Levison *et al.*, 1969; Ruegg *et al.*, 1977; Kirley, 1989). Unfortunately, trialkylphosphines are generally water insoluble, undergo autoxidation, and are extremely odious.

To overcome these issues, the water soluble tris(2-carboxyethyl)phosphine (TCEP) was synthesized and successfully used to cleave organic disulfides to sulfhydryls in water (Burns *et al.*, 1991). The advantage of using this phosphine derivative in disulfide reduction as opposed to previous ones is its excellent stability in aqueous solution, its lack of reactivity with other common functionalities in biomolecules, and its freedom from odor.

The reaction of TCEP with biological disulfides proceeds with initial cleavage of the S–S bond followed by oxidation of the phosphine (Figure 2.78). The stability of the phosphine oxide bond that is formed in this process is great enough to prevent reversal of the reaction. Since this reaction is performed without any added –SH compounds, subsequent conjugation with the generated sulfhydryl groups can be carried out without removal of excess TCEP or reaction byproducts (provided the conjugation step does not involve disulfide exchange reactions, such as with the active disulfide-containing reagent SPDP; Chapter 6, Section 1.1).

Although TCEP is capable of rapidly and quantitatively reducing simple organic disulfides in solution, it requires the presence of a deforming agent to fully reduce all disulfides in proteins. Without opening up the internal disulfides in many protein molecules, TCEP will not be able to reduce them. For complete reduction of IgG, it was found that 20-m*M* TCEP and 5 min of boiling were needed (Hines, 1992). Partial reduction, however, is possible for some more accessible disulfides in protein using aqueous buffers at room temperature. For instance, the use of a 2.75-fold molar excess of TCEP over the concentration of a monoclonal IgG resulted in the reduction of only two disulfide bonds in the hinge region of the antibody, leaving all other disulfides intact (Sun *et al.*, 2005).

TCEP
Tris(2-carboxyethyl)phosphine
(hydrochloride)
MW 250.19

PROTOCOL FOR THE COMPLETE REDUCTION OF DISULFIDE BONDS WITHIN PROTEIN MOLECULES

1. Dissolve the protein to be reduced at a concentration of 1–10 mg/ml in 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4. Other buffers and pH values may also be used. A strong denaturant may be added (6-*M*

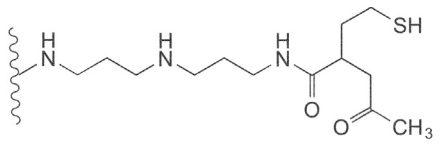
guanidine or 8-*M* urea) to this solution to promote protein unfolding and make buried disulfides more accessible.
2. Add TCEP to a final concentration of 20-m*M*.
3. Place in a sealed tube and incubate in a boiling water bath for 5 min. If a denaturant was included in the buffer from (1), then high temperature may not be necessary. Alternatively, incubate the sample at 50°C for 30 min.
4. To remove excess TCEP and reaction byproducts, dialyze the solution or purify by gel filtration using a buffer containing 1–10-m*M* EDTA.

PROTOCOL FOR PARTIAL REDUCTION OF PROTEIN DISULFIDES OR FOR CLEAVING DISULFIDE-CONTAINING MODIFICATION REAGENTS

1. Dissolve the protein to be reduced at a concentration of 1–10 mg/ml in 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4. Other buffers and pH values may also be used. Do not add a denaturant to unfold protein structure.
2. Add TCEP to a final concentration of 20-m*M*. For partial reduction of antibody disulfides in the hinge region while maintaining a biospecific IgG molecule, add TCEP in a 2.75-fold molar excess over that of the antibody concentration.
3. Incubate for 2 h at room temperature or 37°C.
4. To remove excess TCEP and reaction byproducts, dialyze the solution or purify the protein by gel filtration using a buffer containing 1–10-m*M* EDTA.

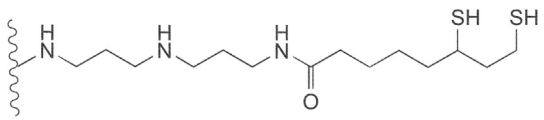
IMMOBILIZED DISULFIDE REDUCTANTS

Many extracellular proteins like immunoglobulins, protein hormones, serum albumin, pepsin, trypsin, ribonuclease, and others contain one or more indigenous disulfide bonds. For functional and structural studies of proteins, it is often necessary to cleave these disulfide bridges. Disulfide bonds in proteins are commonly reduced with small, soluble mercaptans, such as DTT, TCEP, 2-mercaptoethanol, thioglycolic acid, cysteine, etc. High concentrations of mercaptans (molar excess of 20- to 1000-fold) are usually required to drive the reduction to completion.



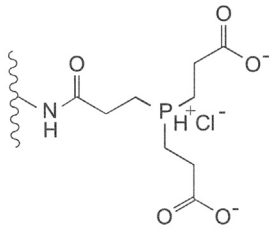
Cleland (1964) showed that dithiothreitol (DTT) and dithioerythritol (DTE) are superior reagents in reducing disulfide bonds in proteins (see previous discussion, this section). DTT and DTE have low oxidation–reduction potential and are capable of reducing protein disulfides at concentrations far below that required with 2-mercaptoethanol. However, even these reagents have to be used in approximately 20-fold molar excess in order to get close to 100% reduction of a protein.

An immobilized disulfide reductant usually consists of an insoluble beaded support material such as agarose that has been modified with a small ligand containing a terminal sulfhydryl group. The presence of densely coupled sulfhydryl groups on the matrix creates enormous disulfide reducing potential. Simply mixing a solution of a disulfide-containing peptide or protein with the immobilized reductant efficiently breaks any disulfide linkages and creates free sulfhydryls. This is done without extraneous sulfhydryl contamination by the reductant, as in the case of soluble reductants.



The use of immobilized disulfide reductants thus has the following advantages over solution-phase agents:

1. Immobilized disulfide reductants can be used to reduce all types of biological disulfides without liberating product or byproducts contaminants.
2. Soluble components that interfere with the assay of free thiol groups are not present if immobilized disulfide reductants are used.
3. Small molecules containing disulfide bonds (such as cystine-containing peptides) may be reduced and isolated simply by removing the immobilized reductant. Separation of reduced molecules from reductant is much more difficult if a soluble reducing agent is used with low molecular weight disulfides.
4. Immobilized disulfide reductants can easily be regenerated and reused many times.



Immobilized dihydrolipoamide (thioctic acid) (Gorecki and Patchornick, 1973, 1975) and immobilized *N*-acetyl-homocysteine thiolactone (Eldjarn and Jellum, 1963; Jellum, 1964) are the two most commonly used immobilized disulfide reductants. In addition, immobilized TCEP provides a reducing matrix that is free of thiols (Thermo Fisher). Such immobilized reductants can successfully be used to reduce many types of biological disulfides, including small molecules such as oxidized glutathione and bovine insulin. They are particularly convenient to reduce peptide disulfides prior to conjugation, which may be necessary even with peptides labeled at their end with a cysteine group, as the sulfhydryl may become oxidized over time and form an inter-peptide disulfide bridge.

Immobilized *N*-acetyl homocysteine attached to a diaminodipropylamine spacer

Immobilized dihydrolipoamide attached to a diaminodipropylamine spacer

Immobilized TCEP attached via an amide bond

Immobilized disulfide reductants may be synthesized as described in Hermanson *et al.* (1992) or by using the immobilization methods described in Chapter 15, or they may obtained commercially (Thermo Fisher).

REDUCTION OF PEPTIDES USING IMMOBILIZED REDUCTANTS

Note: For optimal reduction of peptides, the following steps should be performed at room temperature.

1. Pack an immobilized reductant gel (2 ml settled gel) in a disposable polypropylene column and wash with 5 ml of 0.1-*M* sodium phosphate buffer, pH 8.0, containing 1-m*M* EDTA (equilibration buffer).
2. Prepare the sulfhydryl column by washing with a disulfide reducing agent. Apply 10 ml of freshly made 10-m*M* DTT solution (15.4 mg of DTT dissolved in 10 ml of equilibration buffer). This treatment converts the immobilized ligands into a fully reduced form (free –SH groups).
3. Wash the column with 20 ml of equilibration buffer-1 to remove free DTT.
4. Apply to the column 1.0 ml of peptide solution (dissolved in equilibration buffer) to be reduced. Normally, small peptides (molecular weight less than or equal to that of insulin) require no deforming agent (denaturant) such as guanidine to be completely reduced.
5. After the sample has completely entered into the gel bed, wash the column with 9 ml of equilibration buffer, while collecting 1.0-ml fractions.
6. Monitor the elution of reduced peptide from the column by measuring the absorbance at 280 nm (if peptide absorbs at this wavelength) as well as by performing an Ellman's assay (Section 4.1, this chapter) for thiol groups using a small aliquot (10–20 µl) of each collected fraction
7. Regenerate the sulfhydryl-containing support by following steps 2 and 3 above. Such columns can be regenerated and reused at least ten times without any significant decrease in the reductive capacity.
8. Store the column in 0.02% sodium azide at 4°C.

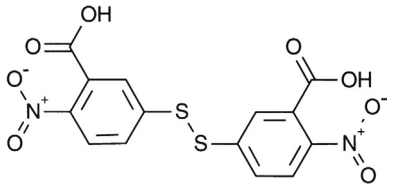
REDUCTION OF PROTEINS USING IMMOBILIZED REDUCTANTS

Note: For optimal reduction of proteins, the following steps must be performed at room temperature.

1. Pack an immobilized reductant gel (2 ml) in a disposable polypropylene column and wash with 5 ml of 0.1-*M* sodium phosphate buffer, pH 8.0, containing 1-m*M* EDTA (equilibration buffer-1).
2. Prepare the sulfhydryl column by washing with a disulfide reducing agent. Apply 10 ml of freshly made 10-m*M* DTT solution (15.4 mg of DTT dissolved in 10 ml of equilibration buffer-1).
3. Wash the column with 10 ml of equilibration buffer-1 and 10 ml of 0.1-*M* sodium phosphate buffer, pH 8.0, containing 1-m*M* EDTA and 6-*M* guanidine hydrochloride (equilibration buffer-2) to remove free DTT.
4. Apply to the column 1.0 ml of protein solution (dissolved in equilibration buffer-2) to be reduced. The inclusion of a denaturant in the solution deforms the protein structure so that inner disulfides are available to the immobilized reductant. Without the presence of guanidine or another deforming agent (e.g., urea, SDS), only partial reduction of the protein is possible.
5. After the sample has completely entered the gel bed, incubate the column at room temperature for 1 h.
6. Wash the column with 9 ml of equilibration buffer-2 while 2-ml fractions are collected.
7. Monitor elution of reduced protein from the column by measuring the absorbance at 280 nm as well as by performing an Ellman's assay for thiol groups (Section 4.1, this chapter) using a small aliquot (50–100 µl) of each collected fraction.
8. Regenerate the sulfhydryl-containing column by following steps 2 and 3 above. Such columns can be regenerated and reused at least 10 times without any significant decrease in the reductive capacity.
9. Store the column in 0.02% sodium azide at 4°C.

SODIUM BOROHYDRIDE

Perhaps the simplest route to the reduction of disulfide groups in peptides is the use of sodium



borohydride ($NaBH_4$). This common reducing agent often used in organic synthesis is able to specifically reduce disulfides to free thiols without affecting any of the other major functional groups in proteins. Gailit (1993) developed a protocol for borohydride reduction, which avoids any purification steps to remove the reducing agent after the reaction. Thus, peptides reduced by this protocol can be used immediately in bioconjugate applications without additional steps.

Protocol

1. Dissolve the peptide to be reduced in a buffer at pH 8 to 10. Sodium phosphate or sodium bicarbonate at 0.1-*M* work well. The optimal pH range for borohydride activity is alkaline; therefore, avoid using buffers at neutral pH.
2. Add sodium borohydride (Aldrich) to the peptide solution to obtain a final concentration of 0.1-*M*. Generation of hydrogen bubbles will occur as the borohydride is dissolved.
3. Incubate at room temperature for 30–60 min.
4. Adjust the pH of the reaction to pH 4.0 using dilute HCl. Incubate for 10 min to ensure the complete destruction of excess borohydride. Hydrogen bubbles again will be evolved from the solution.
5. Readjust the pH to the optimal value for the bioconjugate application to be carried out using the generated thiols. Use the reduced peptide immediately to prevent reoxidation of the thiols to disulfides.

ELLMAN'S ASSAY FOR THE DETERMINATION OF SULFHYDRYLS

Ellman's reagent, 5,5′-dithio*bis*(2-nitrobenzoic acid) (DTNB), reacts with thiols under slightly alkaline conditions to release the highly-chromogenic compound, 5-thio-2-nitrobenzoic acid (TNB) (Ellman, 1959; Riddles, 1979) (Figure 2.79). The reagent contains a disulfide bond between two TNB groups, and reacts with free sulfhydryls to create a mixed disulfide product. The target of the reaction is the unprotonated, conjugate base form of the thiol, $R–S^-$. At pH 8.0, the release of one TNB group per available thiol provides a yellow-colored product with an extinction coefficient at 412 nm of 13,600 $M^{-1}\,cm^{-1}$. The increase in absorbance at this wavelength is directly proportional to the concentration of sulfhydryls in solution. Correlation to a standard curve of known sulfhydryl concentrations allows accurate measurement of thiol content in unknown samples.

Ellman's Reagent
5,5'-Dithio-*bis*-(2-nitrobenzoic acid)
MW 396.4

Ellman's reagent has been used not only for the determination of sulfhydryls in proteins and other molecules, but also as a pre-column derivatization reagent for the separation of thiol compounds by HPLC (Kuwata *et al.*, 1982), in the study of thiol-dependent enzymes (Tsukamoto and Wakil, 1988; Alvear *et al.*, 1989; Masamune *et al.*, 1989), and to create sulfhydryl-reactive chromatography supports for the coupling of affinity ligands (Jayabaskaran *et al.*, 1987) (Chapter 15, Section 2.2). Another important use of the compound is in the assessment of conjugation procedures using sulfhydryl-reactive crosslinking agents (Chapter 6, Section 1).

Depending on the conditions, an Ellman's assay can detect as little as 10-nm cysteine concentration. The linearity can extend into the m*M* range, making the test extremely flexible for different sample situations.

Protocol

1. Dissolve Ellman's reagent (Thermo Fisher) in 0.1-*M* sodium phosphate, pH 8.0, at a concentration of 4 mg/ml.
2. Prepare a set of standards by dissolving cysteine in 0.1-*M* sodium phosphate, pH 8.0, at an initial concentration of 2-m*M* (3.5 mg/ml) and serially diluting this solution (1:1) with reaction buffer down to at least 0.125-m*M*. This will produce five solutions

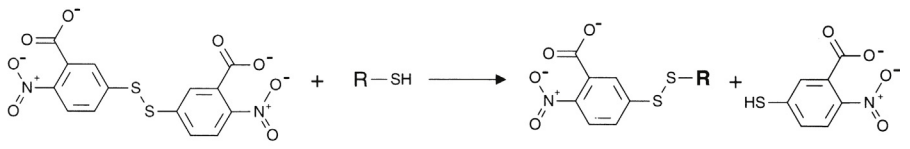


FIGURE 2.79 The reaction of Ellman's reagent with a sulfhydryl group releases the chromogenic TNB anion, which can be quantified by its absorbance at 412 nm.

of cysteine for generating a standard curve. If a more dilute concentration range is required, continue to serially dilute until a set of standards in the desired range is obtained.

3. Label a set of tubes according to the standards and samples to be used. Add 250 µl of each standard and sample to the appropriate tubes. If the samples are in a buffer that may significantly change the pH of the reaction buffer, the samples should be buffer-exchanged or dialyzed into 0.1-*M* sodium phosphate, pH 8.0, before running the assay.
4. Add 50 µl of Ellman's reagent to each standard and sample tube. Mix well.
5. Incubate at room temperature for 15 min.
6. Measure the absorbance of each solution at 412 nm.
7. Plot the absorbance *versus* cysteine concentration for each of the standards. Determine the sulfhydryl concentration of the samples by comparison to the standard curve.

4.2. Introduction of Carboxylate Groups

Modification of various functional groups in macromolecules with the following types of reagents will introduce carboxylate functions for further derivatization purposes. Amines, sulfhydryls, histidine, and methionine side chains are readily modified to contain short molecules terminating in a carboxylic acid. The short chain can serve as a spacer to enhance steric accommodations and the terminal carboxylate group can facilitate subsequent couplings with amines or hydrazides. The introduction of carboxylates also affects the overall charge characteristics or pI of the molecule being derivatized. The modification of amine residues by acylation with anhydrides not only eliminates the positive charge contribution of the protonated amine, but also adds the negative charge contribution of the acid. The result may be a change of minus two in net charge per group modified. While the reactions involved in such derivatizations are conducted under relatively mild conditions, severe alterations in net charge may cause some macromolecules, like proteins, to denature or lose activity. In addition, if the group being modified happens to be critical for active center operation then functionality may be compromised regardless of conditions. While the following reactions are facile and efficient, it should be kept in mind that in certain instances modification may lead to inactivity.

Modification of Amines with Anhydrides

Acid anhydrides, as their name implies, are formed from the dehydration reaction of two carboxylic acid groups (Figure 2.80). Anhydrides are highly reactive toward nucleophiles and are able to acylate a number of the important functional groups of proteins and other macromolecules. Upon nucleophilic attack, the anhydride yields one carboxylic acid for every acylated product. If the anhydride was formed from monocarboxylic acids, such as acetic anhydride, then the acylation occurs with release of one carboxylate group. However for dicarboxylic acid anhydrides, such as succinic anhydride, upon reaction with a nucleophile the ring structure of the anhydride opens, forming the acylated product modified to contain a newly formed carboxylate group. Thus, anhydride reagents may be used to both block functional groups and to convert an existing functionality into a carboxylic acid.

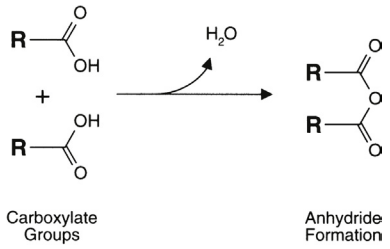

FIGURE 2.80 Anhydrides are created from two carboxylate groups by the removal of one molecule of water.

Protein functional groups able to react with anhydrides include the α-amines at the N-terminals, the ε-amine of lysine side chains, cysteine sulfhydryl groups, the phenolate ion of tyrosine residues, and the imidazolyl ring of histidines. However, acylation of cysteine, tyrosine, and histidine side chains forms unstable complexes that are easily reversible to regenerate the original group. Only amine functionalities of proteins are stable to acylation with anhydride reagents (Fraenkel-Conrat, 1959; Smyth, 1967).

Another potential site of reactivity for anhydrides in protein molecules is modification of any attached carbohydrate chains. In addition to amino group modification in the polypeptide chain, glycoproteins may be modified at their polysaccharide hydroxyl groups to form ester derivatives. Esterification of carbohydrates by acetic anhydride, especially cellulose, is a major industrial application for this compound. In aqueous solutions, however, esterification may be a minor product, since the oxygen of water is about as strong a nucleophile as the hydroxyls of sugar residues.

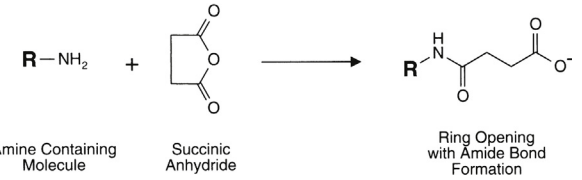
The major side reaction to the desired acylation product is hydrolysis of the anhydride. In aqueous solutions anhydrides may break down by the addition of one molecule of water to yield two carboxylate groups. The presence of an excess of the anhydride in

the reaction medium is usually enough to minimize the effects of competing hydrolysis.

Since both hydrolysis and acylation yield the release of carboxylic acid functionalities, the medium becomes acidic during the course of the reaction. This requires either the presence of a strongly buffered environment to maintain the pH or periodic monitoring and adjustment of the pH with base as the reaction progresses.

SUCCINIC ANHYDRIDE

Succinic acid is a four-carbon molecule with carboxylic acid groups on both ends. The anhydride has a five-atom cyclic structure that is highly reactive toward nucleophiles, especially amines. Attack of a nucleophile at one of the carbonyl groups opens the anhydride ring, forming a covalent bond with that carbonyl and releasing the other to create a free carboxylic acid (Klotz, 1967). Succinylation of positively charged amino groups of proteins and other molecules thus creates amide bond derivatives and converts the cationic site into a negatively charged carboxylate (Figure 2.81). Succinylated proteins often experience dramatic changes in their three-dimensional structure.



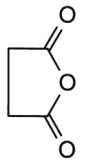


FIGURE 2.81 Succinic anhydride reacts with primary amine groups in a ring-opening process, creating an amide bond and forming a terminal carboxylate.

Subunits may dissociate (Klotz and Keresztes-Nagy, 1962), enzymatic activity may be compromised (Riordan and Valle, 1963, 1964), and the molecular radius and viscosity may be increased (Habeeb *et al.*, 1958). Other effects on protein conformation and function have also been studied (Meighen *et al.*, 1971; Shiao *et al.*, 1972; Shetty and Rao, 1978).

Succinic Anhydride
MW 100

Succinic anhydride may also react with protein phenolate side chains of tyrosine residues and the –OH group of aliphatic hydroxy amino acids (Figure 2.82). The phenolate ester derivatives are unstable above pH 5.0, whereas the serine and threonine esters are more stable but may be cleaved by treatment with hydroxylamine at basic pH (Gounaris and Perlman, 1967).

A succinylated casein derivative that has nearly all its amines blocked can be used as a substrate in protease assays (Hatakeyama, 1992). As the casein is degraded by a protease, free amines are created from α-chain cleavage and release of α-amino groups. The creation of amines can be monitored by an amine detection reagent such as trinitrobenzene sulfonic acid (TNBS; Section 4.3, this chapter). The procedure forms the basis for a highly sensitive assay for protease activity.

Succinylated derivatives of nucleic acids may be prepared by reaction of the anhydride with available –OH groups. The reaction forms relatively stable ester

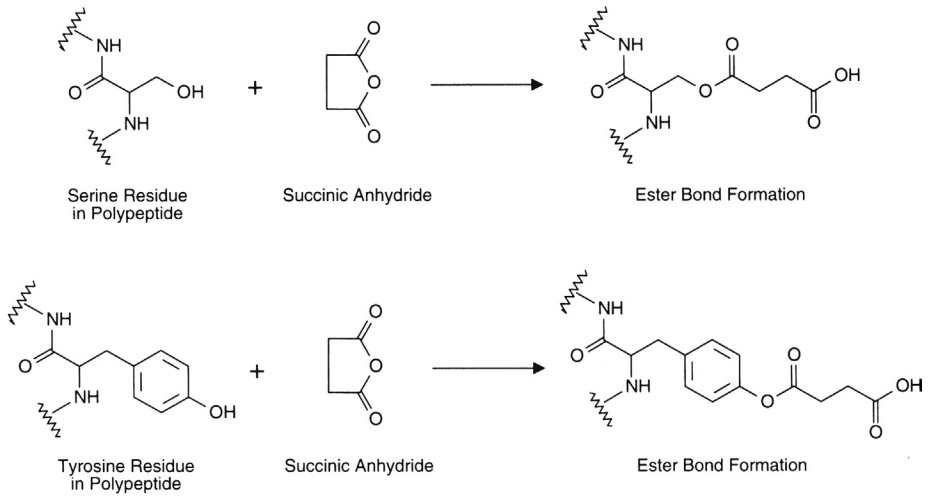

FIGURE 2.82 The hydroxyl group of serine residues and the phenolate ring of tyrosine groups may be modified with succinic anhydride to produce relatively unstable ester bonds. In aqueous conditions these reactions are minor due to competing hydrolysis by water.

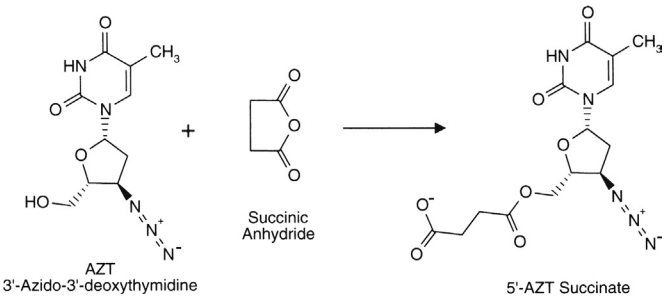

FIGURE 2.83 Succinic anhydride has been used in nonaqueous conditions to modify the 5′-hydroxyl group of nucleic acid derivatives such as AZT.

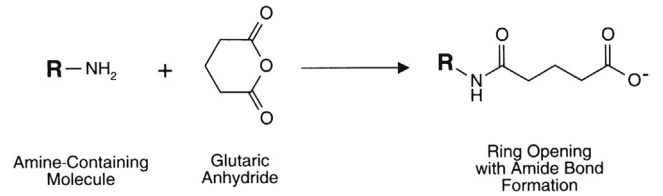

FIGURE 2.84 Glutaric anhydride reacts with amines in a ring-opening process to create an amide bond linkage and a terminal carboxylate group.

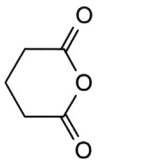
derivatives that create carboxylates on the nucleotide for further conjugation or modification (Figure 2.83). This method has been used in nucleic acid synthesis (Matteucci and Caruthers, 1980) and to derivatize nucleotide analogs such as AZT (Tadayoni, 1993).

Succinic anhydride is also a convenient extender for creating spacer arms on chromatography supports. Supports derivatized with amine-terminal spacers may be succinylated to totally block the amine functionalities and form terminal carboxylic acid linkers for coupling amine-containing affinity ligands (Cuatrecasas, 1970). See Chapter 15 for a complete discussion of immobilization techniques.



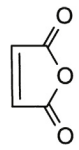
Molecules modified with succinic anhydride to create terminal carboxylate functionalities may be further conjugated to amine-containing molecules by use of amide bond-forming reagents such as carbodiimides (Chapter 4, Section 1).

Protocol

1. Dissolve (or suspend in the case of insoluble polymers or support materials) the amine-containing molecule to be succinylated in a buffer having a pH between 6.0 and 9.0. Higher pH buffers will cause the reaction to occur faster and result in more amines in an unprotonated state. Suitable buffer salts include sodium acetate, sodium phosphate, and sodium carbonate in a 0.1–1.0-*M* concentration. Avoid buffers containing primary amine groups such as Tris. Alternatively, the substance may be dissolved in water and the pH maintained in the proper range by periodic addition of NaOH. This is conveniently done by means of a pH stat. Even in buffered reactions, the pH should be monitored to prevent severe acidification of the reaction solution, which could damage the molecule being modified.
2. Add a quantity of succinic anhydride to the reaction medium to provide at least a 5–10 molar excess of reagent over the amount of amines to be modified. Even greater molar excess may be required for total blocking of all the amines of some proteins. When adding solid succinic anhydride, multiple additions may be carried out to maintain solubility of the reagent in the reaction solution. The anhydride may also be dissolved in dry dioxane before addition to aid in dissolution.
3. React for at least 1–2 h at room temperature. To ensure complete blocking of all amine groups, the reaction may be continued overnight.
4. Remove excess reactants from the succinylated molecule by dialysis, gel filtration, or some other suitable method. The efficiency of amine modification may be assessed by use of the TNBS test for amines (Section 4.3, this chapter). A negative test for amines indicates complete succinylation.

GLUTARIC ANHYDRIDE

Glutaric acid is a linear, five-carbon molecule with carboxylic acid groups on both ends. It contains one more carbon in length than the similar compound succinic acid. The anhydride of glutaric acid forms a cyclic structure containing six atoms. Attack of a nucleophile, such as an amino group, on one of the carbonyl groups of glutaric anhydride opens the ring, forming an amide linkage and liberating the other carboxylic acid (Figure 2.84). Reaction with the phenolate of tyrosine or the sulfhydryl group of cysteine forms unstable linkages (an ester and a thioester, respectively) that can easily hydrolyze. As with succinic anhydride, however, aliphatic hydroxyl groups such as those of serine and threonine may be modified with glutaric anhydride to create more stable ester bonds (see above).



Glutaric Anhydride
MW 114

PROTOCOL The procedure for the modification of amine-containing compounds with glutaric anhydride is identical to that described for succinic anhydride, above.

MALEIC ANHYDRIDE

Maleic acid is a linear, four-carbon molecule with carboxylate groups on either end similar to succinic acid, but with a double bond between the central carbon atoms. The anhydride of maleic acid is a cyclic molecule containing five atoms in its ring. Although the reactivity of maleic anhydride is similar to other such reagents like succinic anhydride, the products of maleylation are much more unstable toward hydrolysis, and the site of unsaturation lends itself to additional side-reactions. Acylation products of amino groups with maleic anhydride are stable at neutral pH and above, but they readily hydrolyze at acid pH values (around pH 3.5) (Butler *et al*., 1967). Maleylation of sulfhydryls and the phenolate of tyrosine are even more sensitive to hydrolysis.

Maleic Anhydride
MW 98

As with other cyclic anhydrides, the acylation of an amine residue will proceed with elimination of the potential positive charge of the amine and addition of the negative charge created by the anhydride ring opening (Figure 2.85). Thus, a molecule can undergo a change of minus two in net charge per site of maleylation. Proteins extensively modified with maleic anhydride may spontaneously dissociate into subunits or experience a general opening of their three-dimensional structures (Sia and Horecker, 1968; Uyeda, 1969).

The double bond of maleic anhydride may undergo free-radical polymerization with the proper initiator. Polymers of maleic anhydride (or copolymers made with another monomer) are commercially available (Polysciences). They consist of a linear hydrocarbon backbone (formed from the polymerization of the vinyl groups) with cyclic anhydrides repeating along the chain. Such polymers are highly reactive toward amine-containing molecules.

Maleic acid imides (maleimides) are derivatives of the reaction of maleic anhydride and ammonia or primary amine compounds. The double bond of a maleimide may undergo an alkylation reaction with a sulfhydryl group to form a stable thioether bond (Chapter 3, Section 2.2). Maleic anhydride may presumably undergo the same reaction with cysteine residues and other sulfhydryl compounds.

Proteins derivatized with maleic anhydride exhibit an increase in their absorptivity at wavelengths below 280 nm, due to the addition of the unsaturated carbon–carbon bond. The extent of maleylation may be estimated by measuring the absorbance increase before and after modification (Freedman *et al*., 1968).

PROTOCOL Modification of amines with maleic anhydride is done essentially the same as that described for succinic anhydride, except the pH of the reaction should be kept alkaline (pH 8–9) at all times to prevent unwanted de-acylation. Deblocking of maleylated amines can be accomplished according to the following procedure of Butler *et al*. (1967).

1. Adjust the pH of the maleylated protein or other molecule to pH 3.5 with formic acid and aqueous NH_3.
2. Incubate the solution at 37°C for 30 h.
3. Stop the deblocking reaction by the addition of NaOH to raise the pH back to neutrality.

CITRACONIC ANHYDRIDE

Citraconic anhydride (or 2-methylmaleic anhydride) is a derivative of maleic anhydride that is even more reversible after acylation than maleylated compounds. At alkaline pH values (pH 7–8) the reagent effectively

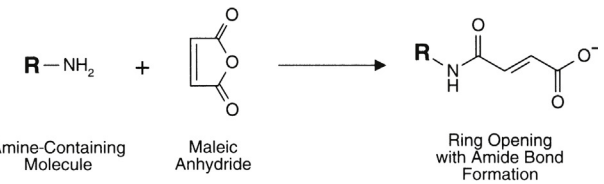


FIGURE 2.85 Maleic anhydride reacts with amine groups in a ring-opening process to create carboxylate derivatives.

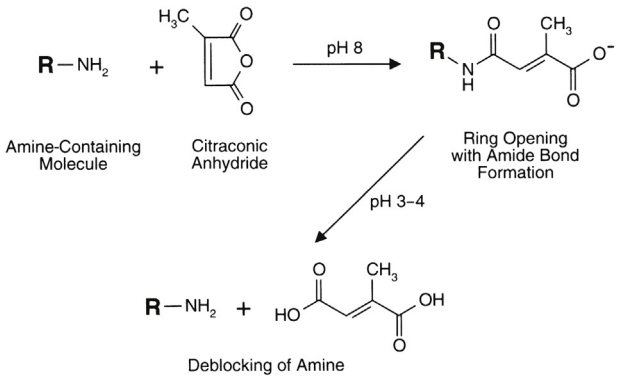

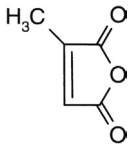

FIGURE 2.86 Citraconic anhydride can be used to block amine groups reversibly. The amide bond derivative is unstable to acidic conditions.

reacts with amine groups to form amide linkages and a terminal carboxylate. However, at acid pH (3–4), these bonds rapidly hydrolyze to release citraconic acid and free the amine (Figure 2.86) (Dixon and Perham, 1968; Habeeb and Atassi, 1970; Klapper and Klotz, 1972; Shetty and Kinsella, 1980). Thus, citraconic anhydride has been used to temporarily block amine groups while other parts of a molecule are undergoing derivatization. Once the modification is complete, the amines can then be unblocked to create the original structure.

Citraconic Anhydride MW 113

Acid-labile, heterobifunctional crosslinking reagents have been synthesized using 2-methylmaleic anhydride at one end (Blattler *et al*., 1985). Amines can be reacted with the anhydride end under alkaline conditions to form amide linkages. The other end, containing another functionality, in this case a maleimide group, is then made to react with a sulfhydryl-containing molecule. After the conjugation is complete, the citraconylamide end can be specifically released by lowering the pH.

Citraconic anhydride has also been used to reverse the effects of formalin fixation in tissue sections. Namimatsu *et al*. (2005) found that heating deparafinized tissue sections in a dilute solution of citraconic anhydride broke the formaldehyde crosslinks and restored antigen recognition of proteins within the samples. In addition, the compound has been used to stabilize certain enzymes and improve their catalytic performance (Rodrigues *et al*., 2011).

Citraconic anhydride is a toxic liquid that should be handled with extreme care in a fume hood. Avoid contact with skin or eyes and inhalation of vapors.

Protocol

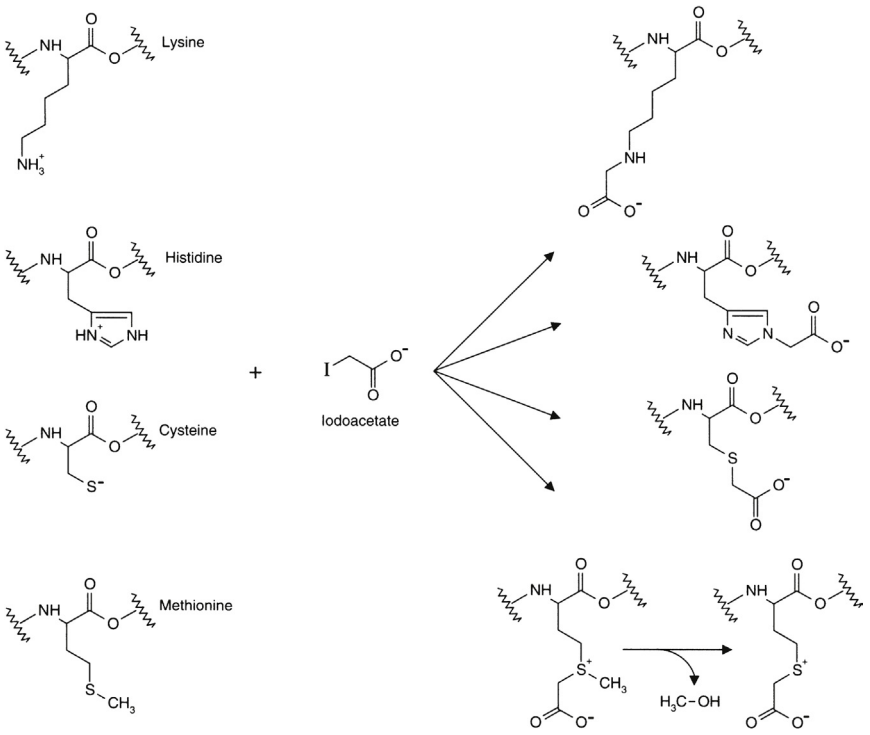
1. Dissolve the amine-containing molecule to be modified in a buffer having a pH of between 8 and 9. Maintenance of this pH range is necessary due to the high tendency of citraconylamides to hydrolyze at lower pH. Suitable buffer salts include sodium phosphate and sodium carbonate in a 0.1- to 1.0-*M* concentration. Avoid buffers containing primary amine groups such as Tris. Also avoid thiol reducing agents containing –SH groups, as these may be acylated by the anhydride. Alternatively, the substance may be dissolved in water and the pH maintained in the proper range by periodic addition of NaOH. This is conveniently done by means of a pH stat.
2. Add a quantity of citraconic anhydride to the reaction medium to provide at least a 5–10 molar excess of reagent over the amount of amines to be modified. Even greater molar excesses may be required for total blocking of all the amines of some proteins.
3. React for at least 1–2 h at room temperature. To ensure complete blocking of all amine groups, the reaction may be continued overnight.
4. Remove excess reactants from the citraconylated molecule by dialysis or gel filtration. The efficiency of amine modification may be assessed by use of the TNBS test for amines (Section 4.3, this chapter). A negative test for amines indicates complete modification.

To remove the citraconic modifications and free the amine groups, the protein may be treated in one of two ways:

1. Adjust the pH of the citraconylated molecule to 3.5–4.0 by addition of acid. Incubate at room temperature overnight or for at least 3 h at 30°C.
   Or
2. Treat the citraconylated molecule with 1-*M* hydroxylamine at pH 10 for 3 h at room temperature.

Modification of Sulfhydryls with Iodoacetate

Iodoacetate (and bromoacetate) can react with a number of functional groups within proteins: the sulfhydryl group of cysteine, both imidazolyl side-chain nitrogens of histidine, the thioether of methionine, and the primary ε-amine group of lysine residues and N-terminal α-amines (Gurd, 1967). The relative rate of reaction with each of these residues is generally dependent on the degree of ionization and thus the pH at which the modification is carried out. The exception to this is methioninyl thioethers, which react rapidly at nearly all pH values above about 1.7 (Vithayathil and Richards, 1960). The reaction products of these groups with iodoacetate are illustrated in Figure 2.87. The only reaction resulting in one definitive product is that of the alkylation of cysteine sulfhydryls, giving the carboxymethylcysteinyl derivative (Cole *et al*., 1958). Histidine groups may be modified at either nitrogen atom of their imidazolyl side chain. Both mono-substituted derivatives and di-substituted products of the imidazole ring are possible (Crestfield *et al*., 1963). With primary amine groups such as in the side chain of lysine residues, the products of the reaction are the secondary amine (monocarboxymethyllysine) or the tertiary amine derivative (dicarboxymethyllysine). Methionine thioether groups give the most



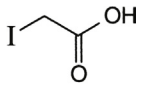


FIGURE 2.87 Iodoacetate can modify a number of amino acid side chains in proteins, forming alkylated derivatives containing a terminal carboxylate.

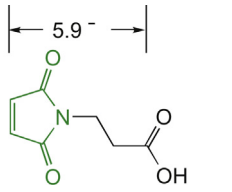
complicated products, some of which rearrange or decompose unpredictably. The only stable derivative of methionine is where the terminal methyl group is lost to form carboxymethylhomocysteine, the same product as the reaction of iodoacetate with homocysteine (Gundlach *et al*., 1959).

Iodoacetate
MW 185.9

The relative reactivity of α-haloacetates toward protein functionalities is sulfhydryl > imidazolyl > thioether > amine. Among halo derivatives the relative reactivity is I > Br > Cl > F, with fluorine being almost unreactive. The α-haloacetamides have the same trend of relative reactivities, but will obviously not create a carboxylate functional group. The acetamide derivatives typically are used only as blocking agents.

Thus, iodoacetate has the highest reactivity toward sulfhydryl cysteine residues and may be directed specifically for –SH modification. If iodoacetate is present in limiting quantities (relative to the number of sulfhydryl groups present) and at slightly alkaline pH, cysteine modification will be the exclusive reaction. The specificity of this modification has been used in the design of heterobifunctional crosslinking reagents, where one end of the crosslinker contains an iodoacetamide derivative and the other end contains a different functionality directed at another chemical target (see SIAB, Chapter 6, Section 1.5).

Protocol



1. Dissolve the sulfhydryl-containing protein or macromolecule to be modified at a concentration of 1–10 mg/ml in 50-m*M* Tris, 0.15-*M* NaCl, 5-m*M* EDTA, pH 8.5. EDTA is present to prevent metal-catalyzed oxidation of sulfhydryl groups. The presence of Tris, an amine-containing buffer, should not affect the efficiency of sulfhydryl modification. Not only do amines generally react more slowly than sulfhydryls, the amine in Tris buffer is of particularly low reactivity. If Tris does pose a problem, however, use 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 5-m*M* EDTA, pH 8.0.
2. Add iodoacetate to a concentration of 50-m*M* in the reaction solution. Alternatively, add a quantity of iodoacetate representing a 10-fold molar excess relative to the number of –SH groups present. An estimation of the sulfhydryl content in the protein to be modified can be accomplished by performing an Ellman's assay (Section 4.1, this chapter). Readjust the pH if necessary. To aid in adding a small quantity of iodoacetic acid to the reaction,

a concentrated stock solution may be made in the reaction buffer, the pH re-adjusted, and an aliquot added to the protein solution to give the desired concentration.

3. Mix and react for 2 h at room temperature. To avoid the possibility of methionine modification, limit the reaction to 30 min.
4. Purify the modified protein from excess iodoacetate by dialysis or gel filtration.
5. An Ellman's assay comparing the unmodified protein to the iodoacetylated protein may be carried out to assess the degree of modification.

Modification of Sulfhydryls with BMPA

BMPA is *N*-β-maleimidopropionic acid (or 3-maleimidopropionic acid), which contains a thiol-reactive maleimide group at one end and a carboxylate group on the other end (Rich, 1975; Moroder, 1983, 1987). The compound is the acid precursor to the short, heterobifunctional crosslinker 3-maleimidopropionic acid *N*-hydroxysuccinimide ester (BMPS; Chapter 6, Section 1.15).

BMPA
N-β-Maleimidopropionic acid
(3-Maleimidopropionic acid)
MW: 169.13

Like BMPS, BMPA is spontaneously reactive toward sulfhydryls through its maleimide, but unlike BMPS it must be activated using a carbodiimide, such as EDC, to couple to amines or hydrazides through its carboxylic acid end. In its use as a blocking or modification agent for sulfhydryls, BMPA may be reacted with a thiol-containing molecule to form a stable thioether bond. The blocking of thiols takes place in buffered aqueous conditions from slightly acidic to moderately basic pH by addition to the double bond of the maleimide group. The final product, which then contains the short propionic acid spacer, terminates in a negatively charged carboxylate. Thus, thiols can be modified and transformed into carboxylate-containing molecules using this reagent.

BMPA has also been used as a crosslinking agent in a number of applications, including the preparation of peptide–protein conjugates for immunogens (Iglesias *et al.*, 2001), to prepare immunomodulating adducts (Gemeiner *et al.*, 1992; Cruz *et al.*, 2001), in the preparation of novel trifunctional compounds containing the metal-chelating group lysine nitrilotriacetic acid (NTA) for conjugation with His-tagged proteins (Meredith *et al.*, 2004), for the immobilization of proteins onto surfaces (Jung and Wilson, 1996), to create thiol-reactive quantum dots for labeling biomolecules (Evident Technologies, Inc., website protocols, 2005), to form albumin–insulin conjugates for slow-release drugs (Shechter *et al.*, 2005), and to synthesize thiol-reactive luminescent chelates for time-resolved fluorescence applications (Chen and Selvin, 1999).

Figure 2.88 shows the reactions of BMPA for the modification of thiols and a subsequent reaction using an EDC-mediated amide bond formation for coupling

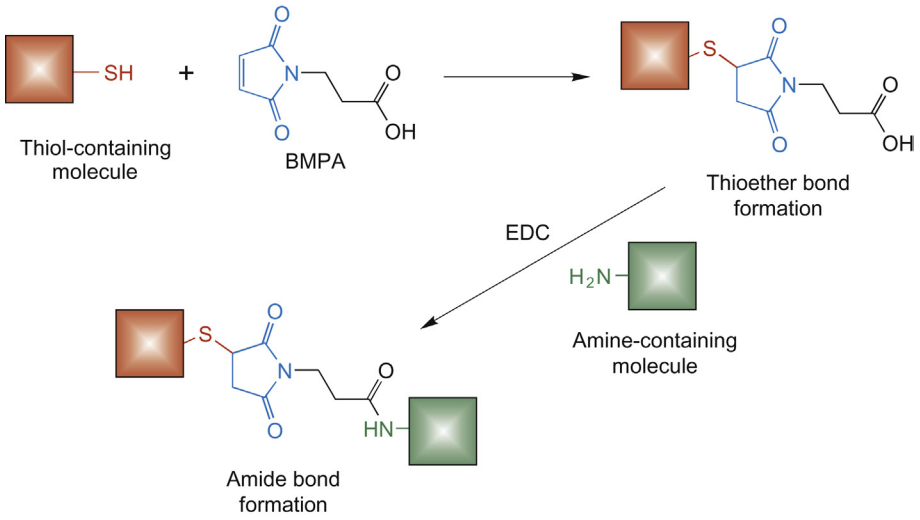


FIGURE 2.88 The maleimide group of BMPA reacts with a thiol-containing molecule to result in a modification having a terminal carboxylate group. Amine-containing molecules can then be conjugated to the carboxylate using a carbodiimide reaction with EDC.

to its carboxylate end. The maleimide–thiol reaction proceeds at physiologic pH to form a stable thioether linkage with sulfhydryl-containing molecules. The combination of EDC and sulfo-NHS (Chapter 4, Section 1.2) may also be used to form an intermediate sulfo-NHS ester, which can enhance the yield of amide bond formation. Cysteine groups in proteins and peptides may be permanently blocked using this reagent, yielding a modification that terminates in the negatively charged carboxylate.

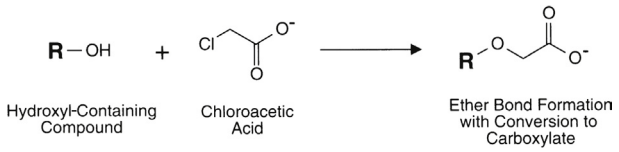
The use of BMPA to block a thiol and create a terminal carboxylate is illustrated in the following protocol. The protocol relates to the modification of proteins, but similar reaction conditions can be used to modify other thiol-containing molecules or surfaces. See Chapter 6, Section 1.15, for additional information related to BMPA and its amine-reactive counterpart, BMPS.

Protocol

1. Dissolve a thiol-containing protein in phosphate buffered saline (PBS), pH 6.5 to 7.5, at a concentration of 1–10 mg/ml. Disulfides may be reduced to yield free thiols using DTT, TCEP, or other reducing agents, but reductants containing sulfhydryls should be completely removed by dialysis or desalting prior to reaction with BMPA.
2. Dissolve BMPA in DMSO or DMF to prepare a stock solution at a higher concentration such that adding an aliquot of this solution to the protein solution will result in the desired molar excess of the maleimide over the concentration of thiols present.
3. Add a quantity of BMPA to the protein solution to obtain at least a 5-fold molar excess of maleimide reagent over the amount of thiol present in the protein. The final concentration of organic solvent in the protein solution should not exceed 10% to prevent protein precipitation. Mix thoroughly to dissolve.
4. React for 2 h at room temperature.
5. Purify the modified protein from reactants and reaction byproducts by dialysis or gel filtration.

Modification of Hydroxyls with Chloroacetic Acid

Chloroacetic acid can be used to transform a rather unreactive hydroxyl into a carboxylate group that can be used in a variety of conjugation reactions. The reaction proceeds under basic conditions, yielding a stable ether bond terminating in a carboxymethyl group (Figure 2.89) (Plotz and Rifai, 1982; Brunswick *et al.*, 1988). Side reactions will occur with other nucleophiles, such as amines, if they are present in the molecule to be modified. The reagent is used most often to modify



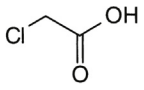


FIGURE 2.89 Chloroacetic acid can be used to create a carboxylate group from a hydroxyl.

pure polysaccharides or hydroxyl-containing polymers that contain no other functionalities.

Chloroacetic Acid
MW 94.47

The following protocol illustrates the modification of a dextran polymer with chloroacetic acid.

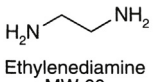
Protocol

1. In a fume hood, prepare a solution consisting of 1-*M* chloroacetic acid in 3-*M* NaOH.
2. Immediately add dextran polymer to a final concentration of 40 mg/ml. Mix well to dissolve.
3. React for 70 min at room temperature with stirring.
4. Stop the reaction by adding 4 mg/ml of solid NaH_2PO_4 and adjusting the pH to neutral with 6-*N* HCl.
5. Remove excess reactants by dialysis.

4.3. Introduction of Primary Amine Groups

Primary amine groups on proteins consisting of N-terminal α-amines and lysine side-chain ε-amines are typically present in abundant quantities for modification or conjugation reactions. Occasionally, however, a protein or peptide will not contain sufficient amounts of available amines to allow for an efficient degree of coupling to another molecule or protein. For instance, horseradish peroxidase (HRP), a popular enzyme employed in the preparation of antibody conjugates, only possesses two free amines that can participate in conjugation protocols. Creating additional amines on HRP allows for higher amounts of modification and thus produces more active conjugates.

Other non-protein molecules, such as nucleic acids and oligonucleotides, may not normally possess primary amines of sufficient nucleophilicity to react with common modification reagents. The ability to add amine functionalities to these molecules is sometimes the only route to successful conjugation. Creating amines at specific sites within these molecules allows for site-directed modification at known positions, thus better ensuring active conjugates once formed.



The following reagents and techniques can be used to directly transform carboxylates or sulfhydryls into reactive amine functional groups. In addition, sugars, polysaccharides, or glycan-containing macromolecules may be modified to contain amines after mild periodate activation to form aldehyde groups or through modification at the reducing end of a carbohydrate.

Modification of Carboxylates with Diamines

Carboxylic acids may be covalently modified with short compounds containing primary amines at either end to form amide linkages. The result of such alterations is to block the carboxylates and form terminal amino groups. Reacting the diamine in high molar excess ensures that only one end of the compound couples to each carboxylate and does not crosslink the molecules being modified. Amide bond formation may be accomplished by several methods including carbodiimide-mediated coupling (Chapter 4, Section 1), active ester intermediates such as *N*-hydroxysuccinimide esters (Chapter 3, Section 1.4), and the use of carbonylating compounds such as *N*,*N*′-carbonyldiimidazole (Chapter 4, Section 3). A combination of the water soluble carbodiimide EDC and sulfo-NHS is also an efficient way of creating amide linkages (Chapter 4, Section 1.2).

Diamines that can be used for aminoalkylation include ethylene diamine, 1,3-diaminopropane, 3,3′-iminobispropylamine (also known as diaminodipropylamine), 1,6-diaminohexane, and the Jeffamine-type compounds containing a hydrophilic chain consisting of polyethylene- or polypropylene-oxide (formerly from Texaco Chemical Co., now Huntsman Corporation). Ethylene diamine is perhaps the most popular choice for protein carboxylate modification. Its short chain length ensures minimal steric effects and virtually no hydrophobic interactions. Diaminodipropylamine provides a longer spacer arm and has been used extensively as a bridging molecule for coupling carboxylate-containing ligands to insoluble supports (Hermanson *et al*., 1992). The long hydrocarbon chain of 1,6-diaminohexane, however, may induce hydrophobic effects and probably should be avoided. The longest diamine of the group is the Jeffamine compound. Its chain is extremely hydrophilic and should function as an excellent modifier of carboxylates when a longer spacer is desired.

In addition, there are other diamine spacers containing discrete PEG chains available with one end blocked using either a t-BOC group or a CBZ-amido group (Quanta BioDesign). These diamine spacers are extremely hydrophilic due to the presence of a PEG_3 or PEG_{11} cross-bridge unit. Since one end of these compounds is masked with a reversible blocking group commonly used in peptide synthesis, the free amine end can be conjugated to a carboxylic acid without the possibility of crosslinking. The blocked end can then be removed with TFA (for t-BOC groups) or by reduction using hydrogen in the presence of a Pd/C catalyst (for CBZ amido groups). This type of deblocking reaction should only be used with molecules that can tolerate these conditions, such as organic molecules and short peptides. Complex proteins, however, may be denatured or lose activity under those conditions.

Diamine modification of proteins can have dramatic effects on the net charge of the molecule, usually significantly raising the pI from the native state. The amide linkage eliminates the negative potential of the carboxylate and the terminal amine adds the potential for a positive charge. Thus, diamine modification may have the net effect of changing the overall charge by plus two for every carboxylate residue coupled. Proteins heavily modified with diamines may exhibit vital changes in activity due to the alteration of microenvironmental charge at each site of modification. In some cases, native conformation may be changed and activity completely lost.

Raising the pI of macromolecules can also significantly alter the immune response toward them upon *in vivo* administration. Cationized proteins (those modified with diamines to increase their net charge or pI) are known to generate an increased immune response compared to their native forms (Muckerheide *et al.*, 1987a,b; Apple *et al.*, 1988; Domen *et al.*, 1988). The use of cationized BSA as a carrier protein for hapten conjugation can result in a dramatically higher antibody response toward a coupled hapten (Chapter 19).

The following protocol using the carbodiimide EDC is an efficient way of modifying protein carboxylates with diamines either to increase the amount of amines present for further conjugation or to create a cationized protein having an increased net charge (Figure 2.90). Note that glycoproteins containing sialic acid may be modified at this sugar's COOH group in addition to coupling at C-terminal, aspartic acid, and glutamic acid functions on the polypeptide chain. Other carboxylate-containing macromolecules may be modified using this procedure as well.

Protocol

1. Dissolve the protein to be modified at a concentration of 1–10 mg/ml in 0.1-*M* MES, pH 4.7 (coupling buffer). Other buffers may be used as long as they do not contain groups that can participate in the carbodiimide reaction. Avoid carboxylate- or amine-containing buffers such as citrate, acetate, glycine, or Tris. Higher pH conditions may be used up to about pH 7.5 (in sodium phosphate buffer) without severely affecting the yield of modification. The protein in solid form also may be added directly to the diamine solution prepared in (2).
2. Dissolve the diamine chosen for modification at a concentration of 1-*M* made up in the coupling buffer. If a free-base form of diamine is used, then the solution will become highly alkaline upon dissolution. This operation will also generate heat—the solution process being highly exothermic. The easiest way to dissolve such a diamine is to initially add the correct amount to a beaker containing a quantity of crushed ice equal to the final solution volume desired. The ice should be made from deionized water or the equivalent to maintain purity. All operations should be carried out in a fume hood. Next, add an equivalent weight of concentrated HCl and mix. As the mixing becomes complete, the ice will almost totally melt and provide nearly the correct final solution volume. Finally, add an amount of MES buffer salt to bring its concentration to 0.1-*M*, and adjust the solution pH to 4.7. In some cases, the dihydrochloride form of the diamine is commercially available and can be used to avoid such unpleasant pH adjustments. For instance, ethylene diamine dihydrochloride is available from Aldrich. It can be added to the 0.1-*M* MES buffer without a significant change in pH.
3. Add the protein solution to an equal volume of diamine solution and mix. Alternatively, the solid protein can be dissolved directly in the diamine

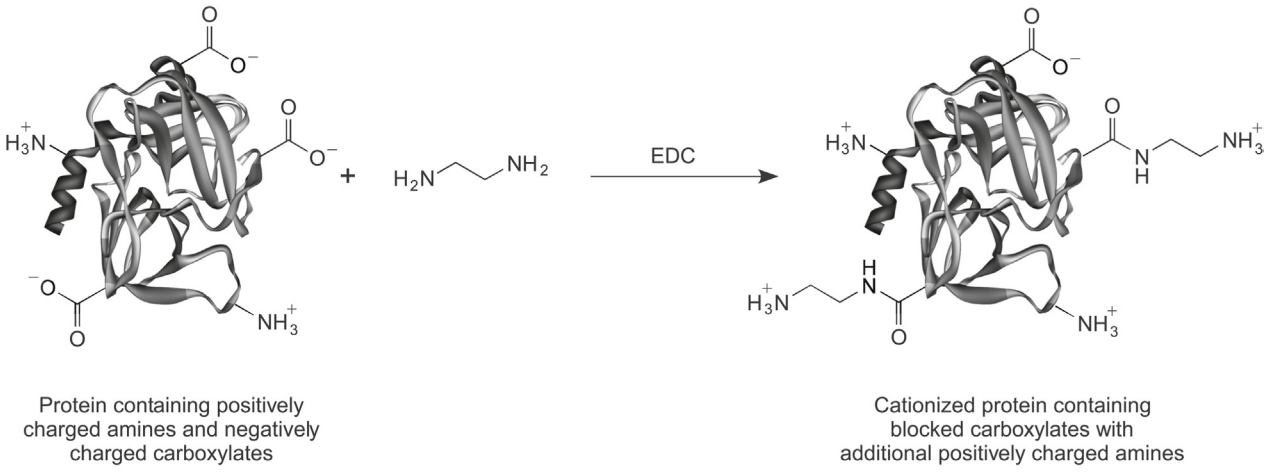

FIGURE 2.90 Cationization of protein molecules can be carried out using ethylene diamine to modify carboxylate groups using a carbodiimide reaction process.

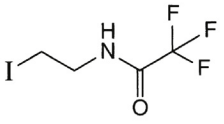

solution (after pH adjustment) at the indicated concentration.
4. Add EDC (1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride; Thermo Fisher) to a final concentration of 2 mg/ml in the reaction solution. To aid in the addition of a small amount of EDC, a higher concentration stock solution may be prepared in water and an aliquot added to the reaction to give the proper concentration. Since EDC is labile in aqueous solutions, the stock solution must be made quickly and used immediately.
5. React for 1–2 h at room temperature.
6. Purify the modified protein by extensive dialysis against 0.02-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4 (PBS), or another suitable buffer.

The changes that occur in the pI of a protein modified with diamines may be assessed by isoelectric focusing or by general electrophoresis based upon relative migration due to charge. A cationized protein will possess a higher pI value or migrate further toward the anode than its native form. Using the above protocol typically alters the net charge of bovine serum albumin from a native pI of 4.9 to the highly basic range of pI 9.5 to over pI 11.0.

Modification of carboxylate groups with diamines may also be carried out in organic solvent for those molecules insoluble in aqueous buffers. Some peptides are quite soluble in solvents such as DMF and DMSO, but relatively insoluble in water. Such molecules may be reacted in these solvents with the carbodiimide DCC (dicyclohexyl carbodiimide) using the same basic reactant ratios as given previously for EDC in aqueous solutions (Chapter 4, Section 1.4).

Modification of Sulfhydryls with N-(β-Iodoethyl) Trifluoroacetamide [Aminoethyl-8]

The conversion of sulfhydryl groups on cysteine residues or other molecules to amine-containing groups may be accomplished by aminoethylation with *N*-(β-iodoethyl) trifluoroacetamide (Schwartz *et al.*, 1980). The haloalkyl group specifically reacts with sulfhydryls to form the aminoalkyl derivative in one step. Under the conditions of the reaction, the trifluoroacetate amine-protecting group spontaneously hydrolyzes to expose the free primary amine without the need for a secondary deblocking step (Figure 2.91). This reagent is commercially available from Thermo Fisher Chemical under the name Aminoethyl-8™.

Aminoethyl–8™ Reagent
N-(iodoethyl)trifluoroacetamide
MW 267

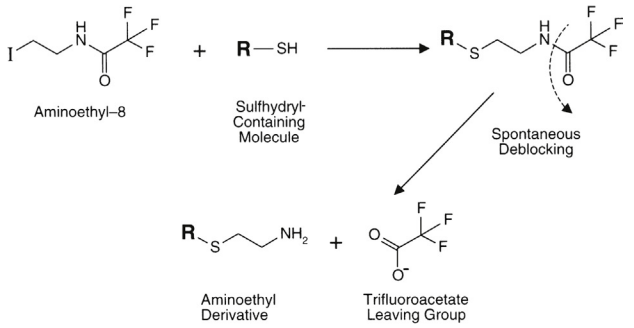

FIGURE 2.91 Aminoethyl-8 can be used to transform a sulfhydryl group into an amine. The intermediate spontaneously undergoes deblocking to release the primary amine group.

Aminoethyl-8 has an advantage over ethylenimine modification (next section), due to the potential polymerization of ethylenimine in aqueous solutions. Such polymers are highly cationic and may nonspecifically block protein molecules by coating them. The specificity of Aminoethyl-8 for sulfhydryls makes it an optimum choice for modification.

For small molecules containing sulfhydryls or for low molecular weight peptides containing cysteine residues, modification may proceed without deforming agents. However, for intact proteins containing both disulfides and free sulfhydryls, a denaturant and a disulfide reducing agent may be required to open buried or structurally inaccessible groups if complete modification is desired.

Protocol

1. Dissolve the protein to be aminoalkylated at a concentration of 1–10 mg/ml in 6-*M* guanidine hydrochloride, 0.2-*M* *N*-ethylmorpholine acetate, pH 8.1. All water used in preparing buffers should be deoxygenated by boiling followed by cooling and bubbling with nitrogen. Small molecules that do not require denaturants to expose internal disulfides or sulfhydryls may be modified without using guanidine treatment.
2. Add dithiothreitol (DTT) to obtain a 20-fold molar excess over the amount of disulfides present.
3. React for 4 h at room temperature, maintaining a blanket of nitrogen over the solution.
4. Adjust the pH to 8.6 with NaOH, and heat the solution to 50°C.
5. Add a quantity of Aminoethyl-8 in methanol to equal a 25-fold molar excess over the amount of sulfhydryl present (including the amount of DTT added). The solution in methanol should be made concentrated enough so that only a small amount of methanol has to be added to the reaction solution (i.e., no more than 10% of the final volume). A second addition of modifying agent may be made after 1 h to drive

the reaction more completely toward total –SH aminoalkylation.
6. React for 3 h at 50°C.
7. Purify the modified protein or other macromolecule by gel filtration or dialysis. Occasionally, complete modification with Aminoethyl-8 will cause precipitation of the protein.

Modification of Sulfhydryls with Ethylenimine

The cyclic compound ethylenimine reacts with protein sulfhydryl groups causing ring opening and forming the aminoalkyl derivative, *S*-(2-aminoethyl)cysteine (Raftery and Cole, 1963, 1966) (Figure 2.92). Under physiological conditions ethylenimine is virtually specific for sulfhydryls with no cross-reactivity toward other protein functionalities. At acid pH, a small degree of reactivity occurs with methionine residues, forming *S*-(2-aminoethyl) methionine sulfonium ion (Schroeder *et al*., 1967). Since aminoethylated cysteine groups resemble the side-chain structure of lysine residues, except for the replacement of one methylene group with a thioether, these modifications make them susceptible to tryptic hydrolysis, although at an abbreviated rate (Plapp *et al*., 1967; Wang and Carpenter, 1968).

Ethylenimine
MW 43

Ethylenimine may be used to introduce additional sites of tryptic cleavage for protein structural studies. In this case, complete sulfhydryl modification is usually desired. Proteins are treated with ethylenimine under denaturing conditions (6- to 8-*M* guanidine hydrochloride) in the presence of a disulfide reductant to reduce any disulfide bonds before modification. Ethylenimine may be added directly to the reducing solution in excess (similar to the procedure for Aminoethyl-8 described previously) to totally modify the –SH groups formed.

The disadvantage of using ethylenimine for protein modification stems from the fact that in the presence of water slow formation of polyethylenimine occurs. The polymer is highly positively charged at physiological pH and can interact strongly with protein molecules, masking sites of potential sulfhydryl modification. Also, the polymer may have terminal aziridine residues (Chapter 3, Section 2.3), making it reactive and potentially forming a covalent attachment with the protein (Dermer and Ham, 1969).

FIGURE 2.92 The small compound ethylenimine can react with sulfhydryls to form aminoethyl derivatives.

Modification of Sulfhydryls with 2-Bromoethylamine

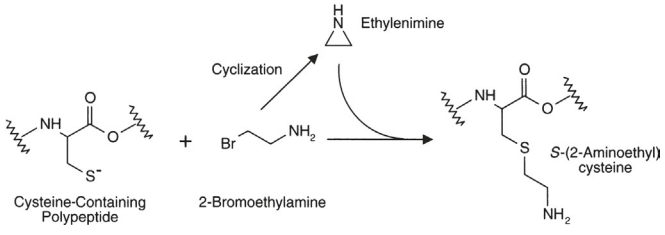
2-Bromoethylamine may undergo two reaction pathways in its modification of sulfhydryl groups in proteins (Figure 2.93). In the first scheme, the thiolate anion of cysteine attacks the number 2 carbon of 2-bromoethylamine to release the halogen and form a thioether bond (Lindley, 1956). This straightforward reaction mechanism is similar to the modification of sulfhydryls with iodoacetate (Section 4.2, this chapter). In a two-step, secondary process, 2-bromoethylamine is converted under alkaline conditions to the cyclic ethylenimine derivative by the intramolecular attack of its primary amine on the number 2 carbon, causing release of the halogen and ring formation (Cole, 1967). Ethylenimine then goes on to react with the sulfhydryl to form the aminoalkylated derivative (as described in the previous section). The two-step reaction is slower than direct aminoalkylation by either 2-bromoethylamine or ethylenimine.

2-Bromoethylamine
MW 123.92

The selectivity of protein alkylation using 2-bromoethylamine was investigated for use in adding a stable isotopically labeled ^{13}C at cysteine residues (Marincean *et al*., 2012). It was documented that the reaction at cysteine thiols was energetically favored over modification of lysine amines by 15.4 kJ mol^{-1} at alkaline pH values.

Protocol

1. Dissolve the protein or peptide to be aminoalkylated at cysteine sulfhydryls in 0.5-*M* sodium carbonate. If cystine disulfides are present, add a 10- to 25-fold molar excess of DTT to fully reduce them to free sulfhydryls.



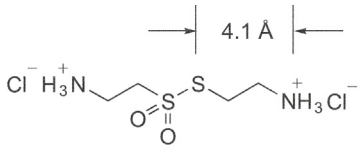


FIGURE 2.93 2-Bromoethylamine can be used to transform a thiol into an amine. The reaction may proceed through the intermediate formation of ethylenimine, yielding an aminoethyl derivative.

2. Add a quantity of 2-bromoethylamine to obtain a 10-fold molar excess over the number of sulfhydryls present in the sample, including any added DTT.
3. React overnight at room temperature.
4. Purify the modified protein by gel filtration or dialysis.

Modification of Sulfhydryls with 2-Aminoethyl-2′-Aminoethanethiolsulfonate (AEAETS)

Thiolsulfonate-containing compounds can react with thiols with release of the sulfonate end of the molecule to yield disulfide derivatives. The modification reagent 2-aminoethyl-2′-aminoethanethiolsulfonate, or AEAETS, reacts with a sulfhydryl with release of taurine (2-aminoethanesulfonate) to form a 2-aminoethyl-dithiol derivative (Figure 2.94). AEAETS can be used to block cysteine residues in proteins and form derivatives containing positively charged amines.

AEAETS
2-Aminoethyl-2'-aminoethanethiolsulfonate dihydrochloride
Mol. Wt.: 257.20

The basic reactions of thiolsulfonates have been known for decades (Field *et al*., 1961, 1964), but more recently they have been applied to the study of protein interactions by site-directed modification of native cysteines or through modification of cysteines introduced at particular points in proteins by mutagenesis. Such studies have yielded insights into the structure and binding site characteristics of proteins (Kirley *et al*., 1989). Pascual *et al*. (1998) used AEAETS to probe the acetylcholine receptor from the extracellular side of the membrane in order to investigate the molecular accessibility and electrostatic potential within the open and closed channel.

The AEAETS reaction with thiols is similar to that of sodium tetrathionate (Section 5.2, this chapter) and the methanethiosulfonate (MTS) or disulfide exchange compounds described in Chapter 3, Section 2.6. All of these reagents form disulfides upon reaction with sulfhydryls, and the modifications can subsequently be reversed using disulfide reducing agents, like DTT or TCEP. AEAETS is moisture sensitive and hydrolyzes slowly in aqueous solution, cleaving to release mecaptoethylamine and taurine. Also, avoid contact with oxidizing agents, such as peroxide, as these will oxidatively cleave and inactivate the reagent.

AEAETS is freely soluble in aqueous buffers and in DMF or DMSO to about 100 mg/ml. A stock solution may be made in organic solvent and a small aliquot transferred to a buffered reaction medium to initiate the reaction. The reaction of AEAETS with thiols takes place rapidly (within minutes) provided the group is accessible. Since cysteine is the least accessible amino acid in proteins (Section 2.1, this chapter), globular proteins may contain sulfhydryls that are buried or not fully accessible to the surrounding aqueous environment, and these may react slowly or not at all. The modification of cysteine thiols may be carried out in 10-m*M* Hepes, pH 7.5, and containing 150-m*M* NaCl using 10–100 µ*M* AEAETS in the final reaction medium.

Modification of Carbohydrates with Diamines

Carbohydrates or oligosaccharides may be modified to contain primary amino groups by selective reaction with a diamine compound. Several reaction pathways may be used to accomplish this modification. In some cases, a particular carbohydrate may contain sugar residues that possess potential amine coupling groups without prior derivatization to form such functionalities. For example, if carboxylate-containing sugars are present, such as sialic or uronic acid (Figure 2.95), then direct modification with a diamine is possible using the carbodiimide coupling protocol described previously in this section.

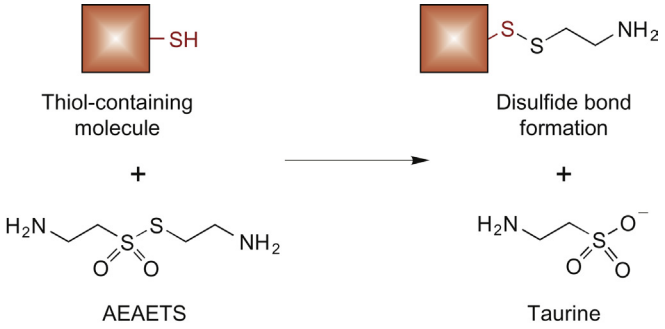

FIGURE 2.94 AEAETS reacts with thiol groups to form a disulfide modification that terminates in a primary amine.

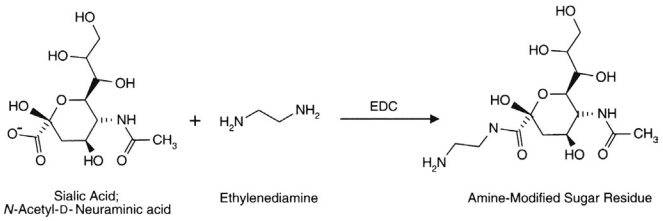

FIGURE 2.95 Carboxylate-containing sugars may be modified with diamines using a carbodiimide-mediated reaction to create available amine groups for subsequent conjugation.

If carboxylates are lacking in the carbohydrate molecule, then indigenous hydroxyls may be utilized to create aldehydes for coupling diamines by one of two routes. The simplest method of creating amine-reactive groups in sugar molecules is by oxidation using sodium periodate (Section 4.4, this chapter). Periodic acid cleaves adjacent hydroxyls to form highly reactive aldehyde groups (Rothfus and Smith, 1963). At a concentration of 1-m*M* in the cold, sodium periodate specifically cleaves only at the adjacent hydroxyls between the number 7, 8, and 9 carbon atoms of sialic acid residues (Van Lenten and Ashwell, 1971; Wilchek and Bayer, 1987). The product is the formation of one aldehyde group on the number 7 carbon and liberation of two molecules of formaldehyde. The sialic acid aldehyde then can be coupled with diamines by Schiff base formation and reductive amination (Chapter 3, Section 5.3, and Chapter 4, Section 4).

Oxidation of polysaccharides using a 10-m*M* or greater concentration of sodium periodate will result in the cleavage of adjacent diol-containing carbon–carbon bonds on other sugars besides just sialic acid residues. Glycoproteins and polysaccharides may be modified using this procedure to form multiple formyl functionalities for coupling diamines or other amine-containing molecules.

In some instances, reducing sugars are present that can be reductively aminated without prior periodate treatment. A reducing end of a monosaccharide, a disaccharide, or a polysaccharide chain may be coupled to a diamine by reductive amination to yield an aminoalkyl derivative bound by a secondary amine linkage (Figure 2.96). Also see Section 4.6, this chapter, for an extensive discussion on carbohydrate modification techniques.

An alternative to the use of chemical means to create formyl groups is the specific modification afforded by sugar oxidases (Section 4.4, this chapter). For instance, galactose oxidase may be reacted with a carbohydrate-containing terminal D-galactose or *N*-acetyl-D-galactosamine residues to transform the C-6 hydroxyl group into an aldehyde (Avigad *et al.*, 1962). Subsequent reaction with a diamine yields the desired amine modification.

The appropriate protocols for diamine modification of various carbohydrate or glycoprotein derivatives may be found in the indicated sections.

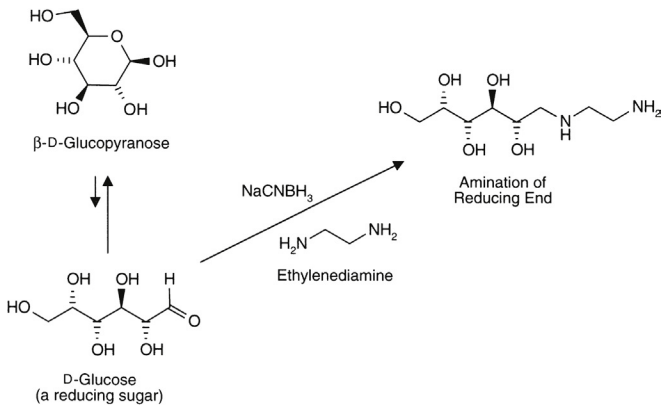

FIGURE 2.96 Reducing sugars may be aminated with diamines in the presence of sodium cyanoborohydride to produce amine modifications.

Modification of Alkylphosphates with Diamines

Alkylphosphate groups can be made to react with diamines to form aminoalkylphosphoramidate modifications. The primary amine thus formed may then be used to conjugate with other molecules containing amine-reactive groups. In this sense, DNA or RNA may be modified with a diamine at the 5′ phosphate group mediated by a carbodiimide reaction. N-substituted carbodiimides can react with a phosphate group to form highly reactive phosphodiester derivatives that are extremely short-lived in aqueous solution (Chapter 4, Section 1) (Figure 2.97). This active species can then react with a nucleophile such as a primary amine to form a phosphoramidate bond (Chu *et al.*, 1986). The process is analogous to the activation of a carboxylate by a carbodiimide with subsequent coupling to an amine-containing molecule to form an amide linkage (Williams and Ibrahim, 1981).

In most procedures, the water soluble carbodiimide EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride) is the most effective mediator of this reaction. Both EDC and its reaction byproducts are fully soluble in aqueous buffers and can be easily separated from the modified aminoalkylphosphate (Chapter 3, Section 1.1).

In some methods, the reaction is carried out in a two-step process by first forming an intermediate, reactive phosphorylimidazolide by EDC conjugation in an imidazole buffer. Next, the diamine, in this case cystamine, is reacted with the activated oligonucleotide, causing the imidazole to be replaced by the amine and creating a phosphoramidate linkage (Chu *et al.*, 1986). An easier protocol was described by Ghosh *et al.* (1990) in which the oligo, cystamine, and EDC were all reacted together in an imidazole buffer. A modification of this method developed by Zanocco (1993) is described in Chapter 23, Section 2.1.

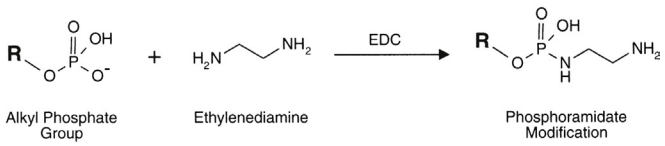

FIGURE 2.97 Phosphate groups may be modified to possess amines by a carbodiimide reaction in the presence of a diamine.

Modification of Aldehydes with Ammonia or Diamines

Aldehyde groups can be converted into terminal amines by a reductive amination process with ammonia or a diamine compound. The reaction proceeds by initial formation of a Schiff base interaction—a dehydration step yielding an imine derivative (or an aldimine). Reduction of the Schiff base with sodium cyanoborohydride or sodium borohydride produces the primary amine (in the case of ammonia) or a secondary amine derivative terminating in a primary amine (for a diamine compound) (Figure 2.98).

This simple strategy can be used to add amine residues to polysaccharide molecules after formation of aldehydes by periodate or enzymatic oxidation (Section 4.4, this chapter). Thus, glycoconjugates or carbohydrate polymers such as dextran may be derivatized to contain amines for further conjugation reactions.

The reaction occurs rapidly at alkaline pH (7–10), with higher pH values resulting in better yields due to faster Schiff base formation. To ensure complete conversion of available aldehydes to amines, add the ammonia or diamine compound to the reaction in at least a 10-fold molar excess over the expected number of formyl groups present. Diamines that are commonly used for this process include ethylene diamine, diaminodipropylamine (3,3′-iminobispropylamine), 1,6-diaminohexane, the Jeffamine derivative EDR-148 containing a hydrophilic, 10-atom chain (Texaco Chemical Co.), and other PEG-based diamines having one end masked with a reversible blocking agent (see previous discussion of discrete PEG diamines in this section).

Introduction of Arylamines on Phenolic Compounds

Compounds having phenol ring structures, such as tyrosine residues in proteins, can often be derivatized to contain aromatic amine groups through a two-stage reaction process. First, the phenolic ring is nitrated with tetranitromethane in aqueous solution to add a nitro group *ortho* (or *para*, if available) to the hydroxyl. This type of modification can be used to detect tyrosine residues by the strong absorptivity of the unprotonated (at pH 9), 3-nitrophenolate ring at 428 nm (extinction coefficient = 4200 $M^{-1}cm^{-1}$) (Sokolovsky *et al*., 1967). The method has been used to quantify the tyrosine content in porcine trypsinogens and trypsins and to modify a variety of other proteins (Vincent *et al*., 1970; Lundblad, 1991).

Nitration of the tyrosine rings in the four binding pockets of avidin or streptavidin can be done to increase the steric hinderance within the biotin binding sites (Morag *et al*., 1996). This process yields chromogenic proteins that have reduced binding affinity for biotin, thus allowing elution of biotinylated molecules under mild conditions.

The nitrophenol group of nitrated molecules may also be reduced to an aminophenyl derivative in alkaline conditions with the use of sodium dithionite (sodium hydrosulfite, $Na_2S_2O_4$) (Pojer, 1979). Dithionite is often used to convert aromatic nitro groups into aryl amines in organic synthesis procedures (Nakayama *et al*., 2011). The aryl amine groups can then be used to conjugate with amine-reactive crosslinking reagents to label peptides or proteins at their tyrosine side chains. In addition, this strategy can be a route to creating modifiable amine groups on aromatic molecules other than just tyrosine. For instance, the Bolton–Hunter reagent (Chapter 12, Section 2.5) can be used to modify amine groups on proteins, leaving a phenolic end that is typically used as a site for radioiodination. However, such a derivative could also be used to create an arylamine for further transformation into a highly reactive diazonium group for coupling to tyrosines or phenolic functionalities in other molecules (Figure 2.99) (Chapter 3, Section 6.1).

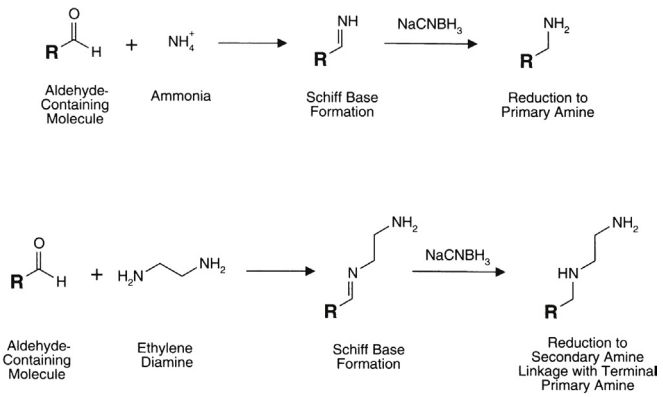

FIGURE 2.98 Aldehydes may be transformed into primary amines by reaction with ammonia or a diamine in the presence of a reducing agent.

Protocol

1. Dissolve the protein containing tyrosine residues (or another phenolic macromolecule) in 0.02-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, at a concentration of 2–4 mg/ml.
2. With stirring, add to each milliliter of the protein solution, 20 µl of 0.15-*M* tetranitromethane in 95% ethanol (Sigma). Make the addition in small aliquots if more than several milliliters of solution are to be derivatized. **Note**: all operations with tetranitromethane should be carried out in a fume hood with extreme care, as this compound is sensitive to heat, friction, and shock or impact.
3. React for 1 h at room temperature.
4. Quench the reaction by immediate gel filtration using a column of Sephadex G-25 (Pharmacia).

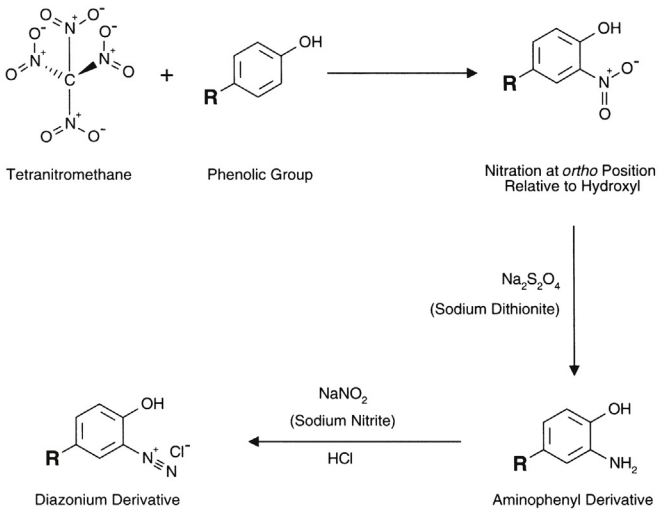

FIGURE 2.99 Phenolic compounds, such as the side chain of tyrosine residues, may be modified to contain an amine group by nitration followed by reduction to the aminophenyl derivative.

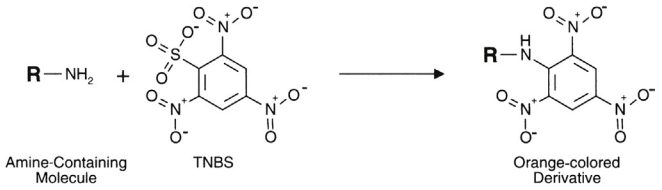

FIGURE 2.100 TNBS may be used to detect or quantify amine groups through the production of a chromogenic derivative.

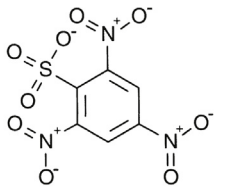
Equilibrate the column and perform the chromatography using 0.2-*M* sodium borate, pH 9.0, so that the protein will be at the proper pH for the reduction step. After the separation, a determination of the modification level may be made by measuring its absorbance at 428 nm.

5. Add sufficient sodium dithionite to bring the final concentration in the reaction medium to 0.1-*M*.
6. React for 1 h at room temperature.
7. Purify the aminophenyl derivative by gel filtration or dialysis.



The formation of a diazonium group from the arylamine derivative can be carried out by treatment with sodium nitrite in HCl (see protocol in Chapter 10, Section 6).

Amine Detection Reagents

There are several methods available for the detection or measurement of amine groups in proteins and other molecules. Accurate determination of target amine groups in molecules before or after modification may be important for assessing reaction yield or suitability for subsequent crosslinking procedures. The following methods use commercially available reagents and are easily employed to detect primary amines with simple spectrophotometric measurement.

TNBS

Molecules containing primary amines or hydrazide groups can react with 2,4,6-trinitrobenzenesulfonate (TNBS) to form a highly chromogenic derivative (Figure 2.100). This reaction may be used to assay the amine content of compounds by measuring the absorbance of the orange-colored product at 335 nm.

TNBS has been used to measure the free amino groups in proteins (Habeeb, 1966; Kakade and Liener, 1969); as a qualitative check for the presence of amines, sulfhydryls, or hydrazides (Inman and Dintzis, 1969); and to specifically determine the number of ε-amino groups of L-lysine in carrier proteins (Sashidhar *et al.*, 1994). It is also a convenient reagent to quantitatively or qualitatively assess the formation or blocking of amine groups during bioconjugation reactions (Tripathi *et al.*, 2011).

The following protocol may be used for the measurement of amines in soluble molecules, such as proteins or other macromolecules.

Protocol

1. Dissolve or dialyze the molecule to be assayed into 0.1-*M* sodium bicarbonate, pH 8.5, at a concentration of 20–200 µg/ml (for large molecules like proteins) or 2–20 µg/ml (for small molecules like amino acids).
2. Dissolve TNBS in 0.1-*M* sodium bicarbonate, pH 8.5, at a concentration of 0.01% (w/v). Prepare fresh. **Note**: TNBS may be prepared as a stock solution in ethanol at a concentration of 1.5%. This solution is stable for long-term storage and may be diluted as needed in the bicarbonate buffer to the required concentration.
3. Add 0.5 ml of TNBS solution to 1 ml of each sample solution. Mix well.
4. Incubate at 37°C for 2 h.
5. Add 0.5 ml of 10% SDS and 0.25 ml of 1-*N* HCl to each sample.
6. Measure the absorbance of the solutions at 335 nm. Determination of the number of amines present in a particular sample may be achieved by

comparison to a standard curve generated by use of an amine-containing compound (i.e., an amino acid) dissolved at a series of known concentrations in the bicarbonate sample buffer and assayed under identical conditions.

OPA

OPA (*o*-phthaldialdehyde) is an amine detection reagent that reacts in the presence of 2-mercaptoethanol to generate a fluorescent product (for preparation, see Section 4.1, 2-Mercaptoethanol, this chapter) (Figure 2.101). The resultant fluorophore has an excitation wavelength of 360 nm and an emission point at 455 nm. OPA can be used as a sensitive detection reagent for the HPLC separation of amino acids, peptides, and proteins (Fried *et al.*, 1985). It is also possible to measure the amine content in proteins and other molecules using a test-tube or microplate format assay with OPA. Detection limits are typically in the µg/ml range for proteins.

Protocol

1. Prepare a series of standards, preferably consisting of serial dilutions of the substance to be measured, dissolved in water or non-amine-containing buffer. The concentration range of the standards can be anywhere between about 500 ng/ml and 1 mg/ml.
2. Prepare the samples dissolved in water or non-amine-containing buffer at an expected concentration level that falls within the standard curve range. The assay can tolerate the presence of most buffer salts, denaturants, and detergents. However, the standard curve should be run in the same buffer environment as the samples to obtain consistent response.
3. To a set of labeled tubes, add 2 ml of OPA reagent (Thermo Fisher) and 200 µl of the appropriate standard or sample. Mix well. If using a microplate format, scale back these quantities 10-fold to fit in the microwells.
4. Measure the fluorescence of each sample and standard using an excitation wavelength of 360 nm and an emission wavelength of 450 nm (or using a filter close to the 436- to 455-nm range).
5. Determine the concentration of the samples by comparison to the standard curve. Since the assay measures the presence of amine groups, the results may be correlated to the relative amount of amines available.

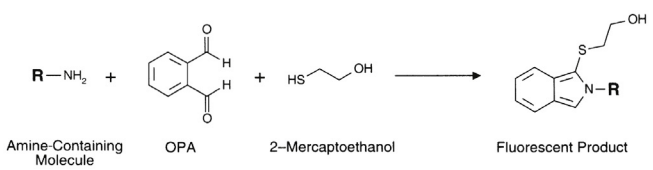


FIGURE 2.101 OPA reacts with amines to form a fluorescent product.

4.4. Introduction of Aldehyde Residues

The formation of an aldehyde group on a macromolecule can produce an extremely useful derivative for subsequent modification or conjugation reactions. In their native state, proteins, peptides, nucleic acids, and oligonucleotides contain no naturally occurring aldehyde residues. There are no aldehydes on amino acid side chains, none introduced by post-translational modifications, and no formyl groups on any of the bases or sugars of DNA and RNA. To create reactive aldehydes at specific locations within these molecules opens the possibility of directing modification reactions toward discrete sites within the macromolecule.

There are two basic ways of introducing aldehyde residues in biological macromolecules: (1) oxidation of carbohydrates or molecules containing diols; and (2) modification of available amino groups with reagents that contain or produce aldehydes. In both cases, aldehydes can be created that will allow easy conjugation to amine-containing molecules by Schiff base formation and reductive amination (Chapter 3, Section 5.3, and Chapter 4, Section 4). The following sections describe these methods.

Periodate Oxidation of Glycols and Carbohydrates

Carbohydrates and other biological molecules that contain polysaccharides, such as glycoproteins, can be specifically modified at their sugar residues to produce reactive aldehyde functionalities. With proteins, this method often allows modification to occur only at specific locals, usually away from critical active centers or binding sites.

Periodate oxidation is perhaps the simplest route to transforming the relatively unreactive hydroxyls of sugar residues into amine-reactive aldehydes. Periodate cleaves carbon–carbon bonds that possess adjacent hydroxyls, oxidizing the –OH groups to form highly reactive aldehydes (Bobbit, 1956; Rothfus and Smith, 1963). Terminal *cis*-glycols result in the loss of one carbon atom as formaldehyde and the creation of an aldehyde group on the former number 2 carbon atom. Varying the concentration of sodium periodate during the oxidation reaction gives some specificity with regard to what sugar residues are modified. Sodium periodate at a concentration of 1-m*M* at near 0°C specifically cleaves only at the adjacent hydroxyls between carbon atoms 7, 8, and 9 of sialic acid residues (Van Lenten and Ashwell, 1971; Wilchek and Bayer, 1987). The product is the formation of one aldehyde group on the number 7 carbon and liberation of two molecules of formaldehyde (Figure 2.102).

Since sialic acid is a frequent terminal sugar constituent of the polysaccharide trees on glycoproteins,

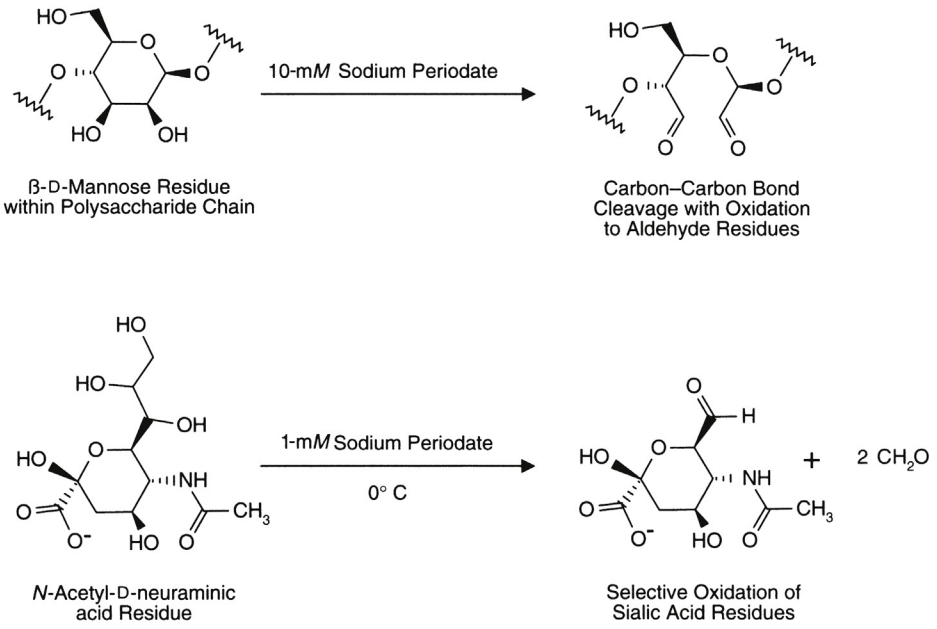

FIGURE 2.102 The reaction of sodium periodate with sugar residues can produce aldehydes for conjugation reactions.

this method selectively forms reactive aldehydes on the most accessible parts for subsequent modifications. The carbohydrate polymer of a protein provides a long spacer arm that can be used to conjugate another large macromolecule, such as a second protein, with few steric problems.

Oxidation of polysaccharides using 10-m*M* or greater concentrations of sodium periodate at room temperature results in the cleavage of adjacent hydroxyl-containing carbon–carbon bonds on other sugars besides just sialic acid residues (Lotan *et al*., 1975). High concentrations of periodate result in sugar ring opening and the creation of many aldehydes on each polysaccharide tree. The oxidation of dextran polymers has been investigated and found to involve the formation of several aldehyde-containing products depending on the diol location being oxidized (Maia *et al*., 2011).

Using these methods, carbohydrate-containing proteins may be altered to contain aldehydes for conjugation with other proteins or for detection using hydrazide-containing fluorescent probes (Chapter 10). The aldehydes thus formed can then be coupled to other amine-containing molecules by Schiff base formation and reductive amination (Chapter 3, Section 5.3 and Chapter 4, Section 4). For instance, the enzyme horseradish peroxidase (HRP) can be activated with periodate for conjugation with antibodies (Nakane and Kawaoi, 1974). Alternatively, such reactive aldehyde groups may be conjugated to hydrazide-containing molecules to form hydrazone bonds (Chapter 5, Section 8, Chapter 10, Section 1, and Chapter 22, Section 2.2). Cell surface polysaccharides may be probed with hydrazide-containing reagents for sialic acid groups or total glycoconjugates. Glycoproteins or glycopeptides in solution may also be tagged in this manner. Gangliosides and other glycolipids may also be modified with hydrazide reagents (Spiegel *et al*., 1982).

Protocol

1. The glycoprotein or diol-containing molecule is dissolved in deionized water or a buffer at physiological pH. Sodium phosphate buffer (0.01–0.1-*M*), pH 7.0, is an appropriate choice. When oxidizing cell surface glycoconjugates, use a buffer suitable for cellular stability requirements. Avoid amine-containing buffers such as Tris and glycine, because they may interact with the aldehyde groups as they are formed. For glycoproteins in solution, a concentration range of 1–10 mg/ml will produce acceptable results in this procedure. For sialic acid modification, place the sample in ice to cool to near 0°C.
2. Dissolve sodium periodate (MW 213.91) in water at a concentration of 10 mg/ml (0.046-*M*). Protect from light. To obtain approximately a 1-m*M* concentration of sodium periodate in the reaction solution (suitable for oxidizing only sialic acid residues), add 21.8 µl of this stock solution to each milliliter of the glycoprotein solution to be oxidized. Maintain the solution on ice. For general oxidation of carbohydrates other than just sialic acid, add 218 µl of the stock solution to obtain an approximate final concentration of 10-m*M* periodate in the reaction. Use room temperature conditions for general

carbohydrate oxidation. Wrap the vial containing the reaction solution with aluminum foil to protect from light. The use of an amber vial also is suitable for this purpose.

3. React for 15–30 min at room temperature.
4. Quench the reaction by the addition of 0.1 ml of glycerol per milliliter of reaction solution. Alternatively, the reaction may be stopped by immediate gel filtration on a desalting column. If a dextran-based resin is used for the chromatography, the support itself will react with sodium periodate to quench excess reagent. Alternatively, *N*-acetylmethionine may be added to quench the reaction, because the thioether of the methionine side chain will react with periodate to form sulfoxide or sulfone products (Geoghegan and Stroh, 1992). In addition, sodium sulfite (Na_2SO_3) was used by Stolowitz *et al*. (2001) to quench the periodate oxidation of HRP in solution. To quench the reaction with cellular samples, wash the cells with buffer to remove remaining traces of periodate.

Oxidase Modification of Sugar Residues

Another method of forming aldehyde groups on carbohydrates and glycoproteins involves the use of specific sugar oxidases. These enzymes only affect the monosaccharide they are specific toward, leaving other sugar residues within polysaccharides unaffected. Probably the most often used oxidase for this purpose is galactose oxidase, which can form C-6 aldehydes on terminal D-galactose or *N*-acetyl-D-galactose residues (Avigad *et al*., 1962) (Figure 2.103). When galactose residues are penultimate to sialic acid residues, another enzyme, neuraminidase, must be used to remove the sialic acid sugars and expose galactose as the terminal residue (Wilchek and Bayer, 1987). The specificity of using glycosidases to create aldehyde residues on carbohydrates may be the method's greatest advantage. However, the use of a simple chemical reagent such as sodium periodate may still be the easiest way to create aldehydes on carbohydrates (Section 4.4, this chapter).

The following protocol was used by Wilchek and Bayer (1987) to label cell-surface galactose residues.

Protocol

1. Prepare a 5% cell suspension in an appropriate buffer. Avoid amine-containing buffers, as these will interact with aldehydes.
2. Add 0.05 units of *Vibrio cholerae* neuraminidase and 5 units of galactose oxidase per milliliter of cell suspension.
3. Incubate for 60 min at 37°C.
4. Wash cells with PBS to remove excess enzymes.

Modification of Amines with NHS-Aldehydes (SFB and SFPA)

Succinimidyl *p*-formylbenzoate (SFB) (SFB) and succinimidyl *p*-formylphenoxyacetate (SFPA) are amine-reactive reagents that contain terminal aldehyde residues. Their NHS ester ends react with primary amines in proteins and other molecules at pH 7 to 9 to yield amide linkages (see Chapter 3, Section 1.4, and Chapter 17, Section 2) (Figure 2.104). The resulting formyl derivatives may be utilized to couple to other amine or hydrazine-containing molecules (Kraehenbuhl *et al.*, 1974; Galardy *et al.*, 1978). In particular, SFB can be used to produce aldehyde groups on alkaline phosphatase for conjugation with 5′-hydrazide-modified DNA for use in hybridization assays (Chapter 23, Section 2.4) (Ghosh *et al*., 1989). It has also been used to couple antibodies to sensor surfaces to produce AFM tips (Wildling *et al*., 2011). The aryl aldehyde group or SFB does not as readily form Schiff base interactions with amines as aliphatic aldehydes. However, it can be used with aminooxy-,

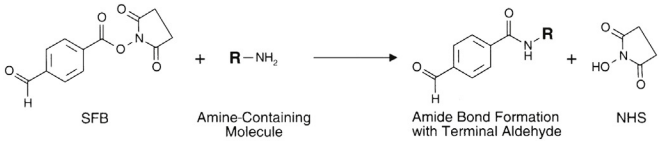

FIGURE 2.104 SFB reacts with primary amines to form amide bond derivatives containing aldehyde groups.

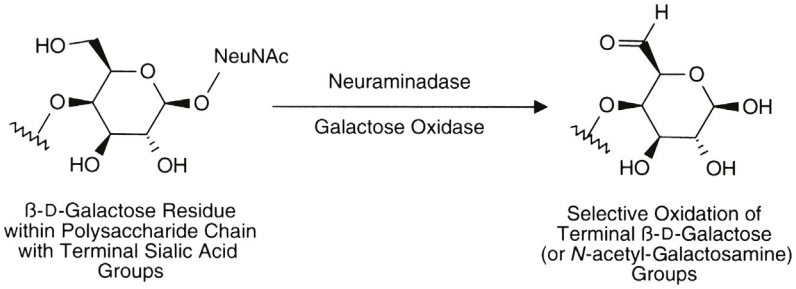

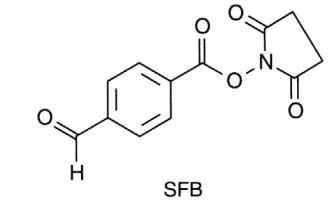

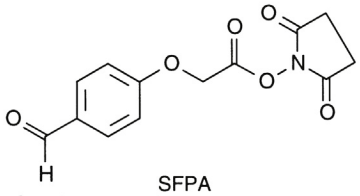

FIGURE 2.103 Galactose oxidase may be used to transform specifically the C-6 hydroxyl group of galactose into an aldehyde.

hydrazide-, and hydrazine-containing reagents in a chemoselective reaction to form crosslinks in the presence of complex biological samples (see Chapters 15 and 17). SFB and SFPA are insoluble in water, but may be predissolved in DMF or acetonitrile before adding a small quantity to an aqueous reaction mixture. Both reagents contain aromatic phenyl rings and have absorptivity at wavelengths less than 300 nm. Their structures may contribute a significant degree of hydrophobicity to macromolecules being modified, especially if high-density couplings are achieved. For this reason, modified proteins and other soluble molecules may have a tendency to precipitate if modification is carried out too heavily. The optimal amount of modification may have to be adjusted to maintain solubility in each application.

SFB
Succinimidyl-*p*-formyl benzoate
MW 247

SFPA
Succinimidyl-*p*-formylphenoxyacetate
MW 277

Protocol

1. Dissolve a macromolecule containing amine groups at a concentration of 1–10 mg/ml in a buffer having a pH of 7.0–9.0 (e.g., 0.1-*M* sodium phosphate, pH 7.5). Higher pH conditions will increase the hydrolysis rate of the NHS ester. Avoid amine-containing or nucleophilic buffers such as Tris, glycine, or imidazole (see Chapter 3, Section 1.4).
2. Dissolve SFB (Thermo Fisher, Solulink) or SFPA (Molecular Probes) in DMF. The concentration should be such that a small aliquot can be added to the reaction medium to obtain at least a 10-fold molar excess of modifying reagent over the amount of amines to be modified. Add no more than 100 µl of the modifier/DMF solution to each milliliter of the macromolecule solution prepared in (1).
3. React for 2 h at room temperature.
4. Purify the modified macromolecule from excess reagent and reaction byproducts by dialysis or gel filtration.

Modification of Amines with glutaraldehyde

Amino groups on proteins may be reacted with the *bis*-aldehyde compound glutaraldehyde to form activated derivatives able to crosslink with other proteins. The reaction mechanism for this modification proceeds by one of several possible routes. In the first option, one of the aldehyde ends can form a Schiff base linkage with ε-amines or α-amines on proteins to leave the other aldehyde terminal free to conjugate with another molecule. Alternatively, a cyclic glutaraldehyde derivative or polymer may undergo vinyl addition reactions to create stable secondary amine bonds, leaving the aldehydes exposed for potential secondary reductive amination reactions. Finally, a cyclized form of glutaraldehyde may also react with the ε-amines of two neighboring lysine side chains to form a quaternary pyridinium crosslink (Figure 2.105). See Chapter 15, Section 2.1, for a more extensive explaination of the many reactions glutaraldehyde can undergo in aqueous solutions.

Schiff base interactions between aldehydes and amines typically are not stable enough to form irreversible linkages. These bonds may be reduced with sodium cyanoborohydride or a number of other suitable reductants (Chapter 3, Section 5) to form permanent secondary amine bonds. However, proteins crosslinked by glutaraldehyde without reduction nevertheless show stabilities unexplainable by simple Schiff base formation. The stability of such unreduced glutaraldehyde conjugates has been postulated to be due to the vinyl addition mechanism, which does not depend on the creation of Schiff bases.

Glutaraldehyde modification readily proceeds at alkaline pH. The higher the pH, the more efficient is Schiff base formation. Using a reductant like sodium cyanoborohydride that does not affect the aldehyde groups, while efficiently transforming Schiff bases into a secondary amines, provides the best possible yields. In many cases, the degree of glutaraldehyde-induced crosslinks is so severe that conjugate precipitation occurs. This is especially well documented in antibody–enzyme conjugation schemes employing this reagent (Chapter 20, Section 1.2).

Glutaraldehyde can also be used to create aldehydes on amine-containing polymers. The use of this reagent in derivatizing chromatography supports and other soluble polymers is well known (Hermanson *et al.*, 1992). See Chapter 15, Section 2.1, for updated protocols on the use of glutaraldehyde for immobilizing affinity ligands on chromatography supports.

The following protocol may be used as the first stage of a two-step glutaraldehyde conjugation reaction. In this initial reaction, glutaraldehyde modification converts available protein amines into reactive aldehyde groups (and possibly sites for Michael-type addition

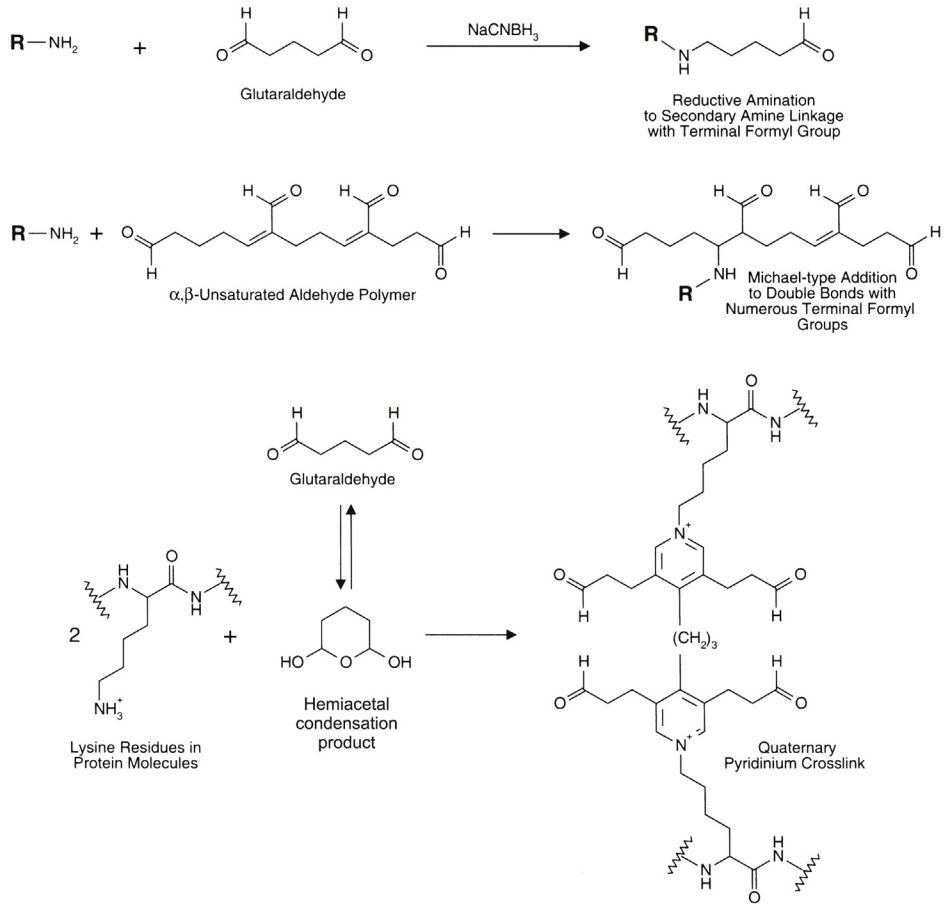

FIGURE 2.105 Glutaraldehyde can undergo complex reactions with amine groups, resulting in aldehyde-containing derivatives that can be used in conjugation reactions.

reactions). The subsequent addition of a second protein or another amine-containing molecule causes the activated protein to crosslink with the amines and forms a conjugate. Glutaraldehyde may also be used in single-step conjugation procedures where the aldehyde-modified protein is not isolated before addition of a second protein. In single-step conjugations both proteins to be crosslinked are together in solution and glutaraldehyde is added to effect crosslinking (Chapter 19, Section 7).

Protocol

1. Dissolve the protein or other amine-containing macromolecule to be modified at a concentration of 1–10 mg/ml in a buffer having a pH from 7 to 10. The higher the pH, the more efficiently Schiff base formation will occur. Phosphate, borate, and carbonate buffers at 0.01–0.1-*M* are acceptable. Avoid amine-containing buffers like Tris and glycine, since they will react with glutaraldehyde.
2. Add a quantity of glutaraldehyde equal to a 10-fold molar excess over the amount of amines to be modified. A typical concentration of glutaraldehyde in the reaction mixture is 1.25%. In some cases, trial experiments will have to be performed to check for solubility of the resultant modified protein. Scale back the quantity of glutaraldehyde added if precipitation occurs.
3. React for at least 2 h at 4°C.
4. Quickly isolate the modified protein by gel filtration using a desalting resin.

In some cases, the modified protein may be stored for long periods before conjugation with another amine-containing molecule by immediate freezing and lyophilization. If stability is a problem, however, the modified protein should be conjugated immediately.

Periodate Oxidation of N-Terminal Serine or Threonine Residues

Sodium periodate can be used to form aldehydes on unmodified N-terminal serine or threonine residues in proteins and peptides (Geoghegan and Stroh, 1992). Periodate cleaves carbon–carbon bonds that both possess primary or secondary hydroxyls or amines (i.e., diols or 2-amino alcohol groups). If a primary hydroxyl

is present, such as in the case of N-terminal serine residues, then the reaction liberates formaldehyde and forms an aldehyde group (an α-*N*-glyoxylyl) at the end of the peptide (Figure 2.106). This reaction can be used to direct bioconjugation to a site-specific point on biomolecules, provided that there are no other periodate-oxidizable groups within the protein structure. A synthetic peptide designed to have an N-terminal serine or threonine residue can provide a site of coupling at the end of the chain. This strategy is a viable alternative to the incorporation of a cysteine group for bioconjugation at the end of a peptide.

If other oxidizable groups are present in a protein, such as carbohydrates or sensitive amino acid side chains (Section 2.1, this chapter), then this method should be avoided, because modification can occur at sites other than just the N-terminal. This method has been used successfully to conjugate tags with small peptides (Geoghegan *et al.*, 1993), to attach fluorescent probes to enzyme substrates (Gaertner *et al.*, 1994), to effect the conjugation of lactamase to a Fab' antibody fragment (Mikolajczyk *et al.*, 1994), for the coupling of antibodies to liposomes (Koning *et al.*, 1999), and to couple a PEG polymer to the amino terminus of proteins (Gaertner and Offord, 1996). The reaction has also been used to selectively label N-terminal serine-containing peptides in the development of a fluorescence caspase assay (Rahman *et al.*, 2012).

When using sodium periodate to oxidize an N-terminal serine or threonine residue on a large molecule like a protein, excess oxidant can be removed simply by dialysis or size exclusion chromatography. However, when using periodate to oxidize a low molecular weight peptide, it can become problematic to remove excess reactant by size separation methods alone. For this reason, the addition of a reducing agent may be used to scavenge any remaining periodate, so long as the reductant chosen does not also reduce the aldehydes that have been formed. Geoghegan and Stroh (1992) used *N*-acetylmethionine for this purpose, because the thioether of the methionine side chain can readily react with periodate to form sulfoxide or sulfone products, but it will not affect the aldehyde groups formed at the end of the peptide chains or interfere

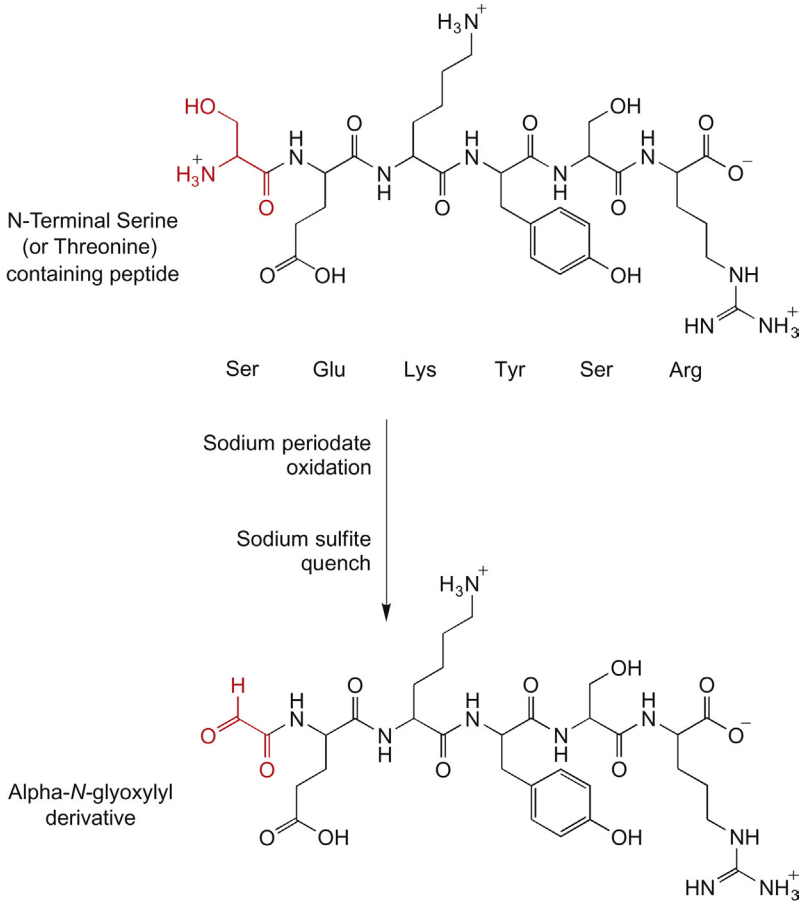

FIGURE 2.106 An N-terminal serine or threonine residue can be oxidized with sodium periodate to produce an aldehyde group. The reaction can be quenched with sodium sulfite to eliminate excess periodate.

with subsequent coupling reactions. A less expensive reagent, sodium sulfite (Na_2SO_3), was used by Stolowitz *et al*. (2001) to quench the periodate oxidation of HRP in solution, and ultimately this may prove to be the best choice for stopping the reaction.

Conjugation of molecules to periodate-oxidized N-terminal serine or threonine residues in peptides is best carried out using hydrazine or hydrazide reagents to avoid potential cross-reactions with lysine amino groups in the peptide structure. The aldehyde group preferentially reacts with the hydrazino group even in the presence of other amines to form a hydrazone bond (Figure 2.107). After the reaction, the hydrazone may be reduced with sodium cyanoborohydride to stabilize the linkage.

The following protocol is based on the methods of Geoghegan and Stroh (1992) and Stolowitz *et al*. (2001).

Protocol

1. Dissolve the peptide containing an N-terminal serine or threonine group at a concentration of at least 2 mg/ml in 0.04-*M* sodium phosphate, pH 7.0. Higher concentrations of peptides or proteins may be used without modification to the rest of the protocol, because the amount of periodate used in the reaction is in sufficient molar excess, even when low molecular weight peptides are being oxidized. Peptides that are initially insoluble at physiological pH may first be dissolved at higher concentration in 0.01% TFA before adding a small aliquot to the buffer. Adjust the pH back to neutral, if needed.
2. With mixing, add sodium periodate to a final concentration of 2.5-m*M*. Periodate should be pre-dissolved as a stock solution at a higher concentration in buffer or water, and then a small aliquot added to the peptide solution to start the reaction. Pre-dissolving the periodate will facilitate immediate dissolution in the final reaction medium without the creation of regions of high concentration, as would occur if solid sodium periodate was added directly to the peptide solution. Protect all solutions containing periodate from exposure to light.
3. React for 3 min at room temperature. Longer reactions increase the likelihood of oxidative damage to other amino acids within the peptide structure.
4. Quench the oxidation by the addition to the peptide solution of at least a 4-fold molar excess of *N*-acetylmethionine or sodium sulfite over the concentration of periodate in the reaction mixture. Pre-dissolve the quencher in buffer at a higher concentration prior to adding an aliquot of it to the reaction solution. React for 10 min.
5. The oxidized peptide may be reacted with an amine- or hydrazide-containing molecule by reductive amination to conjugate with the newly formed aldehyde at the N-terminal (for protocols see the following section, this chapter; Chapter 3, Sections 5.1–5.3; and Chapter 17, Section 2). For conjugation with amine-containing molecules, the peptide must not have any other competing amines (e.g., lysine residues) present or else ring formation or peptide-to-peptide coupling may occur. If lysines are present within the peptide, then the use of a hydrazide (or hydrazine) conjugation process will eliminate interference from lysine amines.

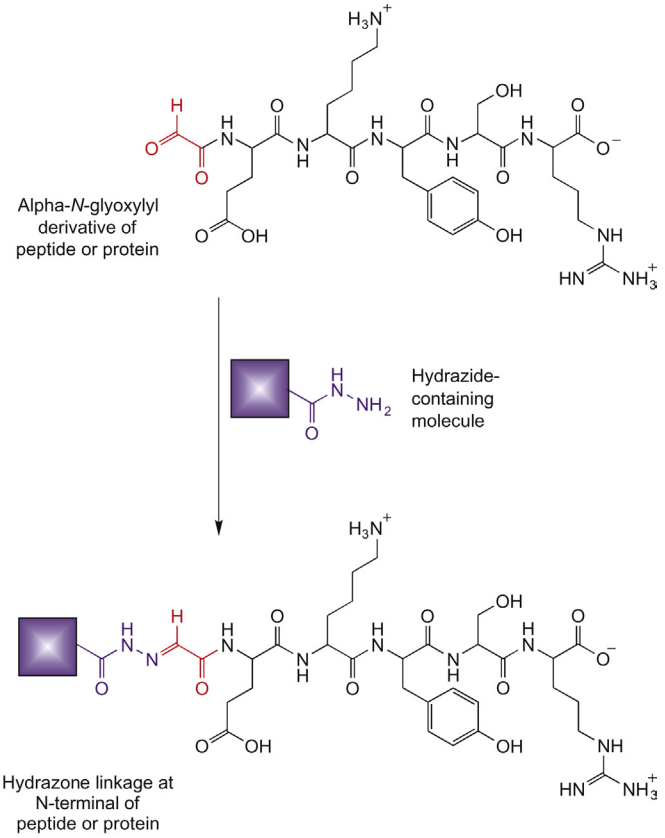

FIGURE 2.107 The N-terminal aldehyde group on a peptide formed from periodate oxidation of serine or threonine residues can be conjugated with a hydrazide-containing molecule to produce a hydrazone bond.

4.5. Introduction of Hydrazine or Hydrazide Functionalities

Hydrazide-containing reagents can be used for probing or conjugation of carbonyl-containing compounds, including macromolecules possessing aldehydes and ketones. Fluorescent or enzymatic probes containing hydrazide functionalities can be used to assay or label carbohydrates, glycoproteins, the polysaccharide portion of cell surfaces, gangliosides, and glycoconjugates on blots (Lotan, 1975; Hurwitz *et al.*, 1980; Spiegal *et al.*, 1982; Gershoni *et al.*, 1985;

Wilchek and Bayer, 1987). Multivalent forms of hydrazide reagents created by modifying enzymes, ferritin, and polymers such as dextran and polypeptides with *bis*-hydrazides can be used to target formyl groups with high avidity and sensitivity (Roffman *et al*., 1980; Kaplan *et al*., 1983).

The creation of hydrazide probes is often based on the derivatization of a detectable molecule with a *bis*-hydrazide compound. Although hydrazine itself (in the form of hydrazine hydrate) can be used in a methanolic solution to modify activated carboxylate molecules forming hydrazides, the availability of the bifunctional hydrazides provides a built-in spacer to accommodate greater steric accessibility.

The following protocols make use of the compounds adipic acid dihydrazide and carbohydrazide to derivatize molecules containing aldehydes, carboxylates, and alkylphosphates. The protocols are applicable for the modification of proteins, including enzymes, soluble polymers such as dextrans and poly-amino acids, and insoluble polymers used as micro-carriers or chromatographic supports. See Chapter 15, Section 2.8, for a discussion on the use of hydrazide-containing spacers in the preparation of affinity supports.

The addition of hydrazide groups into macromolecules containing aldehydes, carboxylates, or alkylphosphates has the effect of increasing the pI or net charge. In the case of carboxylates or alkylphosphates, blocking these groups with hydrazide compounds eliminates the negative charge contribution of the original functionality and adds a potential positive charge contribution due to the terminal hydrazide. The consequence of raising the pI of a macromolecule can have dramatic effects on the molecule's conformation and activity or on its relative nonspecificity in assay systems due to the presence of additional positive charge. For instance, the modification of avidin with adipic acid dihydrazide by coupling through the protein's carboxylate groups significantly increases the net charge of an already highly cationic molecule, and therefore increases its overall cross-reactivity in avidin–biotin assays (Chapter 11, Section 5).

Modification of Aldehydes with bis-Hydrazide Compounds

Aldehyde-containing macromolecules will react spontaneously with hydrazide compounds to form hydrazone linkages. The hydrazone bond is a form of Schiff base that is more stable than the Schiff base formed from the interaction of an aldehyde and an amine. The hydrazone, however, may be reduced and further stabilized by the same reductants utilized for reductive amination purposes (Chapter 3, Section 5.4). The addition of sodium cyanoborohydride to a hydrazide–aldehyde reaction drives the equilibrium toward formation of a stable covalent complex. Mallia (1992) found that adipic acid dihydrazide derivatization of periodate oxidized dextran (containing multiple formyl functionalities) proceeds with much greater yield when sodium cyanoborohydride is present.

The reaction of an excess of adipic acid dihydrazide with aldehyde groups present on glycoproteins or other molecules will result in modified proteins containing alkylhydrazide groups (Figure 2.108). Another *bis*-hydrazide compound, carbohydrazide, may also be employed with similar results, except the spacer afforded through its use is considerably shorter. Target aldehydes may be created on macromolecules according to the protocols described in Section 4.4, this chapter. Thus, glycoproteins and other molecules containing polysaccharides may be periodate-oxidized to contain formyl groups and then modified with a *bis*-hydrazide compound to create the hydrazide-activated reagent. Modification of proteins through glycan residues obviates the blocking of negatively charged carboxylates and only adds a limited number of hydrazides at discrete points on the molecule. The enzyme HRP is conveniently modified with hydrazide functionalities using this approach (Chapter 22, Section 2.4).

Protocol

1. Dissolve a macromolecule (such as a protein) containing aldehyde functionalities at a concentration of about 1–10 mg/ml in 100-m*M* sodium citrate, 150-m*M* NaCl, pH 6.0. Alternatively, a buffered solution at a pH of about 7–8.5 will also work well in this protocol. Phosphate, carbonate, borate, or similar buffers adjusted to this pH range work well. Avoid amine-containing buffers (e.g., glycine or Tris) or other components containing strong nucleophiles, since these may react with the aldehydes. To modify a molecule to contain aldehyde groups, see Section 4.4.
2. Add a quantity of adipic acid dihydrazide or carbohydrazide (Aldrich) to the protein solution to obtain at least a 10-fold molar excess over the amount of aldehyde functionality present. High molar ratios are necessary to avoid protein conjugation during the reaction process. If the concentration of aldehydes is unknown, the addition of 32 mg adipic acid dihydrazide per milliliter of the protein solution to be modified should work well.
3. React for 2 h at room temperature. While hydrazone formation does not require the addition of a reductant to create a linkage, including sodium cyanoborohydride in the reaction considerably increases the yield and stability of bonds formed. If the presence of a reducing agent will not cause harm

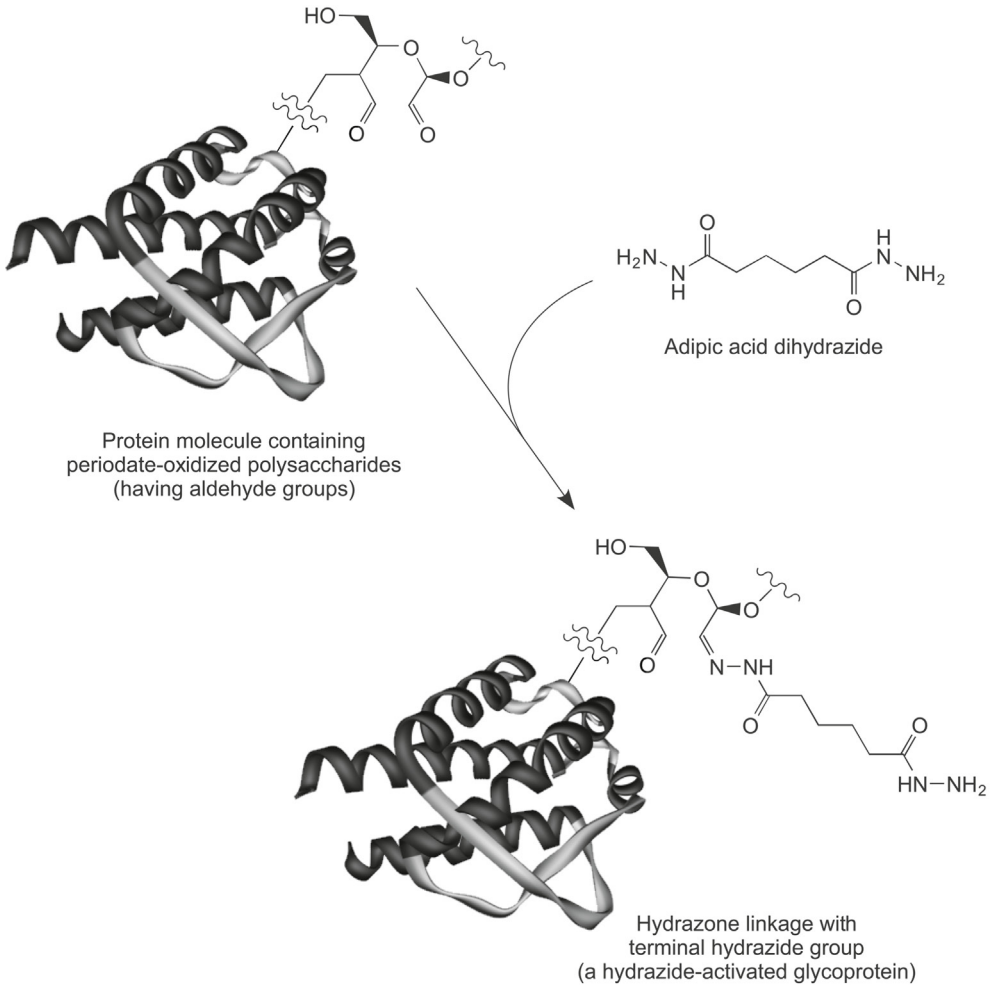

FIGURE 2.108 Glycoproteins that have been treated with sodium periodate to produce aldehyde groups can be further modified with adipic acid dihydrazide to result in a hydrazide derivative.

to the macromolecule being modified, the addition of 10 µl of 5-*M* sodium cyanoborohydride (Sigma) per milliliter of reaction solution may be carried out. Caution: Cyanoborohydride is extremely toxic. All operations should be performed with care in a fume hood. Also, avoid any contact with the reagent, as the 5-*M* solution is prepared in 1-*N* NaOH.

4. Purify the modified protein by dialysis or gel filtration using a desalting resin.

Hydrazide-activated proteins are stable for long-term storage at 4°C in the presence of a preservative (0.05% sodium azide) or in a frozen or lyophilized state.

Modification of Carboxylates with bis-Hydrazide Compounds

Carboxylic acids may be covalently modified with adipic acid dihydrazide or carbohydrazide to yield stable diacyl hydrazide bonds, which also contain extending terminal hydrazide groups. Hydrazide functionalities do not spontaneously react with carboxylate groups the way they do with aldehyde groups (Section 4.5, this chapter). In this case, the carboxylic acid must first be activated with another compound that makes it reactive toward nucleophiles. In organic solutions, this may be accomplished by using a water-insoluble carbodiimide (Chapter 4, Section 1.4) or by creating an intermediate active ester, such as an NHS ester (Chapter 3, Section 1.4).

In aqueous solutions, the easiest method for forming this type of bond is to use the water soluble carbodiimide EDC (Chapter 4, Section 1.1). For proteins and other water soluble macromolecules, EDC reacts with their available carboxylate groups to form an intermediate, highly reactive *O*-acylisourea. This active ester species may further react with nucleophiles such as a hydrazide to yield a stable imide product (Figure 2.109).

Most proteins contain an abundance of carboxylic acid groups from C-terminal functionalities and aspartic and glutamic acid side chains. These groups are

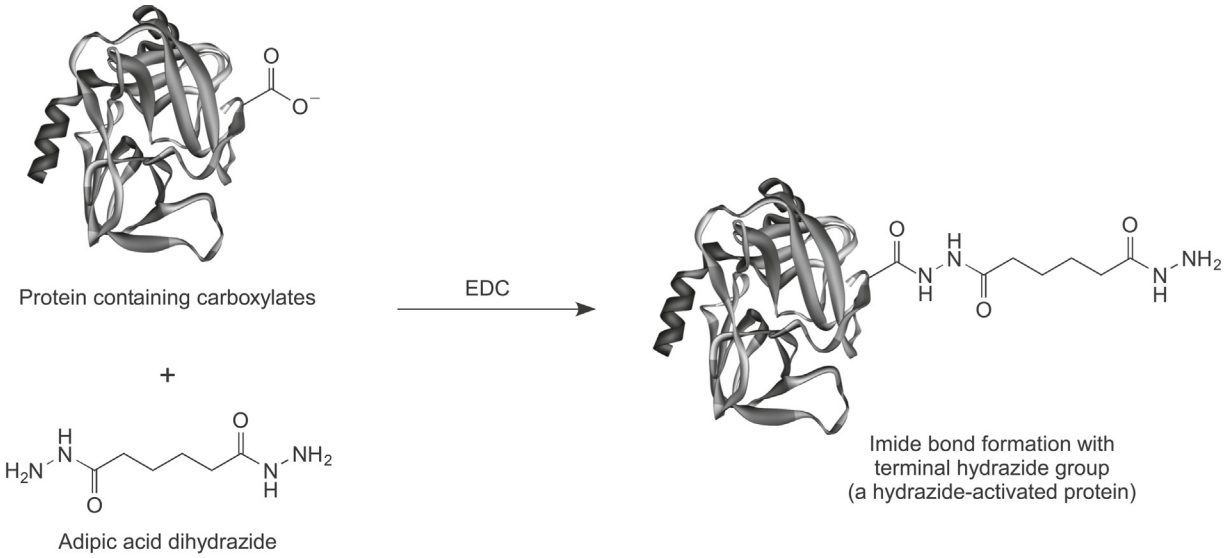

FIGURE 2.109 Carboxylate groups on proteins may be modified with adipic acid dihydrazide in the presence of a carbodiimide to produce hydrazide derivatives.

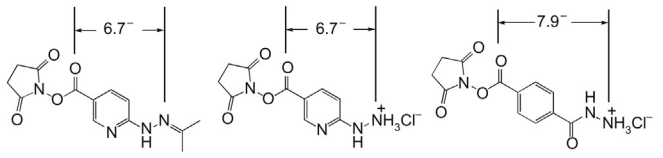

readily modified with *bis*-hydrazide compounds to yield useful hydrazide-activated derivatives. Both carbohydrazide and adipic acid dihydrazide have been employed in forming these modifications using the carbodiimide reaction (Wilchek and Bayer, 1987).

Protocol

1. Dissolve 32 mg of adipic acid dihydrazide per milliliter of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
2. Dissolve 5 mg of the protein or other macromolecule to be modified per milliliter of the above solution.
3. Add 16 mg EDC and react at room temperature for 2–4 h.
4. Purify the modified protein by dialysis or gel filtration using a desalting resin.

Modification of Amines with SANH, SHNH, or SHTH

The introduction of hydrazine or hydrazide functional groups may be performed using the bifunctional crosslinkers that are a part of the hydrazine–aldehyde chemoselective ligation reagents, which are described in Chapter 17, Section 2 (Wong, 1991; Hartmann *et al.*, 2002; Zhong *et al.*, 2003; Kozlov *et al.*, 2004). These are amine-reactive compounds that all have NHS esters on one end and which form amide bonds when coupled to primary amines, such as on the side chain of lysine. SANH (succinimidyl 4-hydrazinonicotinate acetone hydrazone) and SHNH (succinimidyl hydraziniumnicotinate hydrochloride) are both hydrazine derivatives of nicotinic acid, while SHTH (succinimidyl 4-hydrazidoterephthalate hydrochloride) is a hydrazide derivative of terephthalate. Hydrazines and hydrazides react with carbonyl compounds, such as aldehydes and ketones, to form hydrazone bonds. The hydrazone linkage formed between a hydrazine and an aldehyde is much more stable than that formed between a hydrazide and an aldehyde. Thus, hydrazine–aldehyde bonds typically do not require further reduction to stabilize the linkage, as is often the case with hydrazide–aldehyde linkages. For both hydrazide and hydrazine groups, however, the bond that is formed with ketones is typically weaker than the hydrazone formed with aldehydes.

The reaction of SANH, SNHN, or SHTH with an amine-containing molecule proceeds at physiological pH or at slightly basic pH conditions to form an amide bond (Figure 2.110). Reported reaction conditions used the following buffers to modify proteins, amine-modified DNA, or amine-modified surfaces: (a) 0.1-*M* sodium borate buffer, pH 8.1–8.4; or (b) 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2–7.4. Whereas NHS esters are reactive throughout this range, the use of pH buffers closer to neutrality will provide optimal yields while reducing the amount of competing hydrolysis as compared to higher pH conditions. Avoid the use of amine or thiol components in the reaction medium, as

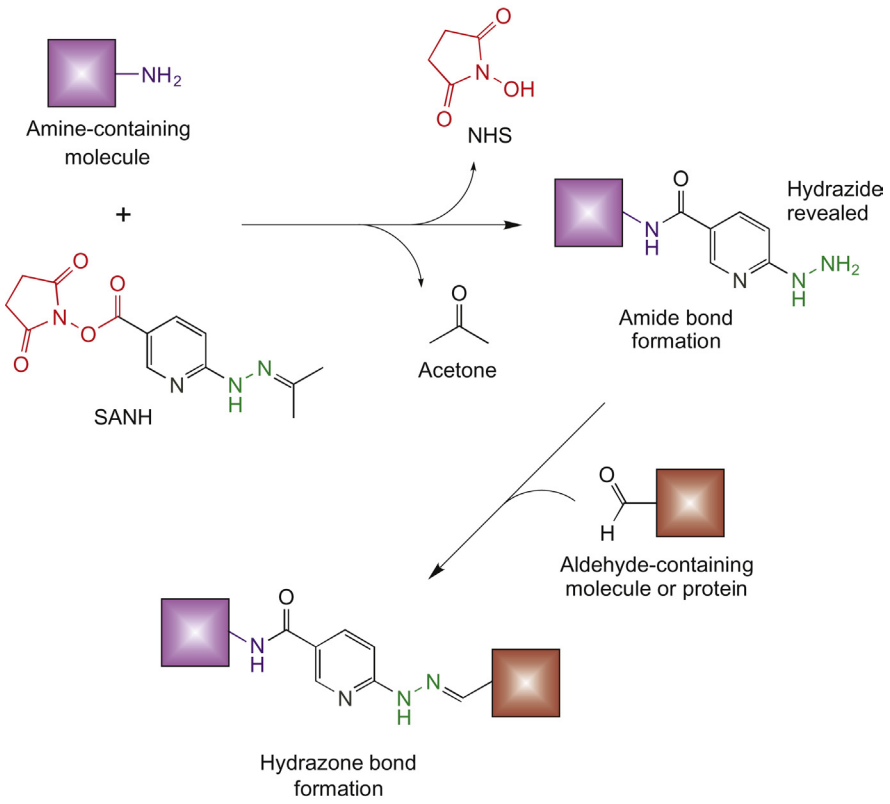

FIGURE 2.110 The reaction of SANH with an amine-containing molecule results in an amide bond derivative that terminates in a protected hydrazine group. Reaction with an aldehyde-containing molecule results in release of the acetone protecting group and formation of a stable hydrazone bond.

these will react with the NHS ester (e.g., avoid Tris buffer, glycine, DTT, or imidazole).

The following protocol describes a general method for modifying amines with SANH, SNHN, or SHTH and assaying for the incorporation of hydrazino groups in the final derivative.

Protocol

A. MODIFICATION OF AMINE GROUPS ON PROTEINS WITH SANH, SHNH, OR SHTH

1. Dissolve SANH, SHNH, or SHTH in DMF to prepare a stock solution at a concentration of 2.0–4.0 mg in 100–200 µl. Use highly pure and dry solvent (H_2O content<0.1% or treat with molecular sieves) to prevent hydrolysis of the NHS ester.
2. Dissolve the protein to be modified in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2–7.4, at a concentration of at least 1–10 mg/ml.
3. With mixing, add an aliquot of the crosslinker solution to the protein solution such that the desired molar excess of reagent over the protein present in the reaction is attained. For most applications, molar ratios in the range of 5:1 to 20:1 will work best to generate a number of hydrazine groups on the protein. Maintain the final percentage of DMF in the reaction mixture at less than 10% to avoid precipitation of protein.
4. React at room temperature for at least 30–60 minutes or 2–3 h at 4°C.
5. Purify the modified protein away from excess reagent and reaction byproducts by gel filtration using a desalting column or dialysis.
6. Calculate the protein concentration in the final preparation using its absorbance at 280 nm or a colorimetric method, such as the Coomassie assay. (Note: The presence of hydrazine or hydrazide groups on the protein will interfere with the BCA assay for total protein concentration.)

B. MEASUREMENT OF HYDRAZINE MODIFICATION LEVEL The number of hydrazine groups per protein molecule can be determined by reacting a small portion of the hydrazine-modified protein with *p*-nitrobenzaldehyde, which forms a chromogenic product upon formation of the hydrazone derivative (Figure 2.111).

1. Prepare a 0.5-m*M* *p*-nitrobenzaldehyde buffer by initially dissolving the compound at a higher concentration in organic solvent (e.g., methanol, DMF, DMSO) and then adding the appropriate

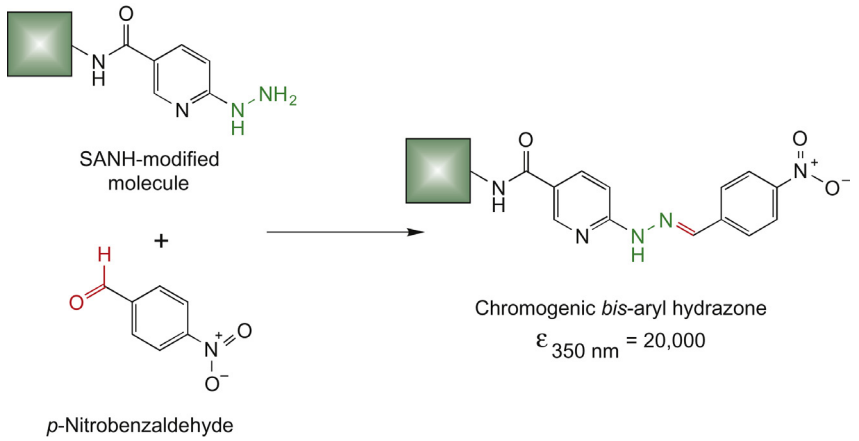

FIGURE 2.111 An SANH-modified molecule can be detected and measured by reaction with *p*-nitrobenzaldehyde, which forms a chromogenic derivative with a characteristic absorbance at 350 nm.

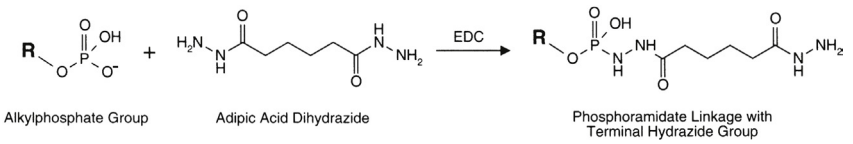

FIGURE 2.112 Phosphate groups can be modified with adipic acid dihydrazide in the presence of a carbodiimide to produce hydrazide derivatives. This is a common modification route for the 5′ phosphate group of oligonucleotides.

aliquot to 100-m*M* acetate, pH 5.0, to result in the final concentration.

2. Add an aliquot of the hydrazine-modified protein solution to the *p*-nitrobenzaldehyde solution and incubate at 37°C for 1 h or at room temperature for 2 h. To ensure accuracy, determine the linear response range of the test by adding a series of different concentrations of the hydrazine-modified protein solution to the *p*-nitrobenzaldehyde buffer. This is achieved by preparing a set of serial dilutions of the protein solution and adding an equal volume of each dilution to an aliquot of the *p*-nitrobenzaldehyde solution in separate tubes. Determine the absorbance of each solution at 380 nm *versus* a blank prepared by the addition of an equal aliquot of buffer alone.
3. Calculate the substitution level of hydrazine groups into the protein by determining the hydrazine concentration using the molar extinction coefficient of the resultant *p*-nitrobenzyl derivative (22,000 $M^{-1}cm^{-1}$) and dividing this value by the protein concentration (moles/liter). Any sample falling within the linear response range of the test can be used for this calculation.

Modification of Alkylphosphates with bis-Hydrazide Compounds

Alkylphosphate groups such as those present at the 5′ end of RNA and DNA molecules may be specifically modified with *bis*-hydrazide compounds. Mediated by the addition of the water soluble carbodiimide EDC and imidazole, adipic acid dihydrazide or carbohydrazide will react with the phosphate group in a two-step process to form phosphoramidate bonds with short linker arms containing terminal hydrazides (Figure 2.112) (Ghosh *et al.*, 1989). In the first stage, EDC activates the phosphate group, forming a short-lived, but highly reactive phosphodiester species, which in turn reacts with a molecule of imidazole to form a longer-lived, active phosphorimidazolide. The second stage involves addition and attack of the hydrazide nucleophile, releasing imidazole and forming the phosphoramidate bond. In a modification of the two-stage reaction, Zanocco (1993) developed a single-pot reaction in which the alkylphosphate molecule is reacted in the presence of EDC, imidazole, and the bis-hydrazide compound. The modification reaction proceeds rapidly at room temperature.

Protocol

1. Weigh out 1.25 mg of the carbodiimide EDC (1-ethyl-3-(3-dimethylaminopropyl)carbodiimide hydrochloride; Thermo Fisher) into a microfuge tube.
2. Add to the tube 7.5 µl of RNA or DNA containing a 5′ phosphate group. The concentration of the oligonucleotide should be 7.5–15 nmol/µl or total of about 57–115.5 µg. Also, immediately add 5 µl of 0.25-*M* adipic acid dihydrazide or carbohydrazide dissolved in 0.1-*M* imidazole, pH 6.0. Because EDC is labile in aqueous solutions, the addition of the oligo and *bis*-hydrazide/imidazole solutions should occur quickly.

3. Mix by vortexing, then place the tube in a microcentrifuge and spin for 5 min at maximal rpm.
4. Add an additional 20 µl of 0.1-*M* imidazole, pH 6.0. Mix and react for at least 2 h at room temperature. The additional buffer prevents pH drift during the carbodiimide reaction.
5. Purify the hydrazide-labeled oligo by gel filtration on a desalting resin using 10-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2. The hydrazide-containing probe may now be used to conjugate with a molecule containing an aldehyde-reactive group.

4.6. Introduction of Saccharide or Glycan Groups

The modification of proteins with sugar groups occurs *in vivo* through both enzymatic and non-enzymatic processes. Approximately 1% of proteins encoded in the genomes of mammals are enzymes that are involved with carbohydrate production or modification. Many of these enzymes digest carbohydrate in foods to provide energy for cellular metabolism, but others are involved with the controlled modification of proteins or other biomolecules to create complex polysaccharide structures. This process results in carbohydrates, called glycans, covalently attached to proteins at discrete locations on only certain amino acid residues within a polypeptide sequence (Section 2, this chapter). The presence of carbohydrate modifications on proteins has a pronounced effect on biological activity *in vivo*.

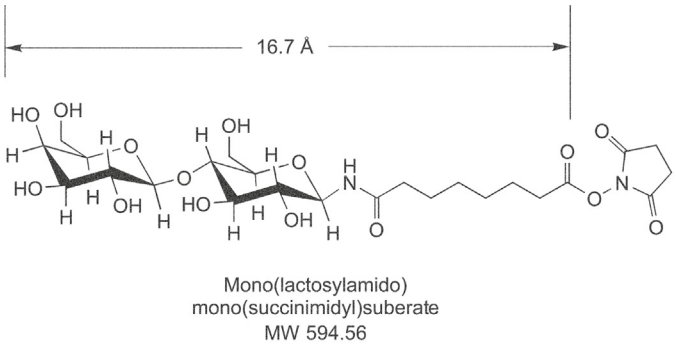
Non-enzymatic modification of proteins with saccharides also occurs *in vivo* through uncontrolled glycation of lysine amines with the reducing end of sugars, especially glucose. This reaction results in the formation of an initial Schiff base with a subsequent rearrangement to form a stable ketoamine derivative. The non-enzymatic glycation reaction has been studied extensively as a result of it being a major factor in the development of the complications associated with diabetes (for a review, see Singh *et al*., 2001).

In vitro modification of protein can be performed synthetically to add specific sugars or complex carbohydrates to proteins for further bioconjugation or for subsequent study of the glycan derivative *in vivo*. Investigations of the effect of these synthetic carbohydrate–protein conjugates (neoglycoproteins) on the immune response date back many decades with the diazonium-mediated coupling of aminophenol glucosides to study type-II and type-III pneumonia polysaccharides (Goebel *et al*., 1932). More recently, conjugation of carbohydrates to protein carriers has been carried out to illicit a specific immune response to glyco-antigens of infectious diseases or tumor cells (Toyokuni and Singhal, 1995; Koganty *et al.,* 1996; Ragupathi *et al.,* 1997; Pozsgay, 1998; Mawas *et al.,* 2002; Karsten *et al.,* 2004). Synthetic peptide–glycan conjugates have also been prepared by conjugation of carbohydrates to peptide sequences that can be presented by MHC (major histocompatibility complex) molecules to enhance the immune response against the carbohydrate component (Kihlberg and Magnusson, 1996). For an excellent review of glycoconjugation, see Davis (1999).

Sugar residues can also be used to modify a protein, molecule, or surface for subsequent use in a bioconjugation procedure or to increase the hydrophilicity of the modified molecule. For bioconjugation purposes, a sugar group can be added to facilitate the covalent conjugation of another molecule. Since many saccharides contain diols that can be oxidized by periodate to create aldehydes, certain sugars can be used after glycol oxidation to couple with amine-containing molecules by reductive amination. For instance, the amine group on the monosaccharide glucosamine can be coupled to an amine-reactive surface or to a protein through its carboxylate groups using EDC (Chapter 4, Section 1.1). The glucosamine-modified surface or molecule subsequently can be oxidized by sodium periodate to create aldehydes (Sections 2 and 4.4, this chapter). This reactive intermediate can be conjugated to another amine-containing molecule to create the final conjugate through reductive amination (Chapter 3, Section 5).

Periodate oxidation of carbohydrates should be avoided, however, if generating an immune response against the saccharide component is desired or antibody recognition needs to be retained against the carbohydrate. Woodward *et al*. (1985) demonstrated that periodate oxidation of glycans effectively destroys antibody binding if the specificity of the antibody is truly toward the carbohydrate. The assay of antibody binding to a carbohydrate with and without periodate oxidation is often used to demonstrate antibody specificity. A specific antibody will fail to bind to periodate oxidized carbohydrate, but will bind to the non-oxidized glycan.

The modification of molecules with saccharides also has the effect of increasing the hydrophilicity of the resultant complex due to the presence of multiple hydroxyl groups. Native glycan modification of proteins functions in much the same manner, because the carbohydrate "tree" becomes fully hydrated through the ability of the hydroxyls to hydrogen bond with the surrounding water molecules. In addition, post-translational modification of proteins helps polypeptides fold properly by assuring that certain regions are maintained near the solvent surface. Chemical modification with saccharides thus can be done to increase the hydrophilicity and solubility of proteins or other molecules in aqueous solution.



Some reports even indicate that the conjugation of proteins or peptides with carbohydrates can dramatically increase their activity compared to that of the

native state (Susaki *et al*., 1998). Carbohydrates can also provide a protective effect on modified peptides toward proteolytic digestion (Rudd *et al*., 1994) or mask recognition of a peptide by the immune system (Harding *et al*., 1993). The creation of neoglycoproteins thus can affect the activity of peptides and proteins, which are not normally glycosylated *in vivo*. Complex glycans can now be obtained through automated synthesis with amino groups on their reducing ends for ready conjugation with surfaces or proteins (Krock *et al*., 2012).

The following sections describe several examples of saccharide modification for the purpose of bioconjugation, the study of glycan function, to prepare immunogens, or to increase the water solubility of a modified molecule.

Modification of Amines with Mono(lactosylamido) Mono(succinimidyl)suberate

The amine-reactive compound mono(lactosylamido) mono(succinimidyl)suberate contains a lactose group at the end of a suberate bridge, which terminates at the other end in an NHS ester. Vetter *et al*. (1995) prepared this reagent by reaction of the corresponding glycosylamine derivative with disuccinimidyl suberate (DSS). The starting lactosylamine derivative was prepared *via* a 5-day reaction of the reducing end of lactose with aqueous ammonia solution in sodium carbonate. Other similar 1-amino, 1-deoxy sugar derivatives may be synthesized in a like manner for subsequent bioconjugation. The final product after reaction with DSS, the mono-NHS ester derivative of lactose containing an 8-carbon suberate spacer, can be used to modify proteins or other amine-containing molecules with a lactose group. The NHS ester spontaneously reacts with an amine at neutral or slightly basic pH values to form an amide bond (Figure 2.113). The presence of the lactose disaccharide provides a hydrophilic modifying group that increases the water solubility of the resultant conjugate. Other glycosylamine derivatives may be prepared using a similar strategy to modify biomolecules or surfaces with specific saccharide compounds.

The following protocol describes the modification of a protein with mono(lactosylamido) mono(succinimidyl)suberate. The reagent is available from Thermo Fisher. The use of this reagent to couple to amine-containing surfaces, such as polystyrene beads, has also been performed using similar reaction conditions (Vetter *et al*., 1995). It was also used to develop an electrochemical binding assay for cholera toxin by affinity interaction with the lactose group conjugated to daunomycin (Kuramitz *et al*., 2011).

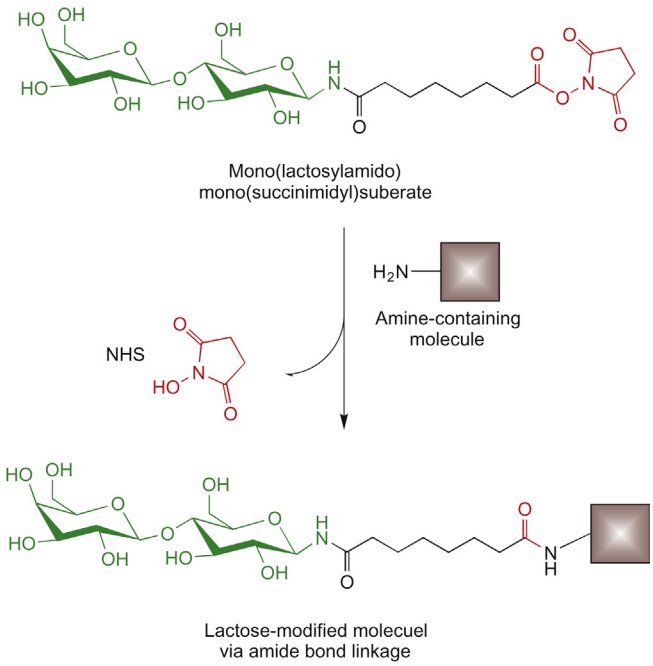


FIGURE 2.113 The NHS ester-suberate derivative of lactose can be used to add lactose groups to amine-containing molecules. The reaction results in the formation of amide bonds containing terminal lactose groups.

Protocol

1. Dissolve mono(lactosylamido) mono(succinimidyl) suberate in dry DMF to prepare a concentrated solution from which an aliquot may be taken and added to a final aqueous reaction medium. The compound is extremely soluble in DMF, and solutions of 100 mg/ml may be prepared. The use of dry solvent is essential to prevent hydrolysis of the NHS ester. However, make only enough of this stock solution so that a small amount added to the protein reaction will provide the appropriate molar excess desired for the modification reaction.
2. Prepare the protein to be modified in a non-amine-containing buffer at a slightly basic pH (i.e., avoid Tris or imidazole). The use of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 works well for NHS ester reactions. The concentration of the protein in the reaction buffer may vary from µg/ml to mg/ml, but highly dilute solutions will result in less efficient

modification yields. A protein concentration from 1 to 10 mg/ml works well in this reaction.

3. With mixing, add a quantity of the mono(lactosylamido) mono(succinimidyl)suberate in dry DMF to the protein solution to result in a 10- to 20-fold molar excess of reagent over the amount of protein present. Depending on the desired application for the lactosyl-modified protein, several different molar ratios of reactant-to-protein may have to be tried to optimize the resulting modification level.
4. React for 30–60 min at room temperature with gentle mixing.
5. Purify the modified protein away from reactants and reaction byproducts using dialysis or size exclusion chromatography.

Modification of Amine or Hydrazide Molecules by Carbohydrates and Glycans

The modification of proteins, surfaces, or other molecules with reducing sugars through a reductive amination process is still perhaps the most common method for glycosyl addition. A saccharide or glycan molecule containing a reducing end typically has a masked carbonyl group (i.e., aldehyde or ketone) that can be reacted with an amine or hydrazide in the presence of a reducing agent (such as sodium cyanoborohydride or borane compounds) to form a secondary amine or a reduced hydrazone bond (Figure 2.114). However, since most reducing ends of sugars or glycans exist mainly in an acetal (or ketal) ring form, while only the open form with the exposed aldehyde can participate in a reductive amination reaction, the rate of modification by this process can be slow and the yield low.

To help overcome the predominance of the cyclic acetal form, which inhibits the desired amination reaction, functional groups other than amines (having greater reactivity) have been used, along with elevated temperatures and high concentrations of reducing agent, to form more efficiently the initial Schiff base and thus drive the coupling reaction to completion. In particular, hydrazide or hydrazine groups have been used successfully to modify reducing glycans and saccharides with or without a reducing agent present (Rothenberg *et al.*, 1993; Toomre and Varki, 1994;

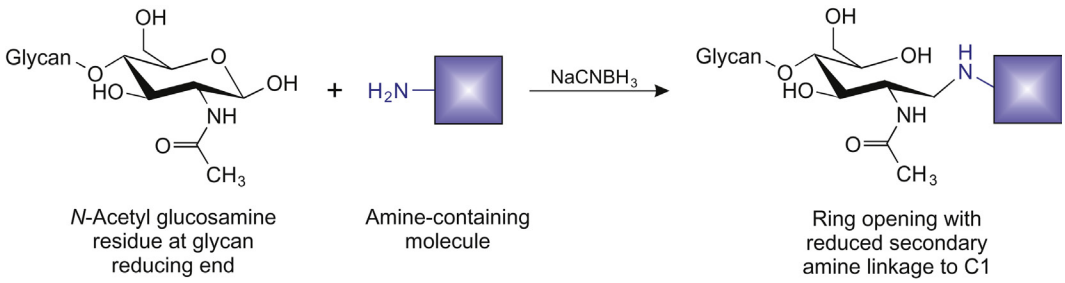

FIGURE 2.114 The reaction of a reducing sugar with an amine-containing compound in the presence of sodium cyanoborohydride results in ring opening with the formation of a secondary amine derivative.

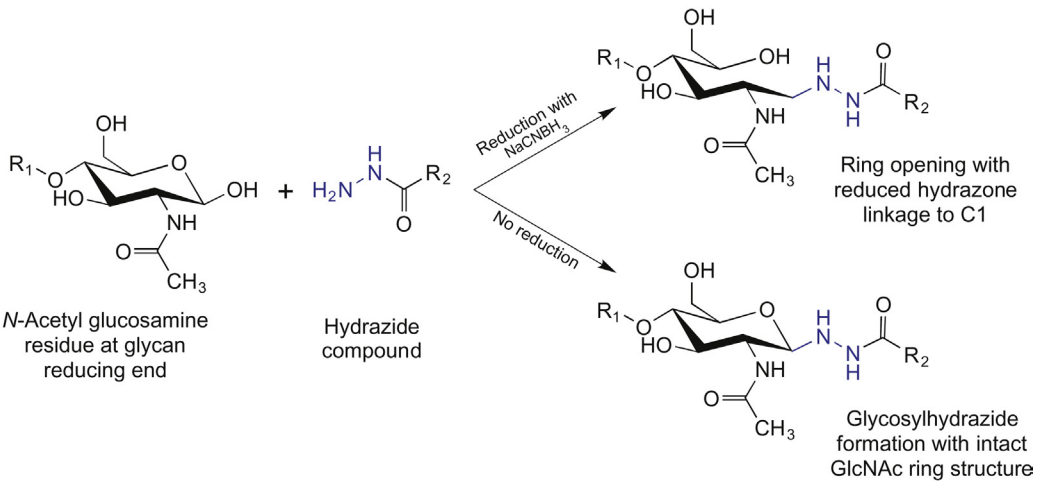

FIGURE 2.115 The reaction of a reducing sugar with a hydrazide-containing molecule can proceed by one of two routes depending on whether a reducing agent is present. If the reaction is performed in the presence of sodium cyanoborohydride, then ring opening will occur followed by the formation of a reduced hydrazone linkage. If no reducing agent is present, then the reaction gives a glycosylhydrazide derivative with retention of the ring structure of the sugar group.

Leteux *et al.*, 1998; Srikrishna *et al.*, 2001) (Figure 2.115). Whereas reactions performed with primary amines at room temperature may take days to reach acceptable coupling yields, the modification of hydrazino groups with the reducing end of a sugar can be done in hours at 60 to 80°C. Also, the modification of glycans with hydrazines can be carried out without the addition of cyanoborohydride, because the resultant hydrazone linkage is more stable compared to the Schiff base formed between an aldehyde and an amine. Although when coupling hydrazino compounds to the reducing end of a glycan, the addition of a reductant is often performed to drive the reaction to completion and further stabilize the hydrazone, reduction of the terminal saccharide can cause changes in the binding potential of some lectins that recognize the core sugar structure (Leteux *et al*., 1998).

The reversible nature of the hydrazone bond formation between the reducing end of a glycan and an immobilized hydrazide group was exploited to enrich glycans prior to analysis (Yang and Zhang, 2012). In this case, hydrazide beads were used to temporarily bind release glycans from glycoproteins and wash off any non-glycan molecules from the sample. Subsequent elution by hydrolysis of the hydrazone resulted in a pure glycan fraction, which can be analyzed by mass spectrometry.

The following protocol may be used to conjugate the available reducing end of a saccharide or glycan with an amine, hydrazide, or hydrazine group. These functional groups may be present on a variety of molecules, such as biotin groups for labeling or molecules having fluorescent properties, which allows detection of the glycan derivative. For specific modification details, see the methods of Rothenberg *et al*. (1993), Toomre and Varki (1994), Leteux *et al*. (1998), and Srikrishna *et al*. (2001). The following method is based on the optimized conditions as determined by Bigge *et al*. (1995). The use of organic solvents should be performed in a fume hood.

Protocol

1. Dissolve a carbohydrate, saccharide, or glycan sample having a free reducing end in 0.1-*M* sodium acetate, pH 5.0. (Note: Glycans may be released from glycoconjugates by hydrazinolysis using pure hydrazine or by endoglycosidase treatment with PNGase F.) Alternative coupling conditions that can be used for the modification reaction include 30% glacial acetic acid in DMSO (v/v) or acetic acid/pyridine (1:2, v/v). The use of DMSO or pyridine often facilitates solubilization of a greater range of carbohydrates or glycans than aqueous buffers. The presence of acetic acid has been found to accelerate the reductive amination reaction when the organic solvent conditions are used (Bigge *et al*., 1995). The concentration of the carbohydrate should be 5–100 μ*M* for glycans. For modification of other more abundant carbohydrates, higher concentrations can be used if required. For glycan modification of biomolecules that are not compatible with organic solvents, such as proteins, the glycan initially may be solubilized in DMSO and then an aliquot added to the aqueous reaction buffer.
2. Add to the glycan solution the molecule to be labeled containing an available amine, hydrazine, or hydrazide group. For small molecule derivatization, the final concentration of the nucleophile in the glycan solution should be about 0.3-*M* to result in maximal efficiency of labeling. For protein modification, an aqueous reaction buffer should be used, and the protein should be as concentrated as possible.
3. Add to the reaction mixture a quantity of reducing agent (e.g., sodium cyanoborohydride or borane dimethylamine, BDA) to give a final concentration of 1.0-*M*.
4. When using nonaqueous reaction conditions, incubation should be carried out for 1–2 h at 60–80°C. For reactions in an aqueous environment with temperature-sensitive molecules, the reaction may be performed at room temperature or 37°C. In this case, the reaction time should be extended to at least 24 h. Longer reaction times are not unusual when modifying carbohydrates by reductive amination at ambient temperature. For instance, the coupling of heparin through its reducing end to a solid phase containing a hydrazide group takes up to 72 h at room temperature to obtain maximal yield.
5. Purify the modified glycan from reactants and reaction byproducts by dialysis, gel filtration, or ion-exchange chromatography, depending on the size and type of the molecule being modified by the carbohydrate. For instance, Rothenberg *et al*. (1993), fractionated glycans modified with a biotin-diaminopyridine derivative from excess biotin compound by size exclusion chromatography on a 1.5×48 cm Toyopearl HW40S column equilibrated with 50% acetonitrile/10-m*M* sodium acetate.

Labeling Glycans with Fluorescent 2-Aminopyridine, 2-Amino Benzamide, or Anthranilic Acid

The ability to label glycans released from glycoproteins and other glycoconjugates is important for tracking complex carbohydrates through purification or analysis, such as HPLC, electrophoresis, and mass spec. Glycan molecules typically do not have spectrally detectable groups and therefore benefit by being labeled with a detectable component for easy assay and

detection. Small, amine-containing fluorescent compounds have been found to be particularly useful in this regard. The compounds 2-aminopyridine, benzamide, and anthranilic acid (2-aminobenzoic acid) have been used to label the reducing end of glycans and other carbohydrates.

Glycosylated proteins and other glycoconjugates may be treated to release the modifying carbohydrate component, making available the reducing end for conjugation. *N*-linked glycans may be released from glycoconjugates by PNGase F or PNGase A or released by anhydrous hydrazine and regenerated to reducing oligosaccharides, thus yielding free reducing ends for bioconjugation. In addition, the enzymes Endo H and Endo F release *N*-linked glycans by cleaving the GlcNAc(β1-4) GlcNAc core, thereby resulting in one less GlcNAc moiety at the reducing end. *O*-linked glycans may be released using *O*-glycanase treatment, or by mild hydrazinolysis followed by regeneration to the reducing oligosaccharides. *O*-linked glycans may also be released by non-reductive beta-elimination. However, one should avoid strong reductive glycan-releasing methods using sodium borohydride, as these may reduce the C1 aldehyde on the core sugar group and make it unreactive for further derivatization.

Bigge *et al*. (1995) described a method to label released glycans by reductive amination with the small fluorescent compounds 2-amino benzamide and anthranilic acid (2-aminobenzoic acid). The result is a secondary amine bond with the C1 carbon atom of the reducing end of the glycan (Figure 2.116). The derivatives provide stable fluorescent modifications on glycans, which can be used for detection during electrophoresis, separation, and purification techniques (such as HPLC). The 2-amino benzamide label was found to work best for chromatographic separations, enzymatic modifications, and mass spec analysis, while the anthranilic acid derivative was more suitable for electrophoretic separations, because its negative charge produced sharper bands.

Rothenberg *et al*. (1993) described the synthesis of a very useful fluorescent glycan labeling agent that contains a biotin group. Diaminopyridine was reacted with sulfo-NHS-biotin to form 2-amino-(6-amidobiotinyl)pyridine

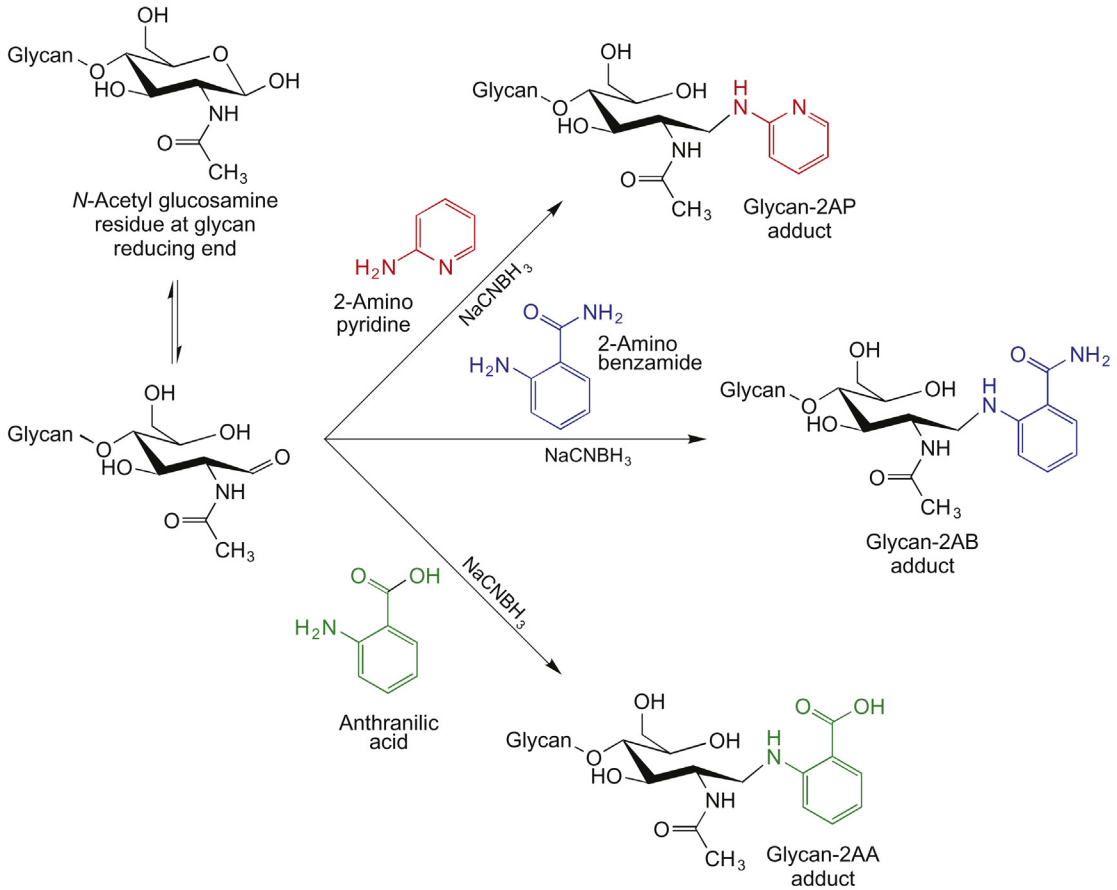

FIGURE 2.116 Released glycans can be labeled with small fluorescent compounds containing amines for subsequent detection upon chromatographic separation. In the presence of sodium cyanoborohydride these compounds react at the reducing end of glycans to form secondary amine derivatives with characteristic spectral properties.

(BAP). This reagent contains the fluorescent diaminopyridine group for detection and a biotin handle for purification or immobilization using its strong interaction with streptavidin. BAP can be used to label the reducing ends of glycans and other carbohydrates by reductive amination to form a secondary amine linkage with the aminopyridine group.

The fluorescent 2-aminopyridine group may also be used without a biotin handle for modification of glycans for detection, similar to the use of anthranilic acid and 2-amino benzamide. In this case, the tag just functions as a fluorescent label, which can be used to track glycans during purification or analysis. Modification of glycans with the bifunctional 2,6-diaminopyridine group using reductive amination produces a fluorescently labeled carbohydrate with an available amine for further coupling to surfaces or other biomolecules. Care should be taken, however, when using amine-reactive reagents to modify such amino glycans, because many electrophilic compounds cross-react with hydroxyls on the sugar molecules.

A similar fluorescent biotin label to the BAP reagent was created by Leteux *et al*. (1998) for labeling glycans without reduction of the reducing end of the monosaccharide. Biotinyl-L-3-(2-naphthyl)-alanine hydrazide (BNAH) contains a strongly UV absorbing naphthalene group, which has fluorescent characteristics, and a hydrazide group for conjugation to the reducing end of glycans. This compound was found to label effectively glycans at the reducing end, while retaining the unreduced nature of the carbohydrate, thus preserving critical protein interactions, which may recognize this region of the sugar.

The reductive amination protocol for coupling these types of small tags to glycans can be found in the previous section.

Synthesis of Glycosylamines for Conjugating Glycans

Reducing sugars and carbohydrates or glycans containing an unmodified reducing end may be derivatized in a simple reaction to provide an amine group on C1 for further conjugation. The anomeric hydroxyl group at the reducing end of such sugars can be converted into an amino group by reaction in an aqueous, saturated solution of ammonium carbonate. Kochetkov amination, as it is called (Likhosherstov *et al*., 1986), can be used to modify a wide variety of reducing carbohydrates and glycans, including neutral and charged monosaccharides, disaccharides, and oligosaccharides (Kallin *et al*., 1989; Urge *et al*., 1991, 1992; Manger *et al*., 1992; Cohen-Anisfeld and Langburg, 1993). A more recent analysis of the reaction mechanisms of glycosylamine formation identified a number of routes to product formation (Ghadban *et al*., 2012). Once an amine is created on the anomeric carbon, subsequent labeling or coupling reactions can be performed using standard amine-reactive conjugation agents, for instance fluorescently labeling with a dye molecule (Song *et al*., 2011).

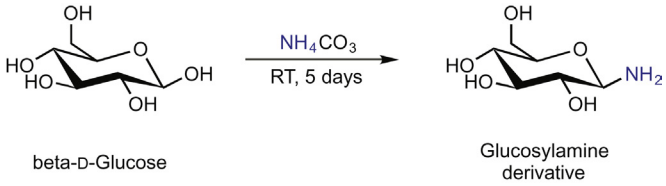

FIGURE 2.117 Glucosylamine derivatives can be prepared at the reducing end of glycans or other reducing carbohydrates by reaction with ammonium carbonate. The resultant amine derivative can be used to conjugate the carbohydrate with other proteins or molecules without disturbing the cyclic character of the reducing end.

Modification using this protocol yields saccharides that are highly stereochemically pure, with typical reactions giving >95% glycosylamines of the β-anomer structure (Figure 2.117). The resulting primary amine group can be further coupled with amine-reactive bioconjugation reagents or used for carbohydrate immobilization onto surfaces or insoluble supports. The major side reaction of amination is the dimeric diglycosylamine derivative, which has two sugar groups attached to a single secondary amine in the middle. This byproduct can be present in up to 10% of the resulting mass of product formed by the reaction.

The following protocol for synthesis of glycosylamines from reducing sugars is based on the method of Likhosherstov *et al*. (1986).

Protocol

1. Prepare a solution of the saccharide to be aminated at a concentration of up to 1% (w/v) in an aqueous solution of saturated ammonium carbonate. Even higher concentrations of saccharides may be used if the carbohydrate being modified is abundant and inexpensive.
2. React with stirring at room temperature for up to 5 days. Over the course of the reaction, add to the solution solid ammonium carbonate at a rate of about 40 mg per mg of saccharide to assure continued saturation.
3. After the reaction, freeze the solution and lyophilize to remove excess ammonium carbonate. Complete removal of volatile salt can be accomplished by re-dissolving the solid in warm methanol. After the completion of CO_2 evolution, dry the saccharide by evaporation under vacuum. Removal of ammonium carbonate is essential, as the ammonium ion will interfere with any subsequent conjugations attempted with the glycosylamine derivative.

5. BLOCKING OR PROTECTING GROUPS

It is often necessary to block specific groups on macromolecules to prevent them from participating in modification or conjugation reactions. In most blocking procedures, a chemical group is covalently coupled to an undesired functional group on the macromolecule to mask or eliminate its reactivity. In this sense, the modification is performed with a compound that is relatively inert in whatever application the macromolecule is intended for use. The blocking agent is usually a small organic compound containing a functional group able to couple with the group to be masked. The blocking molecule may contain another functional group of its own, converting the blocked group into a chemical function of another type, but this conversion is all right, providing the newly created function does not interfere in subsequent reactions or applications.

In some cases, a blocking procedure is performed to direct a conjugation reaction to discrete sites in a macromolecule. In other instances, blocking a group on one of two macromolecules can prevent self-polymerization and promote the desired intermolecular conjugation. For instance, HRP can be blocked with an amine-specific coupling reagent prior to periodate oxidation to prevent the reactivity of its two amino groups during subsequent conjugation with an antibody molecule (Chapter 20, Section 1.3).

In other uses of blocking reagents, proteins dissociated into subunits by the use of denaturants and disulfide reductants may be prevented from re-association or oxidation of their sulfhydryls by blocking the –SH groups with the appropriate reagent. Alternatively, sulfhydryls may be blocked on a protein prior to activation with a heterobifunctional crosslinking agent that contains both amine-reactive and sulfhydryl-reactive ends. The amine-reactive end will couple to the amines of the protein without reaction of the sulfhydryl-reactive end. This can prevent oligomer formation during the activation process and thus ensure that the sulfhydryl-reactive function is available for conjugation with the desired molecule.

Controlled functional studies of a protein's active center may also be carried out by blocking specific groups and observing its effect on activity. Often, this blocking procedure is performed through the use of a reversible blocking agent to subsequently regenerate activity, thus demonstrating that the affect was directed at functionalities present in the active site (Perham and Jones, 1967).

Blocking may also be carried out to quench further modification or conjugation through a targeted functional group. After a conjugation reaction, excess functional groups may be masked from nonspecifically reacting with other molecules. For instance, periodate-oxidized glycoproteins may still contain aldehyde groups after conjugation with another protein by reductive amination. Blocking the aldehydes with a small amine-containing molecule prevents unwanted reactions from occurring when the conjugate is used in an assay or targeting operation. This is also true of excess sulfhydryl groups that may undergo disulfide interchange with other sulfhydryl molecules subsequent to a conjugation reaction. Blocking these groups with the appropriate reagent prevents this type of side-reaction from occurring.

Blocking of amine groups on proteins has also been used to create a sensitive reagent for measuring protease activity (Hatakeyama, 1992). With nearly all the primary amines of casein blocked, an amine detection reagent such as trinitrobenzene sulfonic acid (TNBS) will react only minimally with the protein and form its typical orange derivative. As proteases cleave the protein, however, primary α-amines are created from cleavage of the α-chain peptide bonds, and TNBS then can react with them. The more protease activity present, the more color is formed.

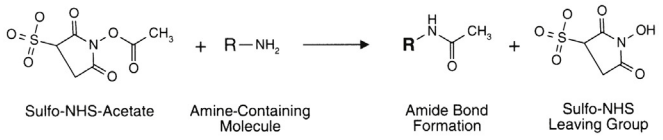
The choice and application of a specific blocking reagent can produce a modified macromolecule with unique and useful properties. Many of the common blocking reagents are discussed in this section. Beyond the scope of this book, however, is a discussion of the numerous blocking agents used in peptide or nucleic acid synthesis to temporarily block specific reactive groups during growth of the polymer chain.

5.1. Blocking or Protecting Amine Groups

The amine functionalities most commonly found in macromolecules are primary amines such as those at the N-terminal of polypeptide chains (α-amines) and the side-chain ε-amino groups of lysine residues. Several acylation reagents can effectively block these primary amines, some of which are reversible under the right conditions. It should be noted that the cyclic anhydrides mentioned in this section react with amino groups to form amide bonds, opening the anhydride ring and effectively transforming the amine function into a carboxylate. There are additional compounds described in Section 4.2 (this chapter) that also create carboxylates from amines, but in this section the two cyclic anhydrides discussed, maleic anhydride and citraconic anhydride, are both reversible and designed more for temporary masking than permanent blocking. For more stable blocking of amines, the compounds sulfo-NHS acetate and acetic anhydride are the best choices.

Sulfo-NHS-Acetate

Sulfo-NHS acetate is the *N*-hydroxysulfosuccinimide ester of acetic acid. The NHS ester end provides high reactivity with the amino groups of proteins at a pH



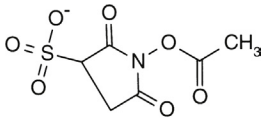


FIGURE 2.118 Sulfo-NHS acetate may be used to block amine groups, forming permanent amide bond derivatives.

range of 7 to 9, acylating the amines and forming nonreversible acetamide modifications (Figure 2.118). The sulfonate derivative of the NHS ester provides good water solubility to the reagent. Thus, the compound can be added directly to an aqueous solution of the protein to be blocked, or a stock solution may be prepared and a small aliquot added to the reaction medium. Stock solutions should be dissolved rapidly and used immediately. In aqueous solutions, the main competing reaction is hydrolysis of the active ester to release nonreactive sulfo-NHS and acetic acid. The use of a 10- to 50-fold molar excess of sulfo-NHS acetate over the molar amount of groups to be blocked should provide good yields of acylated amines. Reaction buffers should contain no extraneous amines that could cross-react with the sulfo-NHS acetate. Avoid Tris, glycine, and imidazole-containing buffers. Phosphate, borate, or bicarbonate buffers work well at a concentration of 0.05–0.1-*M*. React for at least 1 h at room temperature.

It should be noted that complete blocking of all amines on proteins with sulfo-NHS acetate may cause precipitation or loss of native structure and function. The acetate modifications are uncharged and relatively hydrophobic, which may decrease solubility of proteins or other molecules.

Sulfo-NHS Acetate
MW 259.17

Protocol

1. Dissolve the protein or other amine-containing macromolecule at a concentration of 1–10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5.
2. Add a 25-molar excess of sulfo-NHS acetate over the amount of amines present in the sample. If the precise amount of amines is not known, adding an equal mass of reagent to the mass of protein will provide a large excess of reactivity to completely block all amines.
3. React at room temperature for at least 1 h.
4. Purify the modified protein by dialysis or gel filtration.

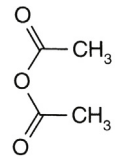

FIGURE 2.119 Acetic anhydride reacts with amines to form amide bond derivatives.

Acetic Anhydride

Acetic anhydride is the only monocarboxylic acid anhydride that is important in modification reactions. The acetylation of the amino groups of proteins can be made relatively specific if the reaction is carried out in saturated sodium acetate, since the *O*-acetyltyrosine derivative is unstable to an excess of acetate ions (Fraenkel-Conrat, 1959). The tyrosine derivative rapidly hydrolyzes in alkaline reaction conditions, even in the absence of added acetate buffer (Uraki *et al.*, 1957; Smyth, 1967). Treatment with hydroxylamine also cleaves any *O*-acetyltyrosine modifications, forming acetylhydroxamate, which can be followed by its purple complex with Fe^{+3} at 540 nm (Balls and Wood, 1956).

At physiological pH values, acetylation of amine groups proceeds rapidly, requiring less than an hour to go to completion (Figure 2.119).

Acetic Anhydride
MW 102

Protocol

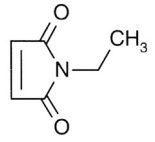
1. Dissolve the macromolecule to be modified at a concentration of 1–10 mg/ml in a buffered solution having a pH between 6.5 and 7.5. Avoid amine-containing buffers such as glycine and Tris. Sodium phosphate buffer at a concentration of 0.1-*M* works well. The addition of an equal volume of a saturated solution of sodium acetate may be carried out to prevent tyrosine derivatization.
2. Cool the solution on ice. With stirring, add an amount of acetic anhydride equal to the mass of macromolecule to be modified. Alternatively, add a 10-fold molar excess of acetic anhydride over the amount of amines present. The addition of the anhydride slowly or in several aliquots over the course of 1 h will ensure good yield of acetylation.
3. React with stirring for at least 1 h while cooling in an ice bath.
4. Purify the acetylated macromolecule by gel filtration or dialysis.

Citraconic Anhydride

Citraconic anhydride (or 2-methylmaleic anhydride) is a derivative of maleic anhydride that is reversible after acylation of amine groups. At alkaline pH values (pH 7–8) the reagent reacts with amines to form amide linkages with an extending terminal carboxylate. However, at acid pH (3–4), these bonds rapidly hydrolyze to release citraconic acid and free the amine (Dixon and Perham, 1968; Habeeb and Atassi, 1970; Klapper and Klotz, 1972; Shetty and Kinsella, 1980). Thus, citraconic anhydride is useful in temporarily blocking amine groups while other parts of a molecule are undergoing derivatization. Once the modification is complete, the amines can then be unblocked to create the original structure. See Section 4.2 for additional information and a protocol for modification of proteins with citraconic anhydride.

Maleic Anhydride

Maleic acid is a linear four-carbon molecule with carboxylate groups on both ends and a double bond between the central carbon atoms. The anhydride of maleic acid is a cyclic molecule containing five atoms. Although the reactivity of maleic anhydride is similar to other cyclic anhydrides, the products of maleylation are much more unstable toward hydrolysis, and the site of unsaturation lends itself to additional side-reactions. Acylation products of amino groups with maleic anhydride are stable at neutral pH and above, but they readily hydrolyze at acid pH values around pH 3.5 (Butler *et al*., 1967). Maleylation of sulfhydryls and the phenolate of tyrosine are even more sensitive to hydrolysis. Thus, maleic anhydride is an excellent reversible blocker of amino groups to temporarily mask them from reactivity while another reaction is being performed. For additional information and a protocol for the modification of proteins with this reagent, see Section 4.2.

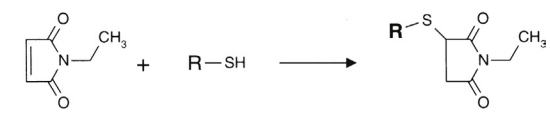


5.2. Blocking or Protecting Sulfhydryl Groups

The sulfhydryl group is among the most highly reactive of nucleophiles found in biological macromolecules. Cysteine sulfhydryls in proteins undergo covalent reactions rapidly with most of the reactive groups utilized in modification and conjugation reagents. To prevent modification from occurring at these sites, it is often necessary to use a blocking agent that ties up the sulfhydryl and renders it inert toward further reactions.

There are two types of sulfhydryl blocking agents: permanent and reversible. The permanent ones form thioether linkages that do not readily break down. The reversible ones form disulfide bonds that are susceptible to cleavage by the addition of the appropriate reducing agent. Reversible sulfhydryl blockers can be used to temporarily mask an –SH group from modification while a reaction is performed at another site. This is especially useful when the sulfhydryl forms a critical part of the active center of a protein. After the final modification is complete, the blocking agent can be removed to regenerate activity.

N-Ethyl Maleimide



N-Ethyl maleimide (NEM) (NEM) is an alkylating reagent that reacts with sulfhydryls to form stable thioether bonds (Smyth *et al*., 1960). Maleimide reactions are specific for sulfhydryl groups in the pH range of 6.5 to 7.5 (Smyth *et al*., 1964; Gorin *et al*., 1966; Heitz *et al*., 1968; Partis *et al*., 1983) (see Chapter 3, Section 2.2). At higher pH values some cross-reactivity with amino groups takes place (Brewer and Riehm, 1967). One of the carbons adjacent to the double bond undergoes nucleophilic attack by the thiolate anion to generate the addition product (Figure 2.120). When sufficient quantities of –SH groups are being blocked, the reaction may be followed spectrophotometrically by the decrease in absorbance at 300 nm as the double bond reacts and disappears. The result is a stable, inert derivative that terminates in the ethyl group. NEM is useful for permanently blocking sulfhydryl residues in proteins and other macromolecules. It has been used for blocking sulfhydryl-containing reagents that interfere in a glucose oxidase assay system (Haugaard *et al*., 1981).

N-Ethylmaleimide
MW 125.12

Protocol

1. Dissolve the macromolecule containing sulfhydryl groups to be blocked in a buffer having a pH of 6.5 to 7.5. Sodium phosphate (0.01–0.1-*M*) at pH 7.2 works well. Avoid amine-containing buffers, since an excess of amines may cause some reactivity with the maleimide groups. Also, avoid the presence of sulfhydryl-containing disulfide reductants such as

N-Ethylmaleimide | Sulfhydryl-Containing Molecule | Thioether Bond Formation

FIGURE 2.120 The reaction of *N*-ethylmaleimide with sulfhydryl groups yields a thioether derivative, permanently blocking the thiol.

DTT or 2-mercaptoethanol, which will rapidly react with NEM.
2. Add at least a 10-fold molar excess of NEM over the amount of sulfhydryls present in the reaction. Alternatively, add an equal mass of NEM to the amount of macromolecule present. To facilitate the addition of a small quantity of reagent, a more concentrated stock solution may be prepared in buffer and an aliquot added to the reaction medium. Make the stock solution up fresh, and use it immediately to prevent loss of activity due to maleimide group breakdown.
3. React for 2 h at room temperature.
4. Purify the modified protein by gel filtration or dialysis.

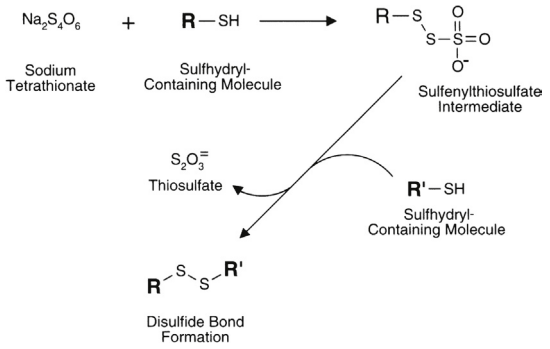


FIGURE 2.121 Sodium tetrathionate reacts with thiols to form reactive sulfenylthiosulfate intermediates. Another sulfhydryl-containing molecule may couple to this active group to create a disulfide linkage.

Iodoacetate Derivatives

Iodoacetate (and bromoacetate) can react with several nucleophilic functional groups within proteins. Their relative reactivity toward protein functionalities is sulfhydryl > imidazolyl > thioether > amine. Among α-haloacetate derivatives the relative reactivity is I > Br > Cl > F, with fluorine being almost unreactive. The α-haloacetamides have the same trend of relative reactivities, but will obviously not create a charged carboxylate functional group. The acetamide derivatives typically are used only as blocking reagents. The bond formed from the reaction of iodoacetamide and a sulfhydryl group is a stable thioether linkage that is not reversible under normal conditions.

Thus, iodoacetamide has the highest reactivity toward cysteine sulfhydryl residues and may be directed specifically for –SH blocking. If iodoacetamide is present in limiting quantities (relative to the number of sulfhydryl groups present) and at slightly alkaline pH, cysteine modification will be the exclusive reaction. For additional information on α-haloacetate reactivities and a protocol for blocking, see Section 4.2.

Sodium Tetrathionate

Sodium tetrathionate ($Na_2S_4O_6$) is a redox compound that under the right conditions can facilitate the formation of disulfide bonds from free sulfhydryls. The tetrathionate anion reacts with a sulfhydryl to create a somewhat stable active intermediate, a sulfenylthiosulfate (Figure 2.121). Upon attack of the nucleophilic thiolate anion on this activated species, the thiosulfate ($S_2O_3^{=}$) leaving group is removed and a disulfide linkage forms (Pihl and Lange, 1962). The reduction of tetrathionate to thiosulfate *in vivo* was a subject of early study (Chen *et al.*, 1934; Theis and Freeland, 1940).

$Na_2S_4O_6$

Sodium Tetrathionate
MW 270.22

Depending on the proximity of cysteine sulfhydryl groups in proteins, intrachain and interchain disulfide formation is possible upon reaction with tetrathionate. When neighboring sulfhydryl groups are not close enough to create disulfide linkages, the sulfenylthiosulfate modification is sufficiently stable to temporarily block exposed –SH groups. For sulfhydryls present in the active centers of enzymes, tetrathionate may lead to reversible inactivation (Parker and Allison, 1969). Thus, the reagent may be used to protect certain sulfhydryl residues during modification reactions performed elsewhere on a protein. Using this approach, the enzyme ficin may be temporarily protected with tetrathionate during modification, conjugation, or immobilization reactions performed through its amine groups (Liener and Friedenson, 1970). Subsequent treatment with thiol-containing disulfide reducing agents frees the sulfenylthiosulfate and regenerates the sulfhydryl with enzymatic activity. The following protocol is an adaptation of Englund *et al*. (1968), used in the purification of ficin.

Protocol

1. The macromolecule containing sulfhydryl residues to be blocked or protected is dissolved in a buffer suitable for its individual stability requirements. The blocking process may be performed on a purified protein or during the early stages of a purification process to protect sulfhydryl active centers from oxidation. PBS buffers containing 1-m*M* EDTA work well.
2. Add sodium tetrathionate to obtain a final concentration of 10-m*M*.
3. React for 1 h at room temperature.
4. Excess tetrathionate may be removed by dialysis or gel filtration.
5. To remove the sulfenylthiosulfate blocking group, add a 300-fold excess of DTT over the amount of

blocked sulfhydryls present. Alternatively, add DTT to obtain a final concentration of 0.01 to 0.1-*M*. Cysteine also may be utilized to regenerate some enzymes to full activity.

6. Incubate for 2 h at room temperature.
7. For removal of excess DTT, a protein of molecular weight greater than 5000 may be isolated by gel filtration using a desalting resin. To maintain the stability of the exposed sulfhydryl groups, include 10-m*M* EDTA in the chromatography buffer. The presence of oxidized DTT can be monitored during elution by measuring the absorbance at 280 nm. The protein should elute in the first peak and the DTT reaction products in the second peak.

Methyl Methanethiosulfonate

Methyl methanethiosulfonate (MMTS) is a small reversible blocking agent for sulfhydryl groups (Thermo Fisher, Toronto Research). It reacts with free thiols to form a dithiomethane modification with release of sulfinic acid (Figure 2.122). The sulfinic acid component decomposes into volatile products, which do not affect the disulfide formed from the MMTS reaction. Alkylthiosulfonates will react rapidly with thiols under mild conditions at physiological pH. The MMTS compound is a liquid at 10.6-*M* concentration and is conveniently added to a reaction medium by pipette. The only caveat in this regard is that the reagent is more viscous than water and will fall to the bottom of most aqueous buffers and form a two-phase solution. Vigorous mixing is necessary to completely cause dissolution in the reaction buffer or medium. Complete thiol modifications of available cysteine residues in proteins can be achieved even using relatively dilute (μ*M* to m*M*) concentrations of the reagent. Typically, MMTS need only be added in several-fold molar excess over the quantity of thiols present to result in stoichiometric sulfhydryl group blocking. Reactions can be performed in organic solvent, aqueous buffers, or a mixture of organic/aqueous solutions, whatever is suitable for the sulfhydryl compound being modified.

MMTS-mediated modification of thiols is reversible by use of disulfide reductants. Reducing agents such as DTT, 2-mercaptoethanol, or TCEP will cleave the dithiomethane modification groups to restore the original sulfhydryl. The reagent has been used to identify the cysteine residues important for organic cation transport in oocytes (Sturm *et al.*, 2007), to study the peptide loading complex within MHC class I (Santos *et al.*, 2007), for investigations of the Zn^{21}-dependent redox switch in an intracellular interface channel (Wang *et al.*, 2007), and to study how disulfide isomerization functions to switch tissue factor from coagulation to cell signaling (Ahamed *et al.*, 2006). MMTS has also been used to block cysteine thiol groups prior to the determination of *S*-nitrosylation within proteins (Sangwung *et al.*, 2012).

MMTS is a popular thiol blocking agent that functions similar to sodium tetrathionate in forming reversible disulfide derivatives (previous section). This reactive group has also been used as the basis of creating sulfhydryl-reactive crosslinking agents, such as the trifunctional compounds MTS-ATF-Biotin and MTS-ATF-LC-Biotin (Chapter 24, Section 3.2). In addition, it has been used to form thiol modification reagents to

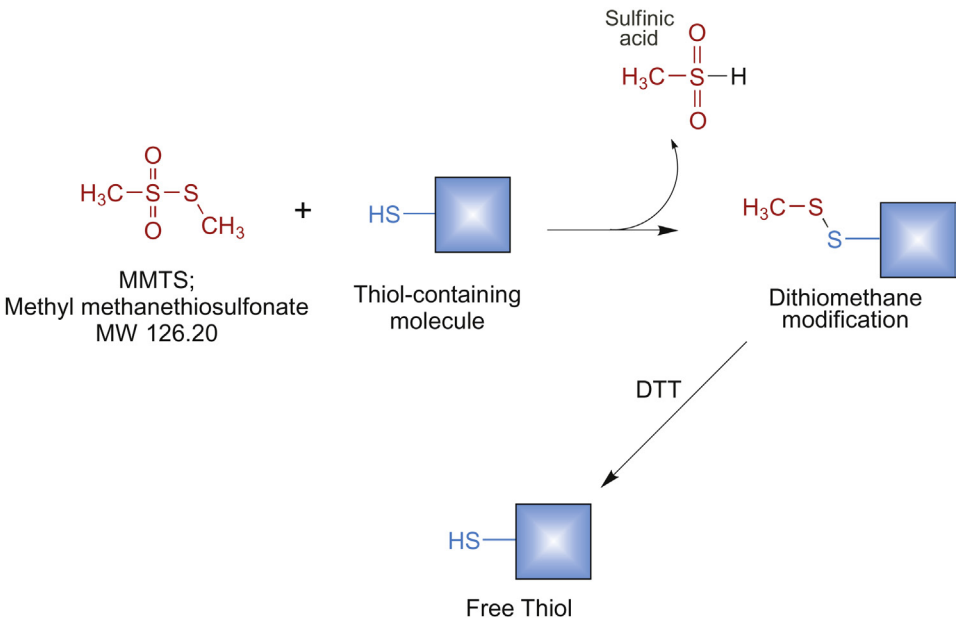

FIGURE 2.122 2,2′-Dipyridyl disulfide reacts with thiols to form an active pyridyl disulfide intermediate.

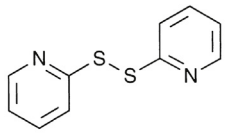
study site-directed mutagenesis, including how small modifications might affect protein folding or protein interactions (Toronto Research).

Ellman's Reagent

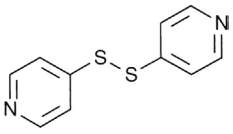
Ellman's reagent or DTNB, is a compound useful for the quantitative determination of sulfhydryls in solution (Ellman, 1958, 1959). The disulfide of Ellman's reagent readily undergoes disulfide exchange with a free sulfhydryl to form a mixed disulfide and release of one molecule of the chromogenic substance 5-sulfido-2-nitrobenzoate, also called 5-thio-2-nitrobenzoic acid (TNB). The intense yellow color produced by the TNB anion can be measured by its absorbance at 412 nm ($\varepsilon = 1.36 \times 10^4 M^{-1} cm^{-1}$ at pH 8.0). Since each sulfhydryl present generates one molecule of TNB per molecule of Ellman's reagent, direct quantitation is easily performed. This reagent has been used to measure the sulfhydryl content in peptides, proteins, and tissue samples (Anderson and Wetlaufer, 1975; Riddles *et al*., 1979). See Section 4.1 in this chapter for the use of Ellman's reagent in the determination of sulfhydryl groups.

The same reaction between Ellman's reagent and the sulfhydryls of macromolecules can be used to temporarily block available –SH groups by the formation of a mixed disulfide bond. Treatment of a sulfhydryl-containing protein with an excess of Ellman's reagent blocks the accessible sulfhydryls with the TNB group, allowing chemistries to be performed on other functionalities. Studies have shown that the rate of Ellman's reaction with the thiol groups in proteins is dependent on their accessibility (Damjanovich and Kleppe, 1966; Colman, 1969). The addition of a disulfide reducing agent then cleaves the TNB group and regenerates the free sulfhydryl. Enzymes containing sulfhydryls in their active sites may be reversibly blocked using this technique to preserve activity after modification or conjugation. Deblocking then restores catalytic activity in most instances.



Protocol

1. Dissolve the protein to be blocked at a concentration of 1–10 mg/ml in 0.1-*M* sodium phosphate, pH 8.0.
2. Dissolve the Ellman's reagent at a concentration of 4 mg/ml in 0.1-*M* sodium phosphate, pH 8.0.
3. Mix the protein solution with an equal volume of the Ellman's reagent solution and react for 15 min at room temperature.
4. Purify the modified protein from excess Ellman's reagent and reaction byproducts by dialysis or gel filtration. A measurement of sulfhydryl content may be carried out by reading the absorbance of the modification reaction at 412 nm ($\varepsilon = 1.36 \times 10^4 M^{-1} cm^{-1}$) *versus* a series of sulfhydryl standards treated in the same manner (e.g., cysteine).



To deblock the TNB modified sulfhydryl residues, treat the protein with an excess of DTT according to the protocol described in Section 4.1, DTT (this chapter).

Dipyridyl Disulfide Reagents

The similar reagents, 4,4′-dipyridyl disulfide (Grassetti and Murray, 1967) and 2,2′-dipyridyl disulfide (Brocklehurst, 1974), react in an analogous manner to Ellman's reagent, both forming pyridyl disulfide bonds with free sulfhydryls and releasing a molecule of either pyridine-4-thione or pyridine-2-thione, respectively (Figure 2.122). Both leaving groups are measurable spectrophotometrically at 324 nm (pyridine-4-thione) or 343 nm (pyridine-2-thione) to quantify the amount of sulfhydryl modification. The reagent 2,2′-dipyridyl disulfide is useful for creating sulfhydryl-reactive cross-linking agents, such as SPDP (Chapter 6, Section 1.1) and for activating particles or chromatography supports for the coupling of thiol-containing ligands (Chapters 14 and 15). Both reagents may be used to temporarily block sulfhydryl groups in macromolecules or to activate –SH groups for coupling to another sulfhydryl-containing molecule. The pyridine disulfide-modifying group can react with a sulfhydryl to form a disulfide linkage. The pyridine disulfide may also be cleaved with an excess of disulfide reducing agents, such as DTT, making it a reversible blocking agent.

2,2'-Dipyridyl disulfide

4,4'-Dipyridyl disulfide

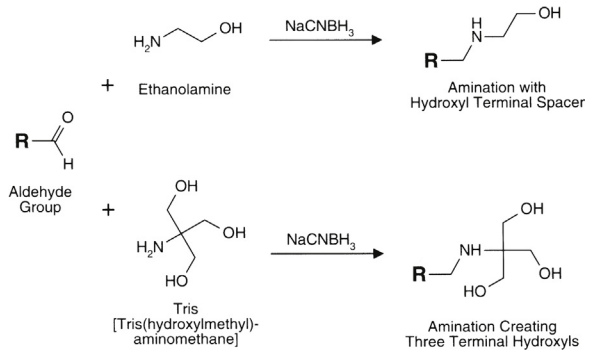


FIGURE 2.123 Aldehyde groups may be blocked with Tris or ethanolamine using a reductive amination process.

Unfortunately, 2,2′-dipyridyl disulfide is relatively insoluble in aqueous buffers. The use of this compound to modify molecules usually involves prior dissolution in an organic solvent such as acetone and then performing the blocking reaction in an aqueous/organic mixture. Many proteins will not tolerate high concentrations of organic solvents without precipitation.

The 4,4′-dipyridyl disulfide can be used in aqueous solutions, but it has been found that modification of proteins with this reagent yields rapid disulfide bond formation. Only when 2-iminothiolane is used in tandem with 4,4′-dipyridyl disulfide can 4-dithiopyridyl groups be introduced into proteins (King *et al.*, 1978) (Section 4.1, this chapter). This is due to disulfide interchange reactions predominating without the addition of 2-iminothiolane.

For one-step methods, the use of Ellman's reagent (previous section) to yield a similar reversible sulfhydryl blocking group is probably a better choice with protein molecules.

5.3. Blocking or Protecting Aldehyde or Ketone Groups

Aldehyde groups are useful in facilitating modification or conjugation reactions, easily forming secondary amine linkages with amine-containing molecules in reductive amination procedures or hydrazone linkages with hydrazide-containing molecules. Macromolecules modified to contain aldehyde groups for use in these reactions (see Section 4.4) should be treated after conjugation to remove any excess formyl functionalities. The blocking step prevents subsequent nonspecific interactions when a conjugate is used in assay or targeting applications.

Reductive Amination with Tris or Ethanolamine

One of the simplest methods for blocking aldehyde functionalities involves reductive amination with a small amine-containing molecule. The best such blockers do not have extra functionalities that may create additional sites of reactivity after blocking. Tris and ethanolamine are ideal in this regard. They both contain primary amines that readily react with aldehydes in the presence of a reductant, and they both possess relatively inert hydroxyl groups that maintain hydrophilicity after coupling. Reductive amination (Chapter 2, Section 5.3, and Chapter 4, Section 4) facilitated by the use of sodium cyanoborohydride can quickly block residual aldehyde groups and transform them into unreactive hydroxyls of low nonspecific binding potential (Figure 2.123).

Protocol

1. Dissolve the macromolecule containing aldehydes to be blocked (e.g., a glycoprotein that has been oxidized with sodium periodate to create formyl groups) at a concentration of 1–10 mg/ml in 0.1-*M* Tris buffer, pH 8.0. Alternatively, dissolve the macromolecule in 0.1-*M* sodium phosphate containing 0.1-*M* ethanolamine, pH 8.0. The use of other buffers having a pH between 7 and 10 will work as well, but the Tris or ethanolamine concentrations should be maintained in high excess to efficiently block all the aldehyde residues.
2. Add 10 µl of 5-*M* sodium cyanoborohydride in 1-*N* NaOH (Aldrich) per milliliter of the macromolecule solution volume prepared in (1). *Caution: Highly toxic compound. Use a fume hood and be careful to avoid skin contact with this reagent.*
3. React for 15 min at room temperature.
4. Purify the derivatized macromolecule by dialysis or gel filtration using a buffer suitable for the nature of the substance being modified.

Oxime Formation with Hydroxylamine

Another convenient option for blocking aldehyde groups is the use of a small aminooxy compound to react spontaneously with aldehydes (or ketones) to form oxime bonds (aldoxime or ketoxime bonds with aldehydes or ketones, respectively). Hydroxylamine is the simplest aminooxy molecule, and the addition of this compound to an aldehyde-containing molecule will block the carbonyl groups and form oximes (Figure 2.124). An oxime bond is a stable linkage under normal conditions, but it may be cleaved under certain circumstances (e.g., in the presence of sodium dithionite) (Pojer, 1979) or by heating in the presence of an inorganic acid (which is typically too harsh for use with many biomolecules). The formation of the oxime reaction product may be accelerated in aqueous solution by the addition of aniline to the reaction, which acts as a catalyst by forming an intermediate imine that goes on to react with the aminooxy compound (hydroxylamine) to make the oxime (Cordes and Jencks, 1962; Dirksen *et al.*, 2006a,b; Dirksen and Dawson, 2008; Byeon *et al.*, 2010).

Hydroxylamine has also been used for the cleavage of certain peptide bonds in proteins, particularly asparagine–glycine bonds (Smith, 2002). For efficient cleavage, the typical reaction conditions require alkaline

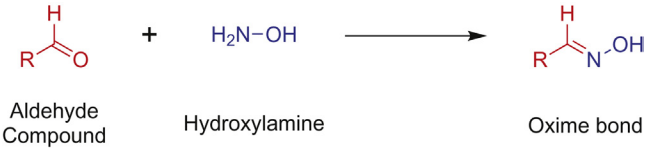

FIGURE 2.124 Reaction of hydroxylamine with an aldehyde to form an oxime.

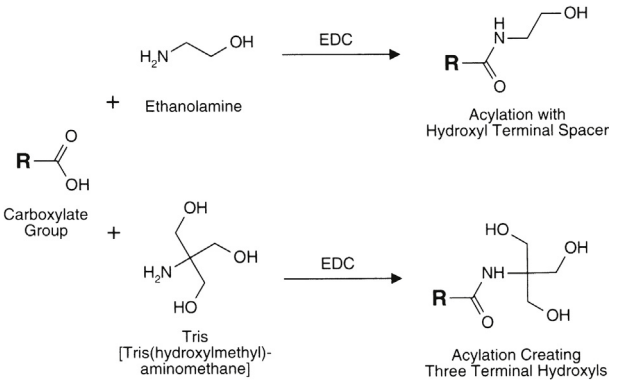

FIGURE 2.125 Carboxylate groups may be blocked with Tris or ethanolamine using a carbodiimide-mediated process.

pH (9.0) along with heating to at least 40°C for 4 h. The use of hydroxylamine as a blocking agent at acid pH and under ambient temperature conditions should not adversely affect protein stability. Hydroxylamine should not be used, however, with heme-containing proteins, as the molecule will irreversibly coordinate with the central metal ion and cause inactivation. It should also be completely removed from serine proteases, as it has been shown to accelerate enzyme activity by acting as a nucleophilic agent within the active site (Nakai *et al.*, 2012).

Protocol

1. Dissolve an aldehyde-containing protein to be blocked at a concentration of 1–10 mg/ml in 1 ml of 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 5.5 (reaction buffer).
2. In a fume hood, prepare a stock solution consisting of 1-*M* hydroxylamine in reaction buffer by adding 0.33 g (0.27 ml) of hydroxylamine to about 7 ml of reaction buffer. Adjust the pH of the solution back down to 5.5 with acid and add sufficient additional reaction buffer to bring the final volume up to 10 ml.

   Note: If using hydroxylamine hydrochloride, add 694 mg to about 8 ml of reaction buffer and adjust the pH back to 5.5 with base if necessary, then add buffer to make a final volume of 10 ml.
3. In a fume hood, add 18 µl of aniline catalyst to the protein solution with stirring. This results in approximately a 0.1-*M* aniline solution in the modification reaction.
4. Add 27 µl of the 1-*M* hydroxylamine stock solution to the protein solution while stirring (results in approximately a 0.1-*M* solution).
5. React for 2–4 h at room temperature with constant mixing by end-over-end rotation in a sealed container.
6. Remove excess reactants by dialysis or size exclusion chromatography using a buffer of choice.

5.4. Blocking or Protecting Carboxylate Groups

The presence of unwanted carboxylate groups in macromolecules may easily be blocked by the use of a small amine-containing molecule coupled *via* the carbodiimide procedure (Chapter 3, Section 1.1).

Tris or Ethanolamine Plus EDC

Tris or ethanolamine are excellent choices for blocking procedures involving carboxylic acid groups, since they contain hydrophilic hydroxyls that mask the carboxylate and create an inert modification with low nonspecific binding potential. Using the water soluble carbodiimide EDC to facilitate this reaction, the carboxylate is activated by forming an intermediate *O*-acylisourea. The amine-containing compound then reacts with this active species to create a stable amide linkage (Figure 2.125).

Protocol

1. Dissolve the macromolecule containing carboxylate groups to be blocked at a concentration of 1–10 mg/ml in 0.1-*M* MES, pH 4.7, containing 0.1-*M* Tris or ethanolamine. Other conditions may be used to perform this reaction. See Chapter 4, Section 1, for further details.
2. Add 10 mg of EDC per ml of the solution prepared in (1).
3. React for 2–4 h at room temperature.
4. Purify by gel filtration or dialysis.

CHAPTER

3

The Reactions of Bioconjugation

Every chemical modification or conjugation process involves the reaction of one functional group with another, resulting in the formation of a covalent bond. The creation of bioconjugate reagents with spontaneously reactive or selectively reactive functional groups forms the basis for simple and reproducible crosslinking or tagging of target molecules. Of the hundreds of reagent systems described in the literature or offered commercially, most utilize common organic chemical principles that can be reduced down to a few dozen or so primary reactions. An understanding of these basic reactions can provide insight into the properties and use of bioconjugate reagents even before they are applied to problems in the laboratory.

This section is designed to provide a general overview of activation and coupling chemistry. Some of the reagents discussed in this chapter are not themselves crosslinking or modification compounds, but may be used to form active intermediates with another functional group. These active intermediates can subsequently be coupled to a second molecule that possesses the correct chemical constituents, which allows bond formation to occur.

Ultimately, this section is meant to function as a ready-reference database for learning or review of bioconjugate chemistry. In this regard, a reaction can quickly be found, a short discussion of its properties and use understood, and a visual representation of the chemistry of bond formation illustrated. What this section is not meant to be is an exhaustive discussion on the theory or mechanism behind each reaction, nor a review of every application in which each chemical reaction has been used. For particular applications where the reactions are employed, cross-references are given to other sections in this book or to outside literature sources.

Table 3.1 is a compendium of the major reactions used in bioconjugation along with the appropriate reaction partners, functional groups, activation agents or catalysts, the bonds formed as a result of the reactions, and in some cases the reactive group intermediate or new functional group which is formed. Each reaction is indicated by reading across a row of the table. For instance, in row one, an amine can react with an isothiocyanate group to give an isothiourea bond. In another example further down the table, an aminooxy group can react with aldehydes or ketones to give an oxime bond. The index may be used to look up the reactions or terms used in this table and find the associated chapters within the book where the topic is discussed in more detail.

1. AMINE REACTIONS

Reactive groups able to couple with amine-containing molecules are by far the most common functional groups present on crosslinking or modification reagents. An amine-coupling process can be used to conjugate with nearly all protein or peptide molecules as well as a host of other macromolecules. The primary coupling reactions for modification of amines proceed by one of two routes: acylation or alkylation (Chapter 2, Section 1.1). Most of these reactions are rapid and occur in high yield to give stable amide or secondary amine bonds.

1.1. Isothiocyanates

Isothiocyanates can be formed by the reaction of an aromatic amine with thiophosgene (Rifai and Wong, 1986). The group reacts with nucleophiles such as amines, sulfhydryls, and the phenolate ion of tyrosine side chains (Podhradsky *et al.*, 1979). The only stable product of these reactions, however, is with primary amine groups. Therefore, isothiocyanate compounds are almost entirely selective for modifying ε-amino groups in lysine side chains and N-terminal α-amines in proteins or primary amines in other molecules (Jobbagy and Kiraly, 1966). The reaction involves attack of the nucleophile on the central, electrophilic carbon of the isothiocyanate group (Reaction 3.1). The resulting electron shift and proton loss create a thiourea linkage

TABLE 3.1 The Major Reactions of Bioconjugation

Functional Group	Reactive Group	Secondary Reactive Group	Activation Agent or Catalyst	Bond Formed	Reactive or Functional Group Formed
Amine	Isothiocyanate			Isothiourea	
Amine	Isocyanate			Isourea	
Amine	Acyl azide			Amide	
Amine	NHS ester			Amide	
Amine	Sulfonyl chloride			Sulfonamide	
Amine					
Amine	Tosyl ester			Secondary amine	
Amine	Tresyl ester			Sulfonamide	
Amine	Aldehyde			Schiff base	
Amine	Aldehyde		Sodium cyanoborohydride	Secondary amine	
Amine	Aldehyde	Active hydrogen compound	Aniline (Mannich reaction catalyst for targeting tyrosine)	Secondary amino-methyl-	
Amine	Amine		Formaldehyde	Secondary amino-methyl-amino-	Quaternary ammonium salt
Amine	Epoxide			Secondary amine	
Amine	Carbonate			Carbamate	
Amine	Aryl halide			Aryl amine	
Amine	Haloacetyl or alkyl halide			Secondary amine	
Amine	Imido ester			Amidine	
Amine	Carboxylate		Carbodiimide	Amide	Carbodiimide active ester
Amine	Alkyl phosphate (e.g., 5′-phosphate of oligonucleotide)		Carbodiimide plus imidazole	Phosphoramidate	
Amine	Anhydride			Amide	
Amine	Fluorophenyl ester			Amide	
Amine	HOBt ester			Amide	
Amine	Hydroxymethyl phosphine			Secondary amine	
Amine	*O*-methylisourea			Guanidine	
Amine	DSC				NHS carbamate
Amine	NHS carbamate			Isourea	
Amine	Glutaraldehyde			Schiff base or secondary amine	Aldehyde, hemiacetal, or double bond
Amine	Activated double bond			Secondary amine	
Amine	Cyclic hemiacetal			Secondary amine	
Amine	NHS carbonate			Carbamate	
Amine	Imidazole carbamate			Carbamate	
Amine	Acyl imidazole			Amide	
Amine	Methylpyridinium ether			Secondary amine	
Amine	Azlactone			Amide	
Amine	Cyanate ester			Isourea	
Amine	Cyclic imidocarbonate			Substituted imidocarbonate	
Amine	Chlorotriazine			Secondary amine	
Amine	Dehydroazepine			Secondary amine	
Amine	6-sulfo-cytosine derivative			4-Amino derivative of cytosine	
Aryl amine			Sodium nitrite, HCl		Diazonium group
Thiol	Haloacetyl or alkyl halide			Thioether	
Thiol	Maleimide			Thioether	
Thiol	Aziridine			Thioether	
Thiol	Aryl halide			Aryl thioether	
Thiol	Pyridyl disulfide			Disulfide	
Thiol	2,2′-dipyridyl disulfide or 4,4′-dipyridyl disulfide				Pyridyl disulfide
Thiol	TNB-thiol			Disulfide	
Thiol	Ellman's reagent				TNB-thiol
Thiol	Peroxide (other oxidants)			Disulfide, sulfonate

TABLE 3.1 (Continued)

Functional Group	Reactive Group	Secondary Reactive Group	Activation Agent or Catalyst	Bond Formed	Reactive or Functional Group Formed
Thiol	Vinylsulfone			Thioether	
Thiol	Metal surface			Dative bond	
Thiol	Phenylthioester (on C-terminal peptides for native chemical ligation)			Thioester (followed by S→N shift to amide on N-terminal of peptide)	
Thiol	Cisplatin			Thioether (thio-platinum bond)	
Thiol	Activated double bond			Thioether	
Carboxylate	Diazoalkanes or diazoacetyl compounds			Ester	
Carboxylate			CDI		Acyl imidazole
Carboxylate			Carbodiimide		Carbodiimide active ester
Carboxylate			Carbodiimide plus NHS or sulfo-NHS		NHS ester or sulfo-NHS ester
Carboxylate			DSC		NHS ester
Carboxylate			TSTU		NHS ester
Hydroxyl	Epoxide			Ether	
Hydroxyl			CDI		Imidazole carbonate
Hydroxyl			DSC		NHS carbonate
Hydroxyl	Haloacetyl or alkyl halide			Ether	
Hydroxyl	Isocyanate			Carbamate	
Aldehyde	Amine			Schiff base	
Aldehyde	Amine		Sodium cyanoborohydride	Secondary amine	
Aldehyde	Amine	Active hydrogen compound (e.g., phenol compound or tyrosine)	Aniline (Mannich reaction catalyst to target tyrosines)	Secondary amine	
Aldehyde	Hydrazide (hydrazine)		Aniline	Hydrazone	
Aldehyde	Aminooxy compound		Aniline	Oxime	
Active hydrogen compound	Diazonium			Diazo bond	
Active hydrogen compound	Amine		Aldehyde ± aniline	Secondary amine (Mannich reaction)	
Active hydrogen compound	I_2		Oxidizing agent	Iodinated compound (R-I)	
Active hydrogen compound	Halogenated phenyl azide		UV light	Nonspecific insertion at active hydrogen site	
Active hydrogen compound	Phenyl azide	Amine	UV light	Secondary amine or low yield nonspecific insertion at active hydrogen site	
Active hydrogen compound	Benzophenone		UV light	Nonspecific insertion at active hydrogen site	
Active hydrogen compound	Anthraquinone		UV light	Nonspecific insertion at active hydrogen site	
Active hydrogen compound	Diazo derivatives		UV light	Nonspecific insertion at active hydrogen site	
Active hydrogen compound	Diazirine derivatives		UV light	Nonspecific insertion at active hydrogen site	
Thymine base	Psoralen derivative		UV light	Cycloaddition at 5,6-double bond of thymine

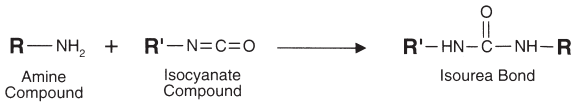
TABLE 3.1 (Continued)

Functional Group	Reactive Group	Secondary Reactive Group	Activation Agent or Catalyst	Bond Formed	Reactive or Functional Group Formed
Diene	Alkene			Cycloalkene (4 + 2 cycloaddition)	
Hydrazine (or hydrazide)	Aldehyde			Hydrazone	
	Aminooxy	Aldehyde or ketone		Oxime	
	Azide	Alkyne	Cu^{1+}	Triazole (3 + 2 cycloaddition)	
	Azide	Alkene	Cu^{1+}	Triazoline (3 + 2 cycloaddition)	
	Azide	Triphenyl phosphine with electrophilic trap (Staudinger ligation)		Aryl amide	
	Azide	Aryl ester triphenyl phosphine derivative (traceless Staudinger ligation)		Amide bond	
	Phenyl boronic acid	Salicylhydroxamate		Boronate-containing 6- or 5-member ring	
Alkyl phosphate (e.g., 5′-phosphate of oligonucleotide)			Carbodiimide plus imidazole		Phosphoryl imidazolide
Cytosine base			Sodium bisulfite		6-Sulfo-cytosine
Guanine base			*N*-Bromosuccinimide		8-Bromo-guanine
Guanine base	Diazo benzoyl derivative			8-(*p*-diazobenzoyl)-guanine derivative	
Diol			Periodate		Cleavage to form two aldehydes
Disulfide			DTT, 2-mercaptoethanol, TCEP,		Cleavage to form two sulfhydryls (thiols)
Diazo bond			Sodium dithionite		Cleavage to form two aryl amines
Ester bond			Hydroxylamine, OH^-		Cleavage to form a carboxylate and a hydroxyl
Sulfone bond			OH^-		Cleavage to form a sulfonate and a hydroxyl
Acyl hydrazone bond			Hydrazide		Cleavage to form a hydrazone and a hydrazide
o-Nitrophenyl group			UV light		Cleavage to form a methyl ketone and an amine

between the isothiocyanate-containing compound and the amine with no leaving group involved.



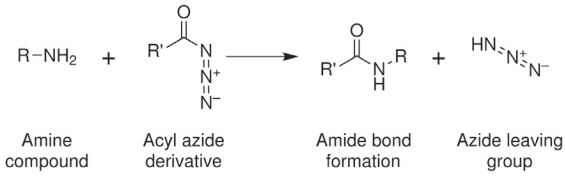
(REACTION 3.1)

Isothiocyanate compounds react best at alkaline pH values where the target amine groups are mainly unprotonated. Many reactions are carried out in 0.1-*M* sodium carbonate buffer at pH 9.0. Reaction times vary from 4 to 24 h at 4°C. Rana and Meares (1990) found that by reacting isothiocyanate-containing chelates at pH 7 they could selectively modify a monoclonal antibody only at its N-terminal α-amines while

leaving lysine amines unmodified. This is an excellent method for selectively modifying only a single site on a protein or peptide molecule. Since the isothiocyanate group is relatively unstable in aqueous conditions, reagents containing this function should be stored desiccated at refrigerator or freezer temperatures.

1.2. Isocyanates

Isocyanates are similar to the isothiocyanates discussed above, except an oxygen atom replaces the sulfur. An isocyanate can be formed from the reaction of an aromatic amine with phosgene (Rifai and Wong, 1986). The group can also be created from acyl azides by treatment at 80°C in the presence of an alcohol (Section 2.6.1.5). Under these conditions, the acyl azide rearranges to form an isocyanate. Isocyanates can react with amine-containing molecules to form stable isourea linkages (Reaction 3.2). The reactivity of isocyanates is greater than that of isothiocyanates, but for the same reason their stability can be a problem. Many commercial suppliers of bioconjugate reagents have found isocyanate compounds too unstable to offer them for sale, since moisture rapidly decomposes them, releasing CO_2 and leaving an aromatic amine.

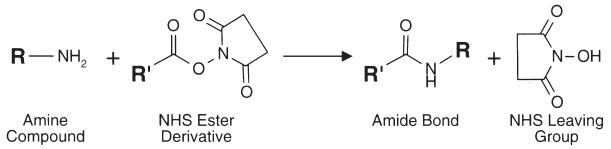


(REACTION 3.2)

Isocyanate-containing reagents can also be used to crosslink or label hydroxyl-containing molecules. Recently, a heterobifunctional compound containing an isocyanate group on one end and a maleimide group on the other end was reported (Annunziato *et al*., 1993). PMPI, or *p*-maleimidophenyl isocyanate, can be used to conjugate hydroxyl-containing compounds such as polysaccharides with sulfhydryl-containing molecules (available from Thermo Fisher).

1.3. Acyl Azides

Acyl azides are activated carboxylate groups that can react with primary amines to form amide bonds. The azide function is a good leaving group similar to the *N*-hydroxysuccinimide group of NHS ester compounds. An acyl azide can be formed by treatment of a hydrazide with sodium nitrite at 0°C (Lowe and Dean, 1974). A coupling reaction with an amine group occurs by attack of the nucleophile at the electron-deficient carbonyl group (Reaction 3.3). Optimum conditions for the reaction are a pH range of 8.5 to 10 in buffers which contain no competing amines or other nucleophiles.



(REACTION 3.3)

The major competing reaction in acyl azide coupling is hydrolysis. The higher the pH of the reaction medium, the faster becomes the reactivity, which is true with regard to both amine reactivity and hydrolysis. Cross-linkers or modification reagents containing this compound must be kept dry to preserve activity. Reactions are complete in 2 to 4 h at room temperature.

1.4. NHS Esters

An *N*-hydroxysuccinimide (NHS) ester is perhaps the most common activation chemistry for creating reactive acylating agents. NHS esters were first introduced as reactive ends of homobifunctional crosslinkers (Bragg and Hou, 1975; Lomant and Fairbanks, 1976). Today, the great majority of amine-reactive crosslinking or modification reagents commercially available utilize NHS esters. An NHS ester may be formed by the reaction of a carboxylate with NHS in the presence of a carbodiimide. To prepare stable NHS ester derivatives, the activation reaction must be performed in nonaqueous conditions using water-insoluble carbodiimides or condensing agents, such as DCC, or, better, an uronium-based activation agent (Chapter 4, Section 1.4, and Chapter 15, Section 2.1).

NHS or sulfo-NHS ester-containing reagents react with nucleophiles with release of the NHS or sulfo-NHS leaving group to form an acylated product (Reaction 3.4). The reaction of such esters with a sulfhydryl or hydroxyl group may not yield stable conjugates, forming thioesters or ester linkages, respectively. Both of these bonds can potentially hydrolyze in aqueous environments or exchange with neighboring amines to form amide bonds. Histidine side-chain nitrogens of the imidazolyl ring may also be acylated with an NHS ester reagent, but they hydrolyze very rapidly in aqueous environments (Cuatrecasas and Parikh, 1972). Thus, the presence of imidazole in reaction buffers only serves to increase the hydrolysis rate of the active ester. Reaction with primary and secondary amines, however, creates stable amide and imide linkages, respectively, that do not readily break down. Thus, in protein molecules, NHS ester crosslinking reagents couple principally with the α-amines at the N-terminals and the ε-amines of lysine side chains.

(REACTION 3.4)

Recent studies with NHS ester crosslinking agents using mass spec analysis have determined that the specificity of their reaction with proteins is dependent on the side-chain amino acid functionalities that may be present (Kalkhof and Sinz, 2008). In addition to the expected reactivity with N-terminal α-amines and lysine side-chain ε-amines, NHS esters can react and couple with tyrosine, serine, and threonine –OH groups. This is especially true if there is a neighboring histidine residue present in the polypeptide sequence (Mädler *et al.*, 2009). The histidine will rapidly react with the NHS ester, but since the intermediate acyl imidazole is highly unstable and also reactive toward nucleophiles, it ends up reacting with the nearby –OH group to form an ester linkage. This reaction does not take place as readily in aqueous solution without a histidine group present, because of competition with water, which is in much higher concentration and can promote hydrolysis of the NHS ester rather than ester formation with serine, threonine, or tyrosine.

NHS esters may also be formed *in situ* to react immediately with target molecules in aqueous reaction media. Using the water soluble carbodiimide EDC (Chapter 4, Section 1.1) a carboxylate-containing molecule can be transformed into an active ester by reaction in the presence of NHS or sulfo-NHS (*N*-hydroxysulfosuccinimide) (Chapter 4, Section 1.2). Sulfo-NHS esters are hydrophilic active groups that couple rapidly with amines on target molecules with the same specificity and reactivity as NHS esters (Staros, 1982). Unlike NHS esters that are relatively water insoluble and must be first dissolved in organic solvent before being added to aqueous solutions, sulfo-NHS esters are relatively water soluble and longer lived and hydrolyze more slowly in water. In the presence of amine nucleophiles that can attack at the electron-deficient carbonyl of the active ester, the sulfo-NHS group rapidly leaves, creating a stable amide linkage with the amine compound. Sulfhydryl and hydroxyl groups will also react with such active esters, but the products of such reactions, thioesters and esters, are unstable in aqueous environments or in the presence of amine nucleophiles.

NHS esters have a half-life on the order of hours under physiological pH conditions. However, hydrolysis and amine reactivity both increase with increasing pH. At 0°C at pH 7.0, the half-life is typically 4 to 5 h (Lomant and Fairbanks, 1976). At pH 8.0 at 25°C it falls to 1 h (Staros, 1988), and at pH 8.6 and 4°C the half-life is only 10 min (Cuatrecasas and Parikh, 1972). The rate of hydrolysis may be monitored by measuring the increase in absorptivity at 260 nm as the NHS leaving group is cleaved. The molar extinction coefficient of the NHS group in solution is $8.2 \times 10^3 M^{-1} cm^{-1}$ in Tris buffer at pH 9.0 (Carlsson *et al.*, 1978), but somewhat decreases to $7.5 \times 10^3 M^{-1} cm^{-1}$ in potassium phosphate buffer at pH 6.5 (Partis *et al.*, 1983). Unfortunately, the relatively low sensitivity of this absorptivity measurement does not allow for determining the rate of reaction in an actual crosslinking procedure.

To maximize the modification of amines and minimize the effects of hydrolysis, maintain a high concentration of protein or other target molecule in the reaction medium. By adjusting the molar ratio of crosslinker to target molecule(s), the level of modification and conjugation may be controlled to create an optimal product. Water insoluble crosslinkers containing NHS esters may be reacted in organic solvents, eliminating the hydrolysis problem, provided the target molecule is soluble and stable in such environments. For nonaqueous reactions, an organic base (proton acceptor) is typically added, such as triethylamine or 4-(dimethylamine)pyridine (DMAP).

1.5. Sulfonyl Chlorides

Sulfonyl chlorides are reactive sulfonic acid derivatives similar in properties and reactivity to acid chlorides of carboxylates. The sulfonic acid group, however, is a highly hindered molecule, containing a tetrahedral configuration of substituents. The attack of a nucleophile on a sulfonyl chloride involves temporary formation of a pentavalent intermediate which is highly crowded and unstable. Unlike the capability of using other condensing agents such as carbodiimides when preparing amide linkages between carboxylate groups and amines, sulfonic acids are too hindered to allow such bulky active intermediates to be formed. Thus, the main activation chemistry employed with sulfonates is to create the sulfonyl chloride derivative. Reaction of a sulfonyl chloride compound with a primary amine-containing molecule proceeds with loss of the chlorine atom and formation of a sulfonamide linkage (Reaction 3.5).

(REACTION 3.5)

Sulfonic acids (sulfonates) are frequent constituents of fluorescent probes to aid in water solubility of the core dyes (Chapter 10, Section 1). The sulfonyl chloride derivative allows simple conjugation of these molecules with proteins and other amine-containing compounds. The derivative is prepared by reaction of the sulfonate with

thionyl chloride or phosphorus pentachloride in nonaqueous conditions. The reaction of a sulfonyl chloride with an amine proceeds under alkaline pH conditions (typically carried out at pH 9–10). It may also be performed in organic solvent for the modification of water-insoluble compounds. Hydrolysis is the major competing reaction in aqueous environments, although the overall rate of sulfonyl chloride reactivity and hydrolysis is less than that of the corresponding acid chlorides of carboxylates. However, sulfonyl chloride-containing reagents should be stored under nitrogen or in a desiccator to prevent breakdown by moisture.

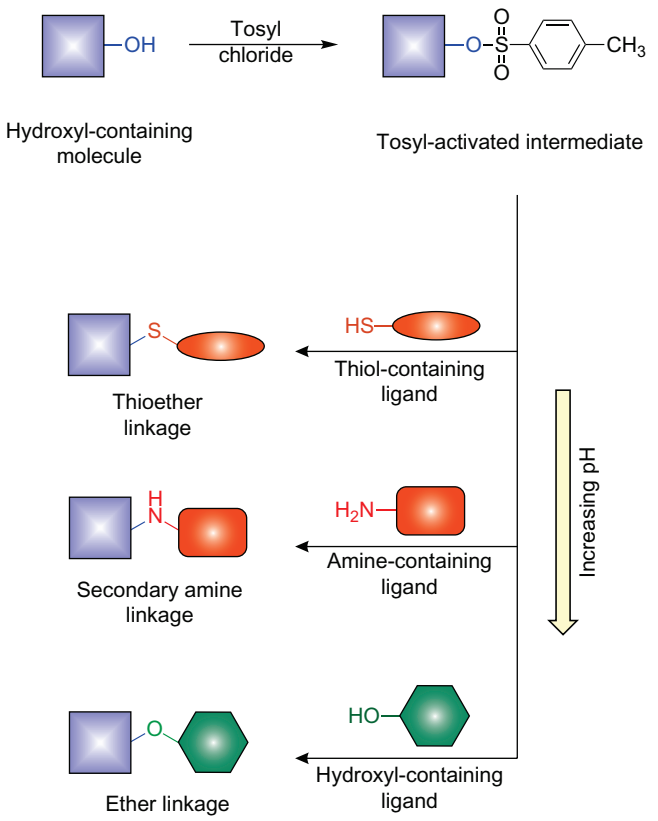
1.6. Tosylate Esters

Reactive groups consisting of tosylate esters can be formed from the reaction of 4-toluenesulfonyl chloride (also called tosyl chloride or TsCl) with a hydroxyl group to yield the sulfonyl ester derivative (Whitaker *et al.*, 2006). The sulfonyl ester is an electrophilic reactive group that can couple with nucleophiles to produce a covalent bond. This can result in a secondary amine linkage with primary amines, a thioether linkage with sulfhydryl groups, or an ether bond with hydroxyls. Tosylate esters are commonly used in organic synthesis and in the immobilization of affinity ligands onto insoluble support materials or surfaces (see Chapter 15, Section 2.1). An interesting aspect of this reaction is the replacement of the original hydroxyl that is activated with TsCl with the reacting nucleophile, which is being coupled.

Nucleophilic attack on the reactive sulfonate ester actually occurs at the carbon atom adjacent to the ester (Cremlyn, 1996; James and Cremlyn, 2002). This causes cleavage of the sulfonyl ester and release of the leaving group, which is the tosyl sulfonate (Figure 3.1). The reaction occurs under basic conditions using aqueous buffers in the pH range of 8.5 to 10. The reactivity of nucleophiles typically is –SH –> $–NH_2$ > –OH, and the optimal pH for the reaction increases for these functional groups in the same order. The reactions may also be carried out in nonaqueous conditions using an organic base to catalyze the reaction process. Suitable bases include pyridine, triethylamine (TEA), diisopropylethylamine (DIEA), or dimethylaminopyridine (DMAP).

1.7. Aldehydes and Glyoxals

Carbonyl groups such as aldehydes, ketones, and glyoxals can react with amines to form Schiff base intermediates which are in equilibrium with their free forms. The interaction is pH dependent, being more efficient at low pH and especially efficient at high pH conditions. Certain compounds, particularly some reducing sugars, may undergo an Amadori rearrangement after Schiff base formation to a stable ketoamine structure



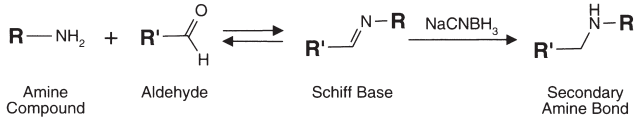


FIGURE 3.1 Tosyl chloride can be used to activate a hydroxyl group in nonaqueous conditions to create a reactive tosyl ester. The sulfonyl ester can react with thiols, amines, and hydroxyls to form thioether, secondary amine, and ether linkages, respectively. In general, an increase in pH from neutral to highly alkaline is needed to efficiently couple with thiols, amines, and hydroxyls.

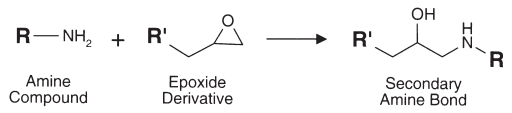
(Chapter 2, Section 2.1). This occurs *in vivo* as glucose modifies amine-containing components in the blood to form glycated derivatives. Such modification is thought to be related to aging and is a signal for protein and cellular regeneration.

The rather labile Schiff base interaction can be chemically stabilized by reduction. The addition of sodium borohydride or sodium cyanoborohydride to a reaction medium containing an aldehyde compound and an amine-containing molecule will result in reduction of the Schiff base intermediate and covalent bond formation, creating a secondary amine linkage between the two molecules (Reaction 3.6).



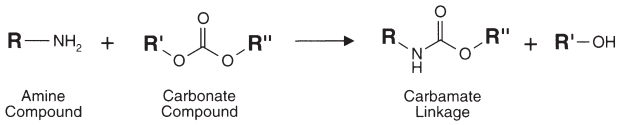
(REACTION 3.6)

Although both borohydride and cyanoborohydride have been used for reductive amination purposes, borohydride will reduce the reactive aldehyde groups to

hydroxyls at the same time it converts any Schiff bases present to secondary amines. Cyanoborohydride, by contrast, is a milder reducing agent. It has been shown to be at least five times milder than borohydride in reductive amination processes with antibodies (Peng *et al.*, 1987). While cyanoborohydride does not reduce aldehydes, it is very effective at Schiff base reduction. Thus, higher yields of conjugate formation can be realized using cyanoborohydride instead of borohydride. Other reducing agents have also been explored for reductive amination processes, including various amine boranes and ascorbic acid (Cabacungan *et al.*, 1982; Hornsey *et al.*, 1986). See Chapter 4, Section 4, for a protocol for reductive amination coupling.

1.8. Epoxides and Oxiranes

An epoxide or oxirane group will react with nucleophiles in a ring-opening process. The reaction can take place with primary amines, sulfhydryls, or hydroxyl groups to create secondary amine, thioether, or ether bonds, respectively. During the coupling process, ring opening forms a β-hydroxy group on the epoxy compound (Reaction 3.7). The reaction of the epoxide functionalities with hydroxyls requires high pH conditions, usually in the range of pH 11 to 12. Amine nucleophiles react at more moderate alkaline pH values, typically needing buffer environments of at least pH 9.0. Sulfhydryl groups are the most highly reactive nucleophiles with epoxides, requiring a buffered system closer to the physiological pH range of 7.5 to 8.5 for efficient coupling.



(REACTION 3.7)

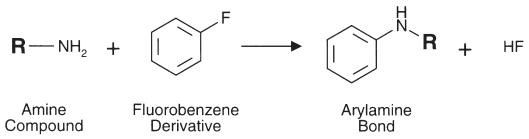
The principal side reaction to epoxide coupling is hydrolysis. Particularly at acid pH values, the epoxide ring can hydrolyze to form adjacent hydroxyls. This diol can be oxidized with periodate to create a terminal aldehyde residue with loss of one molecule of formaldehyde (Chapter 2, Section 4.4). The aldehyde then can be used in reductive amination reactions. The reaction of an epoxide group with an ammonium ion generates a terminal primary amine group that can also be used for further derivatization.

1.9. Carbonates

Carbonates are diester derivatives of carbonic acid formed from its condensation with hydroxyl compounds. These groups may be created from the reaction of a bifunctional carbonic acid compound like phosgene or carbonyl diimidazole (Chapter 4, Section 3) with two alcohols. Carbonates can rapidly react with nucleophiles to form carbamate linkages, which are extremely stable bonds (Reaction 3.8). A commonly used bifunctional carbonate compound, disuccinimidyl carbonate, can be used to activate hydroxyl-containing molecules to form amine-reactive succinimidyl carbonate intermediates (Section 4.3, this chapter). This carbonate activation procedure can be used with great success in coupling polyethylene glycol (PEG) to proteins and other amine-containing molecules (Chapter 18, Section 2.1).

(REACTION 3.8)

Nucleophiles, such as the primary amino groups of proteins, can react with the succinimidyl carbonate functional groups to give stable carbamate (aliphatic urethane) bonds. The linkage is identical to that obtained through CDI activation of hydroxyl groups with subsequent coupling of amines (Chapter 4, Section 3, and Chapter 15, Section 2.1). However, the reactivity of the succinimidyl carbonate is much greater than that of the imidazole carbamate formed as the active species in CDI activation. A succinimidyl carbonate group may hydrolyze in aqueous solution to release NHS and CO_2, essentially regenerating the underivatized hydroxyl. Carbonates formed from esterification of two alcohol groups similarly hydrolyze to release CO_2 plus the original hydroxyl compounds.

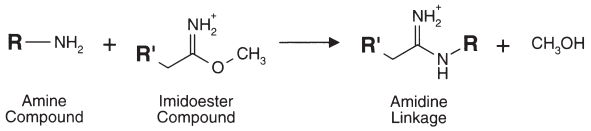


The coupling reaction of a carbonate functional group with an amine is best carried out in slightly alkaline pH (7–9) and in the absence of any competing amine or sulfhydryl components.

1.10. Arylating Agents

Aryl halide compounds such as fluorobenzene derivatives can be used to form covalent bonds with amine-containing molecules like proteins. The reactivity of aryl halides, however, is not totally specific for amines. Other nucleophiles such as thiol, imidazolyl, and phenolate groups of amino acid side chains can also react (Zahn and Meinhoffer, 1958). Conjugates formed with sulfhydryl groups are reversible by cleaving with an excess of thiol (Shaltiel, 1967).

Fluorobenzene-type compounds have been used as functional groups in homobifunctional crosslinking agents (Chapter 5, Section 4). Their reaction with amines involves nucleophilic displacement of the fluorine atom with the amine derivative, creating a substituted aryl amine bond (Reaction 3.9). Detection

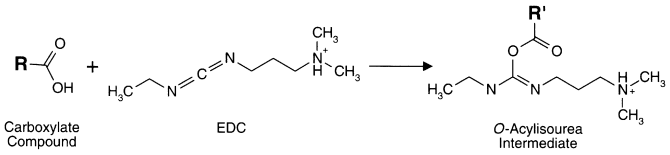


reagents incorporating reactive aryl chemistry include 2,4-dinitrofluorobenzene and trinitrobenzenesulfonate (Eisen *et al.*, 1953). These compounds form colored complexes with target amine groups. The relative rate of reactivity for aryl compounds is F > Cl~Br > sulfonate.

(REACTION 3.9)

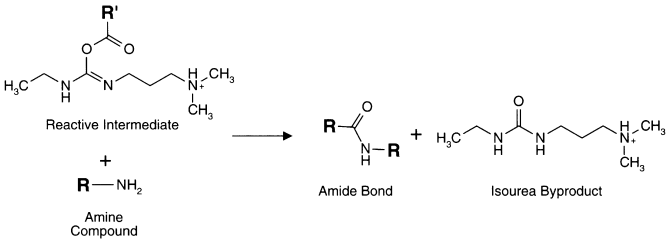
1.11. Imidoesters

The imidoester (or imidate) functional group is one of the most specific acylating agents available for modifying primary amines. Unlike most other coupling chemistries, imidoesters possess minimal cross-reactivity toward other nucleophilic groups in proteins. The α-amines and ε-amines of proteins may be targeted and crosslinked by reacting with homobifunctional imidoesters at a pH of 7 to 10 (optimal pH 8–9). The product of this reaction, an imidoamide (or amidine) (Reaction 3.10), is protonated and thus carries a positive charge at physiological pH (Liu *et al.*, 1977; Kiehm and Ji, 1977; Ji, 1979; Wilbur, 1992).



(REACTION 3.10)

The amidine bond formed is quite stable at acid pH; however, it is susceptible to hydrolysis and cleavage at high pH. A typical reaction condition for using imidate crosslinkers is a buffer system consisting of 0.2-*M* triethanolamine in 0.1-*M* sodium borate, pH 8.2. After conjugating two proteins with a bifunctional imidoester crosslinker, excess imidoester functional groups may be blocked with ethanolamine.

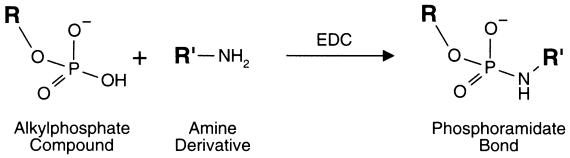


1.12. Carbodiimides

Carbodiimides are zero-length crosslinking agents used to mediate the formation of an amide or phosphoramidate linkage between a carboxylate group and an amine or a phosphate and an amine, respectively (Hoare and Koshland, 1966; Chu *et al.*, 1986; Ghosh *et al.*, 1990). They are called zero-length reagents because in forming these bonds no additional chemical structure is introduced between the conjugating molecules.

N-substituted carbodiimides can react with carboxylic acids to form highly reactive, *O*-acylisourea derivatives that are extremely short-lived (Reaction 3.11). This active species can then react with a nucleophile such as a primary amine to form an amide bond (Reaction 3.12) (Williams and Ibrahim, 1981). Other nucleophiles are also reactive. Sulfhydryl groups may attack the active species and form thioester linkages, although these are not as stable as the bond formed with an amine.

(REACTION 3.11)

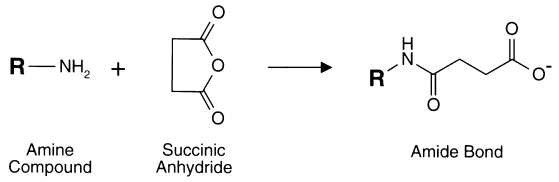


(REACTION 3.12)

Hydrazide-containing compounds can also be coupled to carboxylate groups using a carbodiimide-mediated reaction. Using bifunctional hydrazide reagents, carboxylates can be modified to possess terminal hydrazide groups able to conjugate with other carbonyl compounds (Chapter 5, Section 8).

In addition, oxygen atoms may act as the attacking nucleophile, such as those in water molecules. In aqueous solution, hydrolysis by water is the major competing reaction, both inactivating EDC itself and cleaving off the activated ester intermediate, forming an isourea, and regenerating the carboxylate group (Gilles *et al.*, 1990).

Nakajima and Ikada (1995) investigated the reactions of EDC amide bond formation in aqueous solution using a hydrogel of poly(acrylic acid) to contribute the carboxylate groups and ethylenediamine or benzylamine as the amine functional groups. Their results indicate that carboxylate activation occurs most effectively at pH 3.5 to 4.5, while amide bond formation occurs with highest yield at pH 4 to 6. However, the maximal rate of hydrolysis of EDC occurs at acidic pH values with increasing stability of the carbodiimide in solution at or above pH 6.5. When working with proteins and peptides, experience indicates that EDC-mediated amide bond formation effectively occurs between pH 4.5 and 7.5. Buffer systems using MES or phosphate may be used to stabilize the pH during the course of the reaction. For additional information on specific carbodiimides used in bioconjugate chemistry, see Chapter 4, Section 1.



Molecules containing phosphate groups, such as the 5′ phosphate of oligonucleotides, may also be conjugated to amine-containing molecules by using a carbodiimide-mediated reaction (Chapter 23, Section 2.1). The carbodiimide activates the phosphate to an intermediate phosphate ester similar to its reaction with carboxylates (Chapter 4, Section 1). In the presence of an amine, the ester reacts to form a stable phosphoramidate bond (Reaction 3.13).

(REACTION 3.13)

1.13. Anhydrides

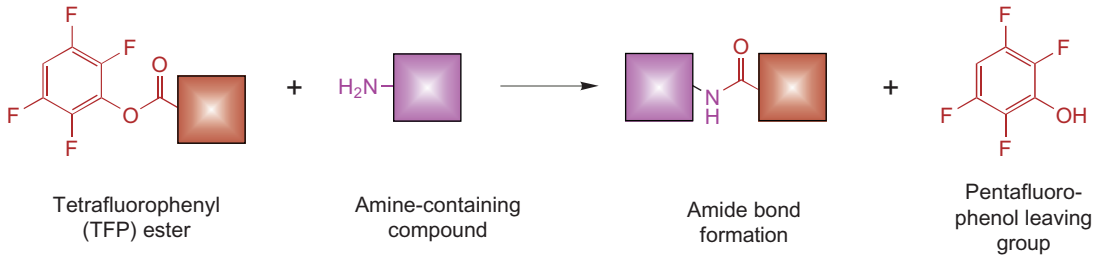
Acid anhydrides, as their name implies, are formed from the dehydration reaction of two carboxylic acid groups. Anhydrides are highly reactive toward nucleophiles and are able to acylate a number of the important functional groups of proteins and other macromolecules. Upon nucleophilic attack, the anhydride yields one carboxylic acid for every acylated product. If the anhydride was formed from monocarboxylic acids, such as acetic anhydride, then the acylation occurs with release of one carboxylate group. However, for dicarboxylic acid anhydrides, such as succinic anhydride, upon reaction with a nucleophile the ring structure of the anhydride opens, forming the acylated product modified to contain a newly formed carboxylate group (Reaction 3.14). Thus, anhydride reagents may be used to both block functional groups and to convert an existing functional group into a carboxylic acid.

(REACTION 3.14)

Protein functional groups able to react with anhydrides include the α-amines at the N-terminals, the ε-amine of lysine side chains, cysteine sulfhydryl groups, the phenolate ion of tyrosine residues, and the imidazolyl ring of histidines. However, acylation of cysteine, tyrosine, and histidine side chains forms unstable complexes that are easily reversible to regenerate the original group. Only amine functional groups of proteins are stable to acylation with anhydride reagents, forming amide bonds (Fraenkel-Conrat, 1959; Smyth, 1967).

Another potential site of reactivity for anhydrides in protein molecules is modification of any attached carbohydrate chains. In addition to amino group modification in the polypeptide chain, glycoproteins may be modified at their polysaccharide hydroxyl groups to form esterified derivatives. Esterification of carbohydrates by acetic anhydride, especially cellulose, is a major industrial application for this compound. In aqueous solutions, however, esterification will be a minor product, since the oxygen of water is about as strong a nucleophile as the hydroxyls of sugar residues.

The major side reaction to the desired acylation product is hydrolysis of the anhydride. In aqueous solutions, anhydrides may break down by the addition of one molecule of water to yield two unreactive carboxylate groups. The presence of an excess of the anhydride in the reaction medium usually is used to minimize the effects of competing hydrolysis.



Since both hydrolysis and acylation result in the release of carboxylic acid functionalities, the medium becomes acidic during the course of the reaction. This requires either the presence of a strongly buffered environment to maintain the pH or periodic monitoring and adjustment of the pH with base as the reaction progresses.

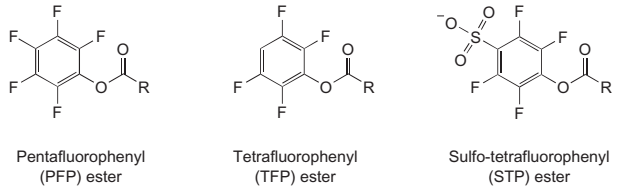
1.14. Fluorophenyl Esters

Another type of carboxylic acid derivative that reacts with amines consists of the ester of a fluorophenol compound, which creates a group capable of forming amide bonds with proteins and other molecules. Several types of fluorophenyl esters have been used as reactive groups: a pentafluorophenyl (PFP) ester, a tetrafluorophenyl (TFP) ester, and a sulfo-tetrafluorophenyl (STP) ester. All of these derivatives have similar reactivity with amines, but the uncharged ones are hydrophobic and the sulfonated one is negatively charged in aqueous solution, thus providing water solubility to active ester compounds (Gee *et al*., 1999) (Figure 3.2).

Fluorophenyl esters react with amine-containing molecules at slightly alkaline pH values to give the same amide bond linkages as NHS esters (Reaction 3.15). However, in most cases, the fluorophenyl ester compound will display better stability toward hydrolysis in aqueous solution. It has been reported that a TFP ester has over twice the half-life in basic pH buffers (pH ~8) than a corresponding NHS ester on the same compound (Molecular Probes).

Fluorophenyl ester compounds can be coupled to amines at a pH range of 7 to 9, with 0.1-*M* sodium bicarbonate, pH 8, a suggested reaction medium.

(REACTION 3.15)



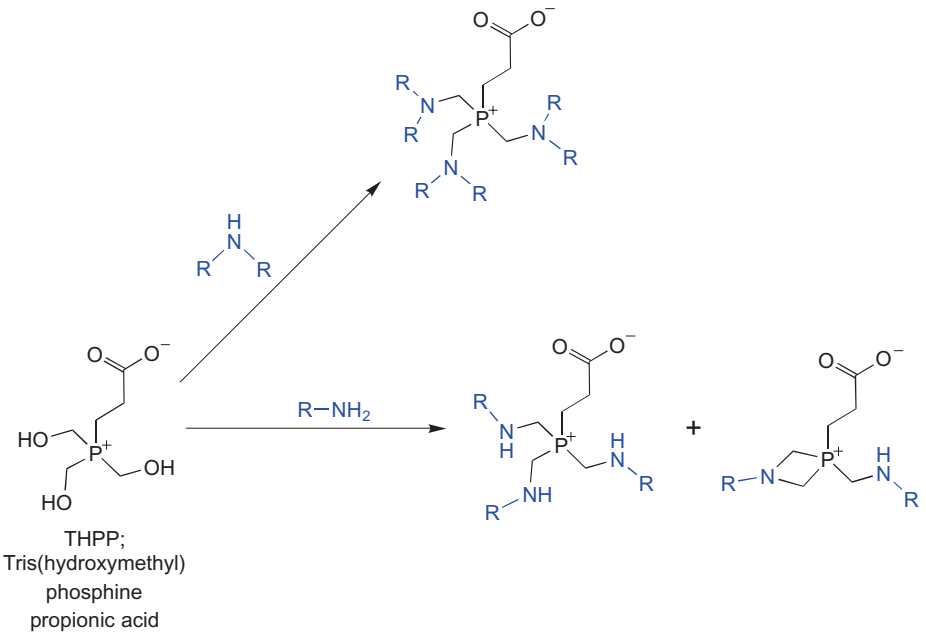


FIGURE 3.2 Three types of fluorophenyl esters have been used for coupling to amine-containing molecules. The pentafluorophenyl and tetrafluorophenyl esters are relatively hydrophobic and typically have better stability toward hydrolysis in aqueous solution than NHS esters. The sulfo-tetrafluorophenyl ester is water soluble due to the negatively charged sulfonate group, and it provides better solubility to associated crosslinkers or bioconjugation reagents similar to that of a sulfo-NHS ester group.

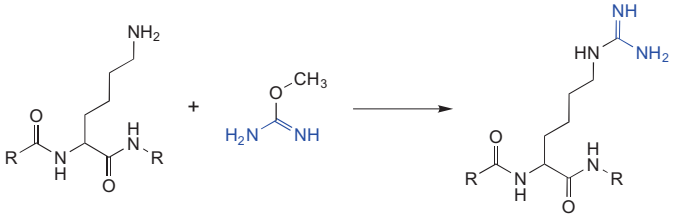
1.15. Hydroxymethyl Phosphine Derivatives

Phosphine compounds are often thought of only in terms of having reductant properties, especially in biological applications. However, there are classes of phosphine derivatives with hydroxymethyl group substitutions that can also act as bioconjugation agents for coupling or crosslinking purposes. Tris(hydroxymethyl) phosphine (THP) and β-[tris(hydroxymethyl)phosphino] propionic acid (THPP; Thermo Fisher) are small trifunctional compounds that spontaneously react with nucleophiles, such as amines, to form covalent linkages (Henderson *et al.*, 1994; Katti, 1996; Katti *et al.*, 1999). Nucleophiles react with the hydroxymethyl arms of THP and THPP by attack on the electron-deficient carbon atom next to the oxygen with loss of water to form secondary or tertiary amine bonds (Reaction 3.16).

Both THP and THPP are stable in aqueous solution, as the only potential product of hydrolysis is the reformation of the hydroxymethyl groups. It is unusual for an amine-reactive functional group to have long-term stability in water or buffer, which makes these reagents uniquely suitable for creating reactive surfaces or reactive molecules for subsequent conjugation with proteins or other amine-containing compounds. Hydroxylic chromatographic supports have also been activated with hydroxymethyl phosphine derivatives for immobilization of enzymes (Petach *et al.*, 1994).

Hydroxymethyl phosphines are susceptible to oxidation to form the phosphine oxide derivative. Therefore,



(REACTION 3.16)

avoid excess oxygen, oxidizing agents, or azide compounds, which react with phosphines in the Staudinger reaction (Chapter 17, Section 6). In addition, metallic surfaces can be modified via the phosphine group to result in hydroxymethyl group substitutions.

1.16. Guanidination of Amines

The addition of a guanidino group to amine-containing molecules can be performed using the compound *O*-methylisourea (as the hemisulfate salt). Guanidination has been used to increase the ionization potential of lysine-containing peptides for greater sensitivity in mass spec analysis (Brancia *et al.*, 2000). The process has also been used to add stable isotope labels (^{15}N) to tryptic peptides (Cristea *et al.*, 2004). Upon trypsin digestion, protein samples are cleaved at arginine and lysine residues to yield peptide fragments containing these amino acids at their C-terminal. The guanidine group of arginine is known to aid in the ionization of peptides for MS analysis. The reaction of *O*-methylisourea hemisulfate with lysine ε-amino groups produces homoarginine (Reaction 3.17), which ionizes far better than lysine and aids in the detection of these peptides (Warwood *et al.*, 2006). The addition of a guanidine group to a lysine residue adds 42.02 Daltons to the resultant modified peptide, which needs to be taken into account for mass spec purposes.

(REACTION 3.17)

Protocols for guanidination reactions typically use basic conditions to deprotonate all the lysine ε-amino groups, which is necessary to achieve efficient yields. The amount of N-terminal α-amine labeling is minimal, but may occur to some extent, especially for peptides containing an N-terminal glycine residue (Beardsley and Reilly, 2002). The initial protocols for guanidination usually use reaction times of several hours, but optimization has resulted in decreasing this to 5 to 10 min at elevated temperature. The following protocol is based on the method of Beardsley and Reilly (2002).

Protocol

1. Dissolve 50 mg of *O*-methylisourea hemisulfate in 51 µl of water.
2. Prepare 5 µl of a peptide solution to undergo guanidination at a concentration of 1 pmol/µl and add 5.5 µl of 7-*N* ammonium hydroxide.
3. Add 1.5 µl of the *O*-methylisourea hemisulfate solution to the peptide solution with mixing.
4. React for 5–10 min at 65°C in an oven.
5. Stop the reaction with the addition of 15 µl of 10% TFA (v/v).

2. THIOL REACTIONS

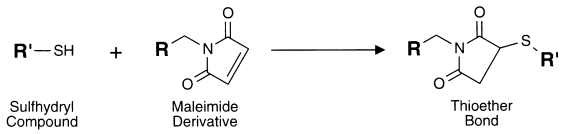
Reactive groups able to couple with sulfhydryl-containing molecules are perhaps the second most common functional groups present on crosslinking or modification reagents. Especially in the design of heterobifunctional crosslinkers, sulfhydryl-reactive groups are frequently present on one of the two ends. The other end of such crosslinkers is often an amine-reactive group that is coupled to a target molecule before the sulfhydryl-reactive end, due to the labile nature of amine acylation chemistries. The primary coupling reactions for modification of sulfhydryls proceed by one of two routes: alkylation or disulfide interchange. Many of the reactive groups that undergo these reactions are stable enough in aqueous environments to allow a two-step conjugation strategy to be used (Chapter 6, Section 1). Once initiated, most of these reactions are rapid and occur in high yield to give stable thioether or disulfide bonds.

2.1. Haloacetyl and Alkyl Halide Derivatives

Three forms of activated halogen derivatives can be used to create sulfhydryl-reactive compounds: haloacetyl, benzyl halides that react through a resonance activation process with the neighboring benzene ring, and alkyl halides that possess the halogen β to a nitrogen or sulfur atom, as in N- and S-mustards. In each of these compounds, the halogen group is easily displaced by an attacking nucleophilic substance to form an alkylated derivative with loss of HX (where X is the halogen and the hydrogen comes from the nucleophile). Haloacetyl compounds and benzyl halides typically are iodine or bromine derivatives, whereas the halo-mustards mainly employ chlorine and bromine forms (see Chapter 5, Section 10, for examples of homobifunctional reagents that employ reactive halogen groups). Iodoacetyl groups have also been used successfully to couple affinity ligands to chromatography supports (Chapter 15, Section 2.2).

Although the primary utility of active halogen compounds is to modify sulfhydryl groups in proteins or other molecules, the reaction is not totally specific. Iodoacetyl (and bromoacetyl) derivatives can react with a number of functional groups within proteins: the sulfhydryl group of cysteine, both imidazolyl side chain nitrogens of histidine, the thioether of methionine,

and the primary ε-amine group of lysine residues and N-terminal α-amines (Gurd, 1967). The relative rate of reaction with each of these residues is generally dependent on the degree of ionization and thus the pH at which the modification is performed. The exception to this rule is methioninyl thioethers which react rapidly at nearly all pH values above 1.7 (Vithayathil and Richards, 1960). The only reaction resulting in one definitive product is that of the alkylation of cysteine sulfhydryls, giving the carboxymethylcysteinyl derivative (Cole *et al.*, 1958) (Reaction 3.18). Histidine groups may be modified at either nitrogen atom of their imidazolyl side chain, thus producing the possibility of either mono-substituted or di-substituted products (Crestfield *et al.*, 1963). With primary amine groups such as in the side chain of lysine residues, the products of the reaction are the secondary amine, monocarboxymethyllysine, or the tertiary amine derivative, dicarboxymethyllysine. Methionine thioether groups give the most complicated products, some of which rearrange or decompose unpredictably. The only stable carboxy derivative of methionine is where the terminal methyl group is lost to form carboxymethylhomocysteine, the same product as the reaction of iodoacetate with homocysteine. For a complete illustration of these reactions, see Chapter 2, Section 4.2.



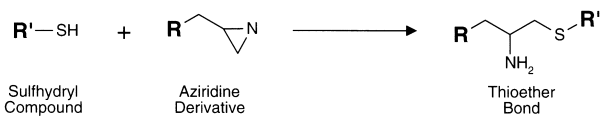
(REACTION 3.18)

The relative reactivity of α-haloacetates toward protein functional groups is sulfhydryl > imidazolyl > thioether > amine. Among halo derivatives the relative reactivity is I > Br > Cl > F, with fluorine being almost unreactive. The α-haloacetamides have the same trend of relative reactivities, but will create a terminal amide group not a terminal carboxylate.

Thus, iodoacetate has the highest reactivity toward sulfhydryl cysteine residues and may be directed specifically for –SH modification. If iodoacetate is present in limiting quantities (relative to the number of sulfhydryl groups present) and at slightly alkaline pH, cysteine modification will be the exclusive reaction. The specificity of this modification has been used in the design of heterobifunctional crosslinking reagents, where one end of the crosslinker contains an iodoacetamide derivative and the other end contains a different functionality directed at another chemical target (see SIAB, Chapter 6, Section 1.5).

2.2. Maleimides

Maleic acid imides (maleimides) are derivatives of the reaction of maleic anhydride and ammonia or an amine derivative. This functional group is a popular constituent of many heterobifunctional crosslinking agents (Chapter 6). The double bond of maleimides may undergo an alkylation reaction with sulfhydryl groups to form stable thioether bonds. Maleimide reactions are specific for thiols in the pH range of 6.5 to 7.5 (Smyth *et al.*, 1964; Gorin *et al.*, 1966; Heitz *et al.*, 1968; Partis *et al.*, 1983). At pH 7.0, the reaction of the maleimide with sulfhydryls proceeds at a rate 1000 times greater than its reaction with amines. At higher pH values, some cross-reactivity with amino groups takes place (Brewer and Riehm, 1967). One of the carbons adjacent to the maleimide double bond undergoes nucleophilic attack by the thiolate anion to generate the addition product (Reaction 3.19). When sufficient quantities of –SH groups are being alkylated, the reaction may be followed spectrophotometrically by the decrease in absorbance at 300 nm as the double bond reacts and disappears.

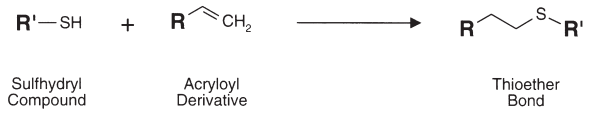


(REACTION 3.19)

The maleimide group may also undergo hydrolysis to an open maleamic acid form that is unreactive toward sulfhydryls (Chapter 19, Section 5). Hydrolysis may also occur after sulfhydryl coupling to the maleimide. This ring opening reaction typically happens faster the higher the pH becomes. Hydrolysis is also dependent on the type of chemical group next to the maleimide function. For instance, the cyclohexane ring of SMCC (Chapter 6, Section 1.3) provides increased stability to maleimide hydrolysis, probably due to its steric effects and its lack of aromatic character. However, the adjacent phenyl ring of MBS allows much greater rates of hydrolysis to occur at the maleimide ring (Chapter 6, Section 1.4).

2.3. Aziridines

An aziridine reactive group is a small ring system composed of one nitrogen and two carbon atoms. The highly hindered nature of this heterocyclic ring gives it strong reactivity toward nucleophiles. Sulfhydryls will react with aziridine-containing reagents in a ring-opening process, forming thioether bonds (Reaction 3.20). The simplest aziridine compound, ethylenimine, can be used to transform available sulfhydryl groups into amines (Chapter 2, Section 4.3).



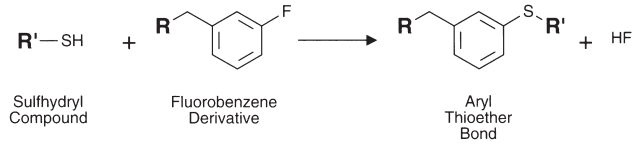
(REACTION 3.20)

The reaction of an aziridine with a thiol is highly specific at slightly alkaline pH values. In aqueous solution, the major side reaction is hydrolysis.

Substituted aziridines have been used to form homobifunctional and trifunctional crosslinking agents, although their use has been limited (Ross, 1953; Alexander, 1954). The functional group has found use, however, in the design of the fluorescent probe dansyl aziridine (5-dimethylaminonaphthalene-2-sulfonyl aziridine) (Johnson *et al.*, 1978; Grossman *et al.*, 1981).

2.4. Acryloyl Derivatives

Reactive double bonds are capable of undergoing additional reactions with sulfhydryl groups. A popular example of this type of functional group is the maleimide group (Section 2.2, this chapter). However, derivatives of acrylic acid or methacrylic acid (more stable) are also able to participate in this reaction, although the rate of sulfhydryl addition is somewhat slower than that of maleimides. The reaction of an acryloyl compound with a sulfhydryl group occurs with the creation of a stable thioether bond (Reaction 3.21).

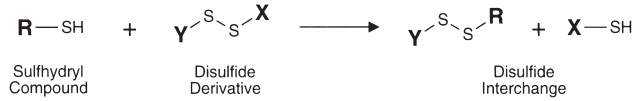


(REACTION 3.21)

Although acryloyl crosslinking agents have not been common, the reactive group has found use in the design of the sulfhydryl-reactive fluorescent probe, 6-acryloyl-2-dimethylaminonaphthalene (acrylodan; Molecular Probes) (Epps *et al.*, 1992; Yem *et al.*, 1992).

2.5. Arylating Agents

Arylating agents are reactive aromatic compounds containing a constituent on the ring that can undergo nucleophilic substitution. The most common arylating agents are derivatives of benzene which possess either halogen or sulfonate groups on the ring. The presence of electron-withdrawing constituents, such as nitro groups, increases the reactivity of the replaceable group. Although aryl halides are commonly used to modify amine-containing molecules to form aryl amine derivatives, they also react quite readily with sulfhydryl groups.



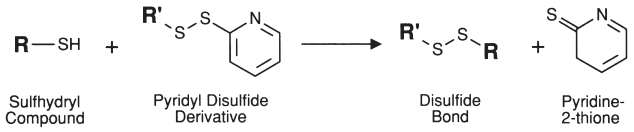
Fluorobenzene-type compounds have been used as functional groups in homobifunctional crosslinking agents (Chapter 5, Section 4). Their reaction with nucleophiles involves bimolecular nucleophilic substitution, causing the replacement of the fluorine atom with the sulfhydryl derivative and creating a substituted aryl bond (Reaction 3.22). Conjugates formed with sulfhydryl groups are reversible by cleaving with an excess of thiol (such as DTT) (Shaltiel, 1967). Detection reagents incorporating reactive aryl chemistry include 2,4-dinitrofluorobenzene and trinitrobenzenesulfonate (Eisen *et al.*, 1953). The relative rate of reactivity for aryl compounds is F > Cl~Br > sulfonate.

(REACTION 3.22)

2.6. Thiol–Disulfide Exchange Reagents

Compounds containing a disulfide group are able to participate in disulfide exchange reactions with another thiol. The disulfide exchange (also called interchange) process involves attack of the thiol at the disulfide, breaking the -S–S- bond, with subsequent formation of a new mixed disulfide comprising a portion of the original disulfide compound (Reaction 3.23). The reduction of disulfide groups to sulfhydryls in proteins using thiol-containing reductants proceeds through the intermediate formation of a mixed disulfide (Chapter 2, Section 4.1). If the thiol is present in excess, the mixed disulfide can go on to form a symmetrical disulfide consisting entirely of the thiol reducing agent—thus completely reducing the original disulfide to free sulfhydryls. If the thiol reductant is not present in large enough excess, the mixed disulfide product is the end result.

(REACTION 3.23)



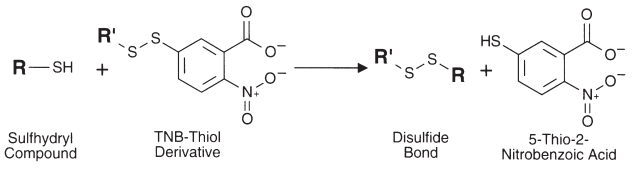
Crosslinking or modification reactions using disulfide exchange processes form disulfide linkages with sulfhydryl-containing molecules. These bonds are reversible using disulfide reducing agents. Thus, conjugates may be created and later released for analysis by incubation with DTT or other disulfide reductants (e.g., TCEP). The disulfide bond within these crosslinks also permits important reactions to occur *in vivo*, such as the release of the toxin component of immunotoxin conjugates, allowing the cytotoxic portion to penetrate target cells and cause cell death (Chapter 20, Section 3).

Disulfide exchange reactions occur over a broad range of conditions—from acid to basic pH—and in a wide variety of buffer constituents. Most crosslinking reactions involving disulfide exchange are carried out under physiological conditions or those most appropriate to maintain stability of the protein or other molecule being modified.

Pyridyl Disulfides

A pyridyl dithiol is perhaps the most popular type of thiol-disulfide exchange functional group used in the construction of crosslinkers or modification reagents. Pyridyl disulfides can be created from available primary amines on molecules through the reaction of 2-iminothiolane in tandem with 4,4′-dipyridyl disulfide (King *et al*., 1978). For instance, the simultaneous reaction among a protein, 2-iminothiolane, and 4,4′-dipyridyl disulfide yields a modification containing reactive pyridyl disulfide groups in a single step (Chapter 2, Section 4.1).

A pyridyl disulfide will readily undergo an interchange reaction with a free sulfhydryl to yield a single mixed disulfide product. This is due to the fact that the pyridyl disulfide contains a leaving group that is easily transformed into a non-reactive compound not capable of participating in further mixed disulfide formation. Thus, the thiol–disulfide exchange reaction can be controlled to occur with only one-half of the original disulfide compound. For instance, a reagent system containing a pyridyl disulfide group, such as SPDP (Chapter 6, Section 1.1), is able to react with sulfhydryl groups by releasing the electron-stabilized compound pyridine-2-thione (Reaction 3.24). Since the leaving group does not possess a free thiol, it cannot undergo disulfide exchange with another molecule of the attacking sulfhydryl compound. Thus, only one end of the reagent has potential for becoming attached to the sulfhydryl-containing molecule.

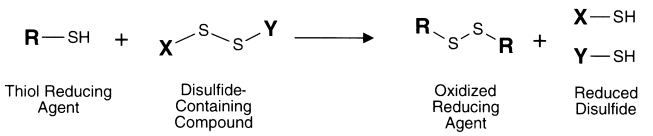


(REACTION 3.24)

Pyridyl-dithiol containing crosslinking and modification reagents are highly efficient in forming disulfide bonds with sulfhydryl-containing molecules. Newer reagents containing a hydrophilic PEG crossbridge in the structure provide increased water solubility and decreased nonspecific binding character (Chapter 18, Section 1.2), which is an advantage in many assay and detection applications for the resultant conjugates. In addition, during the course of a pyridyl disulfide reaction, the pyridine-2-thione leaving group has unique spectral properties that allow the measurement of sulfhydryl coupling by monitoring the increase in absorbance at 343 nm ($\varepsilon = 8.08 \times 10^3 M^{-1} cm^{-1}$). Once a disulfide linkage is formed, it may be cleaved using standard disulfide reducing agents (Chapter 2, Section 4.1). The activation of chromatography supports to contain pyridyl disulfide reactive groups and their subsequent coupling with thiol-containing affinity ligands is described in Chapter 15, Section 2.2.

TNB-Thiol

Sulfhydryl groups activated with the leaving group 5-thio-2-nitrobenzoic acid can be used to couple free thiols by disulfide interchange similar to pyridyl disulfides, as discussed previously. A TNB–thiol-activated species may be created by reaction of a sulfhydryl group with Ellman's reagent, 5,5′-dithio-*bis*(2-nitrobenzoic acid), or DTNB, a compound useful for the quantitative determination of sulfhydryls in solution (Ellman, 1958, 1959) (Chapter 2, Section 4.1). The disulfide of Ellman's reagent readily undergoes disulfide exchange with a free sulfhydryl to form a mixed disulfide with concomitant release of one molecule of the chromogenic substance 5-sulfido-2-nitrobenzoate, also called 5-thio-2-nitrobenzoic acid (TNB). The TNB–thiol group can again undergo interchange with a sulfhydryl-containing target molecule to yield a disulfide crosslink. Upon coupling with a sulfhydryl compound, the TNB group is released (Reaction 3.25). The intense yellow color produced by the TNB anion can be measured by its absorbance at 412 nm ($\varepsilon = 1.36 \times 10^4 M^{-1} cm^{-1}$ at pH 8.0). Since each sulfhydryl which is coupled generates one molecule of TNB per molecule of Ellman's reagent, the possibility for quantifying the reaction exists.



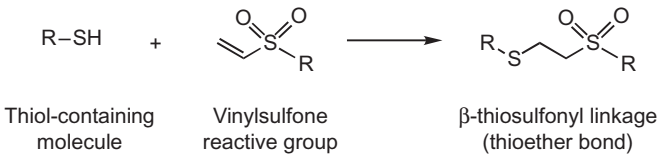
(REACTION 3.25)

Disulfide exchange with a TNB–thiol group occurs efficiently at physiological to slightly alkaline pH conditions. Avoid the presence of disulfide reducing agents, as these will cleave the TNB group and prevent specific coupling.

Disulfide Reductants

Disulfide reduction by the use of disulfide interchange can be performed using thiol-containing compounds such as TCEP, DTT, 2-mercaptoethanol, or 2-mercaptoethylamine (Chapter 2, Section 4.1). The formation of free sulfhydryls from a disulfide group occurs in two stages. First, one molecule of the reducing agent undergoes disulfide exchange, cleaving the disulfide and forming a new, mixed disulfide. In the next stage, a second molecule of the thiol cleaves the mixed disulfide, releasing a free sulfhydryl

and forming a molecule of oxidized reducing agent (Reaction 3.26).

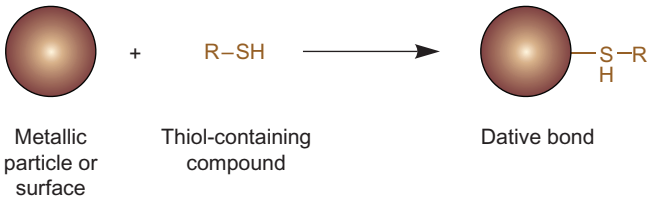


(REACTION 3.26)

Disulfide reduction occurs over a broad pH range and in a variety of buffer environments. The reaction can be performed in denaturants, chaotropic agents, detergents, and in high salt conditions.

2.7. Vinyl Sulfone Derivatives

A vinyl sulfone group can be used to conjugate with nucleophiles, especially thiol groups, in aqueous solution and under mild conditions (Masri and Friedman, 1988). In addition to thiols, they can react with amines and hydroxyls under higher pH conditions. As opposed to a maleimide group, the vinyl sulfone group is not as strong an electrophile, but efficiently couples with thiols at slightly alkaline pH values to give stable β-thiosulfonyl linkages (Reaction 3.27). The product of the reaction of a thiol with a vinyl sulfone gives a single stereoisomer structure, unlike conjugation with maleimides, which produces two potential stereoisomers. In addition, crosslinkers and modification reagents containing a vinyl sulfone can be used to activate surfaces or molecules to contain thiol-reactive groups. These vinyl sulfone groups are stable in aqueous solution for extended periods, as they are not subject to hydrolysis at neutral pH. Thus, they retain excellent coupling potential for thiol-containing proteins or other molecules even when used in aqueous buffer conditions.



(REACTION 3.27)

Vinyl sulfone-activated chromatography supports have long been used for coupling affinity ligands that contain thiols or other nucleophiles (Porath, 1974) (see Chapter 15, Section 2.2). This reactive group has also been used to activate PEG polymers for modification of thiol-containing molecules (Morpurgo *et al.*, 1996). There are now homobifunctional and heterobifunctional crosslinking agents commercially available that use the vinyl sulfone reactive group (Thermo Fisher and Molecular Biosciences).

2.8. Metal–Thiol Dative Bonds

Thiol-containing molecules can interact with metal ions and metal surfaces to form dative bonds. Dative bonds are also known as coordinate covalent bonds. They differ from normal covalent linkages, because they are formed by two electrons coming from a single atom, instead of two atoms each sharing one electron. In a coordinate bond formed with a thiol, the unshared pair of electrons on the sulfur atom is able to form a dative bond with a metal atom. In this sense, even disulfides are able to datively link to a metal surface without prior reduction to thiols (Reaction 3.28).

(REACTION 3.28)

Other atoms containing a lone pair of electrons are also effective at forming coordinate bonds. Oxygen- and nitrogen-containing organic molecules are often used to chelate metal ions, such as in various lanthanide chelates (Chapter 10, Section 9), bifunctional metal chelating compounds (Chapter 12, Section 1), and FeBABE (Chapter 24, Section 4.1). In addition, amino acid side chains and prosthetic groups in proteins frequently form bioinorganic motifs by coordinating a metal ion as part of an active center (Degtyarenko, 2000). Thiol organic compounds, however, are used routinely to coat metallic surfaces or particles to form biocompatible layers or create functional groups for further conjugation of biomolecules.

Thiol ligand modification in particular has been used extensively to create water soluble quantum dots (Sapsford *et al.*, 2006) and gold nanoparticles having reduced nonspecific binding character to the metallic surface and to form surface groups for coupling proteins and other affinity molecules (Chapter 10, Section 10, and Chapter 14, Section 6). For instance, thiol-containing aliphatic/PEG linkers have been used to form self-assembled monolayers (SAMs) on planar gold surfaces and particles (Prime and Whitesides, 1991).

A monodentate thiol–metal bond is not as strong as a true covalent linkage. These bonds are subject to displacement by other molecules containing thiols or other atoms with a lone pair of electrons. The thiol may also oxidize off the surface if exposed to oxygen in air or oxygen dissolved in aqueous solutions. Instead of monodentate compounds, the use of multidentate molecules can dramatically increase the stability of a coordination bond. A bidentate DOPA ligand, for instance, was found to have far greater bonding adhesion to a

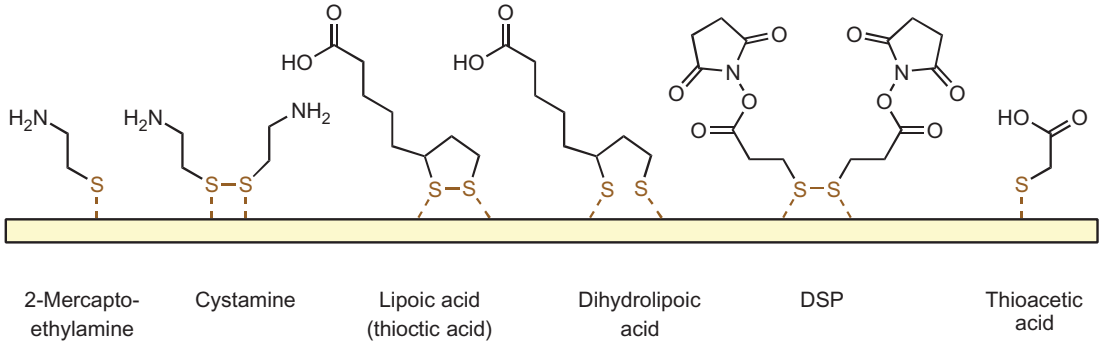


FIGURE 3.3 A number of small thiol-containing molecules have proven useful for modification of gold or metallic surfaces. The dithiol derivatives provide better dative bond stability and cannot be displaced easily by competing thiols or oxidation. Most thiol-containing compounds used for surface modification also contain terminal functional groups or reactive groups for coupling affinity ligands.

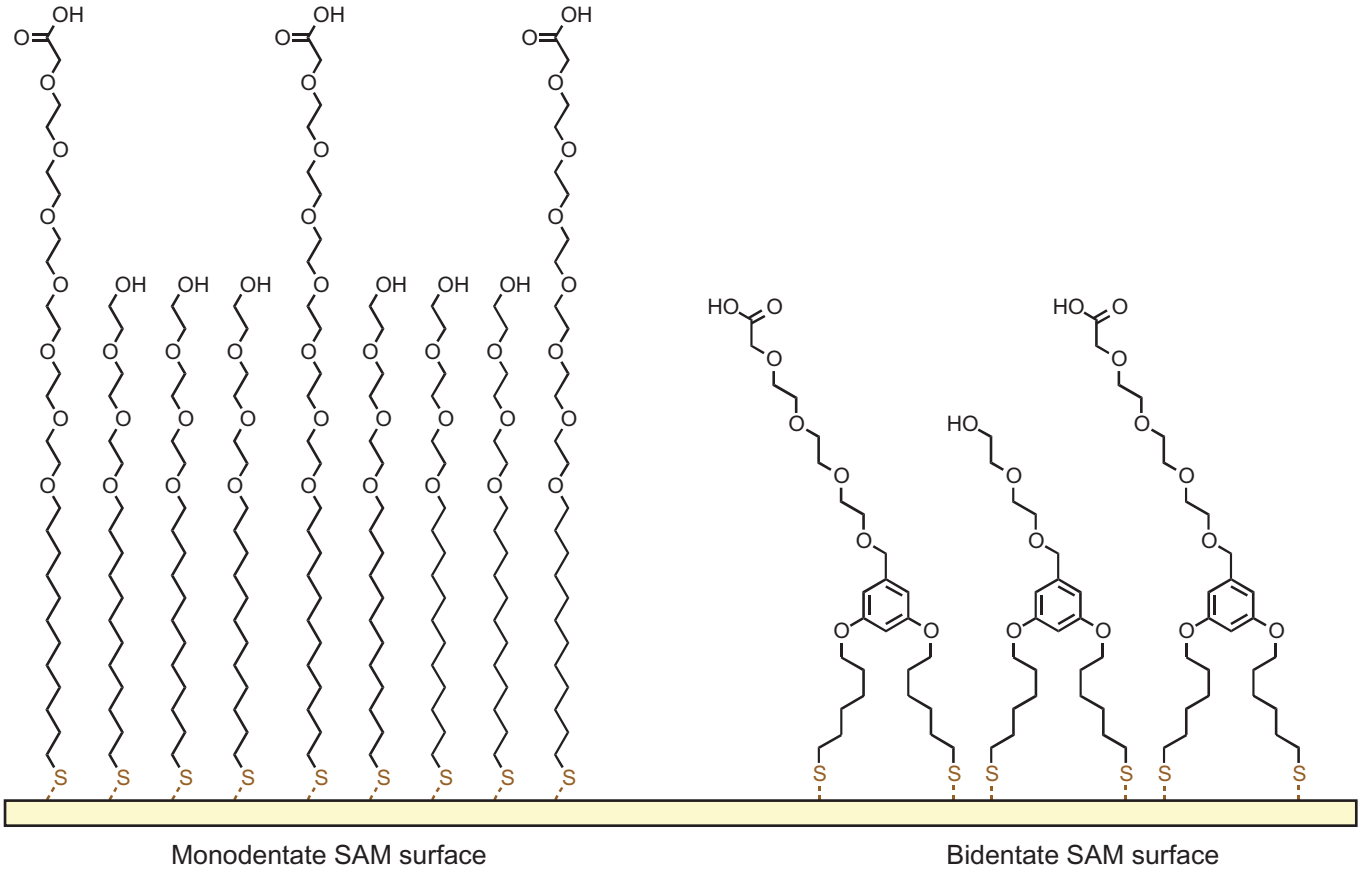

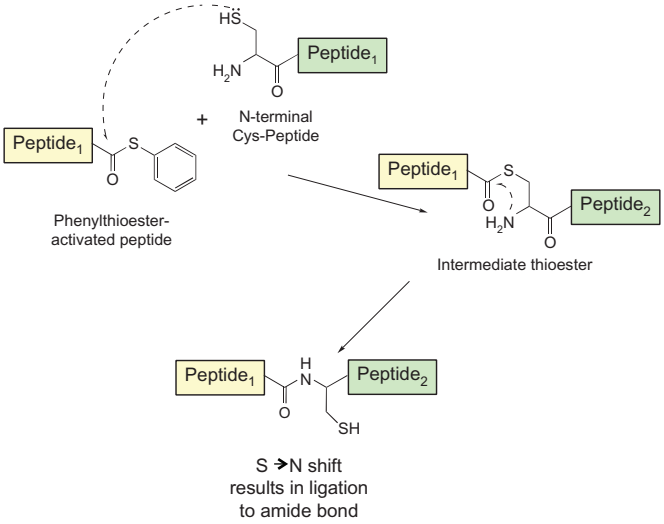

FIGURE 3.4 SAM surface modification has been performed using monothiol and dithiol compounds containing PEG linkers. Useful coatings typically contain mainly PEG–hydroxyl or PEG–monomethyl ether linkers that provide a biocompatible lawn, which prevents nonspecific binding of proteins to the metallic surface. About 10% of the surface modifications are performed using a longer carboxylate-containing thiol-PEG linker that provides sites for attachment of affinity ligands.

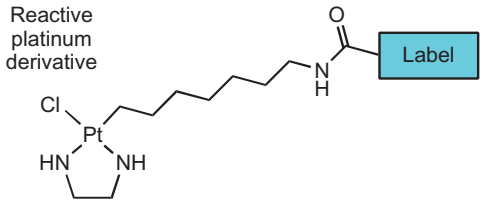
surface than monodentate ligands and nearly as much as a covalent bond (Lee *et al.*, 2006).

To increase the strength of thiol dative linkages, the application of multivalent thiols has been used to increase the overall strength of a single molecule tether bound to a metal. Bidentate thiol ligands that have been designed for metal surface modification include lipoic acid (thioctic acid) derivatives (Cheng and Brajter-Toth, 1992; Willey *et al.*, 2004; Hahn *et al.*, 2007), dithiobis(succinimidyl)propionate (DSP) modifications (Grubor *et al.*, 2004) (Chapter 5, Section 1.1), and a dithiol linker built from a central phenyl ring, which contains a PEG spacer for hydrophilicity on the SAM surface (Spangler *et al.*, 2004) (Figures 3.3 and 3.4).

2.9. Native Chemical Ligation

Native chemical ligation involves reactions that are very similar to intein splicing and peptide ligation found in certain protein expression systems. A peptide having a C-terminal thioester reacts with an N-terminal cysteine residue in another peptide to undergo a trans-thioesterification reaction, which results in the formation of an intermediate thioester with the cysteine thiol. However, due to the proximity of the neighboring α-amine group on cysteine, a subsequent nucleophilic attack of the electron-rich nitrogen on the ester carbonyl results in an S→N shift; this then forms a native amide (peptide) bond (Reaction 3.29).



(REACTION 3.29)

Native chemical ligation is effective at conjugating two peptides together in aqueous solution to form a longer peptide. The reaction proceeds at physiological pH under mild conditions without any additional additives, except for the presence of the thioester-containing peptide and the cysteine-containing peptide. In addition, other thioester compounds may be used in this reaction to label specifically N-terminal cysteine peptides through amide bond formation. For instance, a biotin thioester derivative may be used to add a biotin group to a peptide or a fluorescent label may be added by the same process. Thus, native chemical ligation is an excellent way of discretely labeling peptides only at their N-terminal. See Chapter 17, Section 7, for additional information on the use of this reaction.

2.10. Cisplatin Modification of Methionine and Cysteine

Platinum complexes have long been used as tumor therapeutic agents for their ability to bind to DNA at guanine and adenine residues and interfere with transcription (Repta and Long, 1980; Eastman, 1987; Reedijk *et al.*, 1987). The reaction of Platinum II compounds with nucleic acids has been studied in great detail (Anin *et al.*, 1992), and the reactive group has been applied to bioconjugation labeling reagents (van Belkum *et al.*, 1994; Heetebrij *et al.*, 2003).

Cisplatin modification agent
MW 444.86
(without label)

FIGURE 3.5 The general design of a cisplatin modification agent consists of the reactive cisplatin group and a short linker that typically terminates in a detectable label.

Cisplatin reagents also react with certain amino acid residues in proteins. Rapid coupling occurs with methionine and cysteine residues over a broad pH range (2–9), while slower reaction kinetics results in modification of histidine imidazole ring with an optimal pH at 8.0. The relative rate of reaction of cisplatin derivatives for sulfur nucleophiles is over 100 times more than their reaction with nitrogen nucleophiles (Hay and Porter, 1999). The basic structure of cisplatin labeling reagents is shown in Figure 3.5, and Figure 3.6 illustrates the modification reactions of a cisplatin derivative with amino acid or nucleic acid targets. The reactive group is stable in aqueous conditions and covalent bonds formed with it are stable to typical conditions used in biological assays and detection procedures. Reagent systems are available from Kreatech.

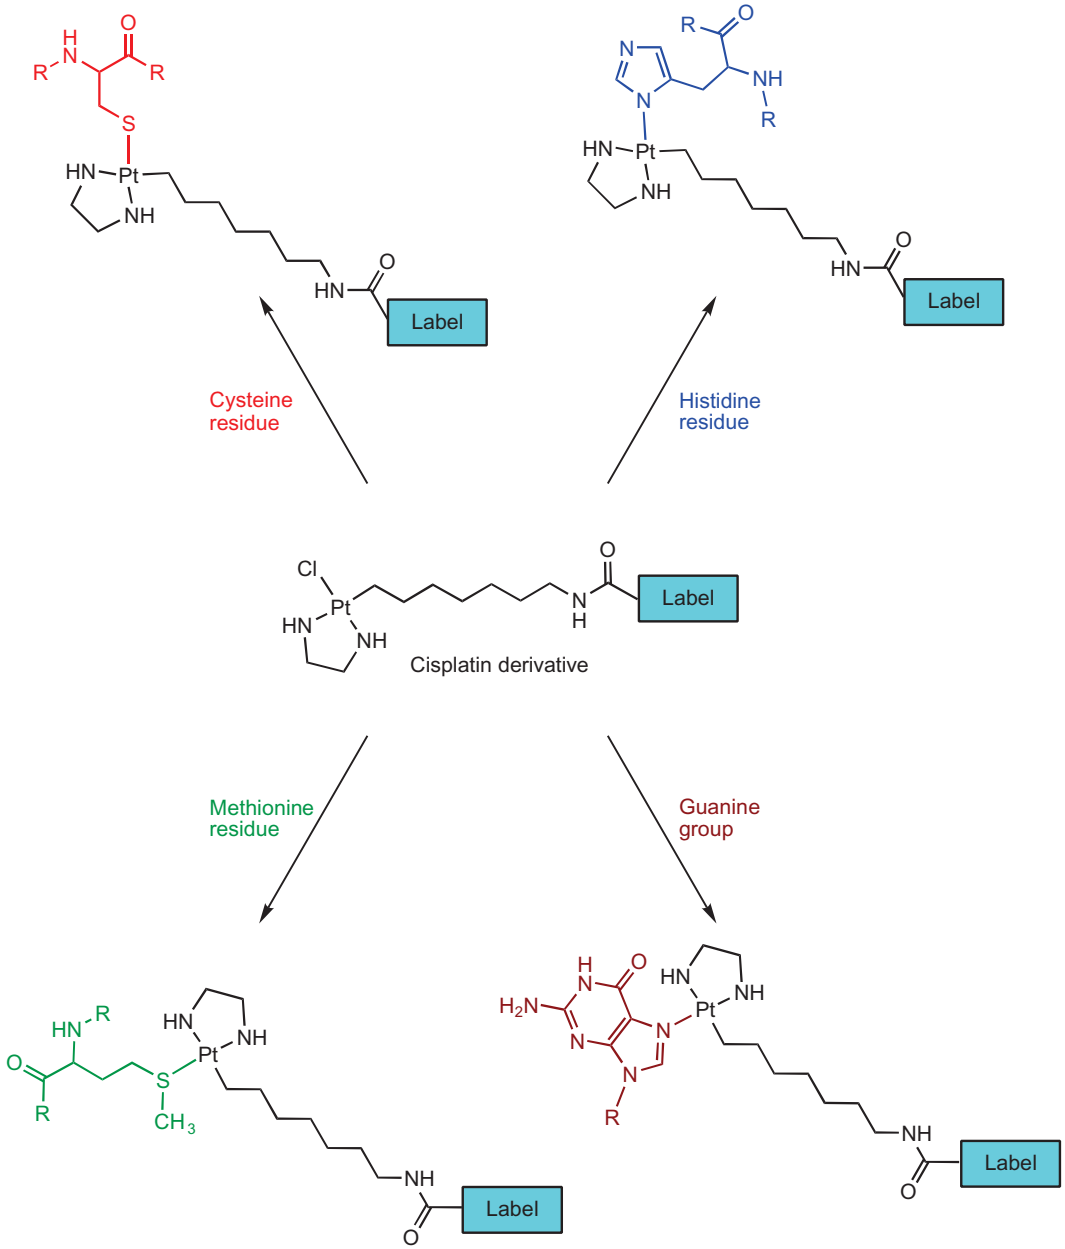
3. CARBOXYLATE REACTIONS

Chemical groups that specifically react with carboxylic acids are limited in variety. In aqueous solutions, the carboxylate functionality displays rather low nucleophilicity. For this reason, it is unreactive with the great majority of bioconjugate reagents which couple through a nucleophilic addition process.

Several important chemistries, however, have been developed that allow conjugation through a carboxylate group. The following sections briefly describe these reactions.

3.1. Diazoalkanes and Diazoacetyl Compounds

Diazomethane and other diazoalkyl derivatives have long been used to label carboxylate groups for analysis (Herriott, 1947; Riehm and Scheraga, 1965). A major



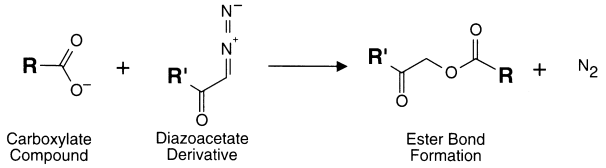


FIGURE 3.6 The cisplatin reactive group can covalently couple to methionine-, cysteine-, and histidine-containing peptides or proteins. It also reacts with guanine groups to form a covalent modification on the N_7 nitrogen.

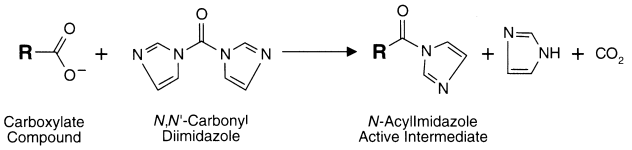
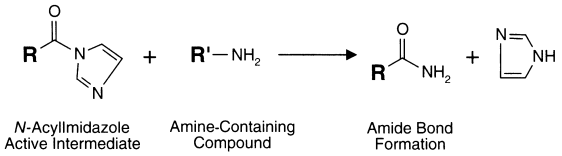
application of such reagents has been in the HPLC analysis of low-molecular-weight compounds such as fatty acids (DeMar *et al.*, 1992). Several coumarin derivatives containing stable, carboxylate-reactive diazoalkane functionalities are also available for fluorescent labeling of target molecules (Molecular Probes) (Ito and Sawanobori, 1982; Ito and Maruyama, 1983).

Diazoalkanes and diazoacetyl compounds (amides and esters) are spontaneously reactive with carboxylate groups without addition of other reactants or catalysts. The reaction mechanism involves attack of a negatively charged carboxylate oxygen atom on a protonated diazoalkyl group, liberating nitrogen gas and forming a covalent linkage (Reaction 3.30).



(REACTION 3.30)

The reaction with carboxylates occurs over a range of pH values, but is optimal at pH 5.0. Unfortunately, the



diazoalkyl compounds will cross-react with sulfhydryl groups at this pH. At higher pH conditions, the reaction is even less specific due to reaction with other nucleophiles. In aqueous solution, the most-likely side reaction is hydrolysis.

3.2. N,N′-Carbonyl Diimidazole

N,*N*′-Carbonyl diimidazole (CDI) is an active carbonylating agent that contains two acylimidazole leaving groups (Chapter 4, Section 3, and Chapter 15, Section 2.1). CDI reacts with carboxylic acids under nonaqueous conditions to form *N*-acylimidazoles of high reactivity (Reaction 3.31). The active intermediate forms in excellent yield due to the driving force created by the liberation of carbon dioxide and imidazole (Anderson, 1958). An active carboxylate can then react with amines to form amide bonds or with hydroxyl groups to form ester linkages (Reaction 3.32). The reaction has been used successfully in peptide synthesis (Paul and Anderson, 1960, 1962). In addition, activation of a styrene/4-vinylbenzoic acid copolymer with CDI was used to immobilize the enzyme lysozyme through its available amino groups to the carboxyl groups on the matrix (Bartling *et al*., 1973).

(REACTION 3.31)

(REACTION 3.32)

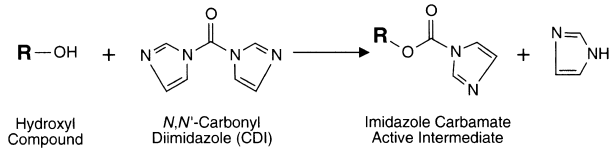
CDI functions as a zero-length crosslinker if the activated species is a carboxylic acid, because the attack of another nucleophile liberates the imidazole leaving group. The conjugation reaction can be performed in organic solvent or aqueous conditions, depending on the solubility of the nucleophile. For aqueous coupling of *N*-acylimidazoles to amine-containing compounds, optimal conditions include an alkaline pH environment from about pH 7 to 9 and in buffers containing no amines (avoid Tris or imidazole).

3.3. Carbodiimides

Carbodiimides function as zero-length crosslinking agents capable of activating a carboxylate group for coupling with an amine-containing compound. There are several major types of carbodiimide reagents commonly available that can be used for organic or aqueous reactions, depending on their individual solubility characteristics (Chapter 4, Section 1). The water soluble reagents are used mainly for biological conjugations involving proteins and other macromolecules. The water-insoluble carbodiimides can be used in peptide synthesis or for the synthesis of other organic compounds.

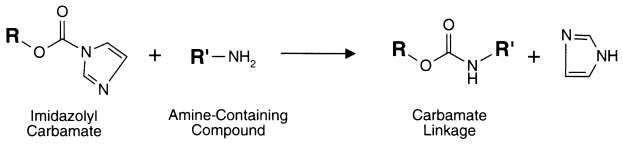
Carbodiimides are used to mediate the formation of amide or phosphoramidate linkages between a carboxylate and an amine or a phosphate and an amine, respectively (Hoare and Koshland, 1966; Chu *et al*., 1986; Ghosh *et al*., 1990). Regardless of the type of carbodiimide, the reaction proceeds by the formation of an intermediate *O*-acylisourea that is highly reactive and short-lived in aqueous environments. The attack of an amine nucleophile on the carbonyl group of this ester results in the loss of an isourea derivative and formation of an amide bond (see Reactions 3.11 and 3.12). The major competing reaction in water is hydrolysis.

4. HYDROXYL REACTIONS



Hydroxyl-reactive chemical compounds include not only those modification agents able to directly form a stable linkage with an –OH group, but also a broad range of reagents that are designed to temporarily activate the group for coupling with a secondary functional group. Many of the chemical methods for modifying hydroxyls originally were developed for use with chromatography supports in the coupling of affinity ligands. Some of these same chemical reactions have found application in bioconjugate techniques for crosslinking a hydroxyl-containing molecule with another substance, usually containing a nucleophile. For instance, carbohydrate-containing molecules such as polysaccharides or glycoproteins can be coupled through their sugar residues using hydroxyl-specific reactions. In addition, polymers and other organic compounds containing hydroxyls (such as PEG) may be conjugated with another molecule using these chemistries.

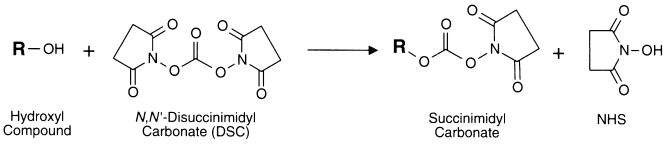
4.1. Epoxides and Oxiranes



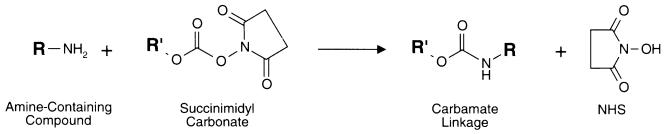
An epoxide or oxirane group can react with nucleophiles in a ring-opening process. The reaction can take place with primary amines, sulfhydryls, or hydroxyl groups to create secondary amine, thioether, or ether bonds, respectively. See Section 1.7 (this chapter) for further information on this reaction.

4.2. N,N′-Carbonyl Diimidazole

N,N′-Carbonyl diimidazole (CDI) is an active carbonylating agent that contains two acylimidazole leaving groups (Chapter 4, Section 3, and Chapter 15, Section 2.1). The compound can react with a carboxylate to form an active acylimidazole group capable of coupling with amine-containing molecules (Section 3.2). However, CDI can also react with hydroxyl groups to create a reactive intermediate. If CDI is used to activate a hydroxyl functional group, the reaction proceeds quite differently from its reaction with carboxylates. The active intermediate formed by the reaction of CDI with an –OH group is an imidazolyl carbamate (Reaction 3.33). Attack by an amine releases the imidazole, but not the carbonyl. Thus, hydroxyl-containing molecules may be coupled to amine-containing molecules with the result of a one-carbon spacer, forming stable urethane (*N*-alkyl carbamate) linkages (Reaction 3.34). This coupling procedure has been applied to the activation of hydroxyl-containing chromatography supports for the immobilization of amine-containing affinity ligands (Bethell *et al.*, 1979, 1979, Hearn *et al.*, 1983) and also to the activation of polyethylene glycol for the modification of amine-containing macromolecules (Beauchamp *et al.*, 1983).



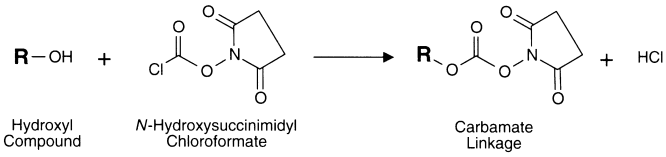
(REACTION 3.33)



(REACTION 3.34)

4.3. N,N′-Disuccinimidyl Carbonate or N-Hydroxysuccinimidyl Chloroformate

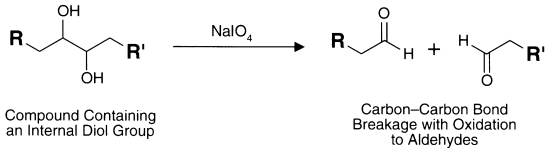
N,N′-Disuccinimidyl carbonate (DSC) consists of a carbonyl group containing, in essence, two NHS esters. The compound is highly reactive toward nucleophiles. In aqueous solutions, DSC will hydrolyze to form two molecules of *N*-hydroxysuccinimide (NHS) with release of one molecule of CO_2. In nonaqueous environments, the reagent can be used to activate a hydroxyl group to a succinimidyl carbonate derivative (Reaction 3.35). DSC-activated hydroxylic compounds can be used to conjugate with amine-containing molecules to form stable crosslinked products (Reaction 3.36). The linkage created from this reaction is a urethane derivative or a carbamate bond, displaying excellent stability.



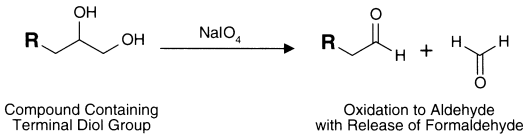
(REACTION 3.35)

(REACTION 3.36)

A related reagent, *N*-hydroxysuccinimidyl chloroformate is also a bifunctional carbonyl derivative containing an NHS ester and a acid chloride. In aqueous solutions, the compound is unstable to hydrolysis, rapidly breaking down to NHS, CO_2, and HCl. In nonaqueous environments, however, NHS-chloroformate may be used to activate a hydroxyl group similar to DSC. Reaction of the chloroformate with a hydroxylic residue forms the same succinimidyl carbonate derivative as the reaction of DSC with –OH groups (Reaction 3.37). Subsequent conjugation with an amine-containing compound yields a carbamate linkage. The bond is identical to that formed from the reaction of CDI-activated hydroxyls with amine-containing compounds (see previous section).

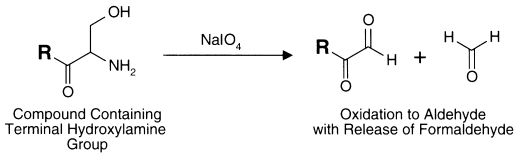


(REACTION 3.37)



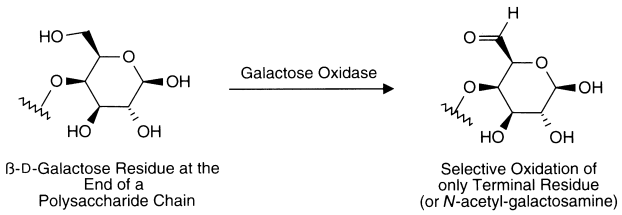
4.4. Oxidation with Periodate

Sodium periodate can be used to oxidize hydroxyl groups on adjacent carbon atoms, forming reactive aldehyde residues suitable for coupling with amine- or hydrazide-containing molecules. The reaction occurs with two adjacent secondary hydroxyls to cleave the carbon–carbon bond between them and create two terminal aldehyde groups (Reaction 3.38). When one of the adjacent hydroxyls is a primary hydroxyl, reaction with periodate releases one molecule of formaldehyde and leaves a terminal aldehyde residue on the original diol compound (Reaction 3.39). These reactions can be used to generate crosslinking sites in carbohydrates or glycoproteins for subsequent conjugation of amine-containing molecules by reductive amination (Chapter 2, Section 4.4,



and Chapter 4, Section 4). Sodium periodate also reacts with 2-aminoethanol derivatives—compounds containing a primary amine and a secondary hydroxyl group on adjacent carbon atoms. Oxidation cleaves the carbon–carbon bond, forming a terminal aldehyde group on the side that had the original hydroxyl residue (Reaction 3.40). This reaction can be used to create reactive aldehydes on N-terminal serine residues of peptides (Geoghegan and Stroh, 1992).

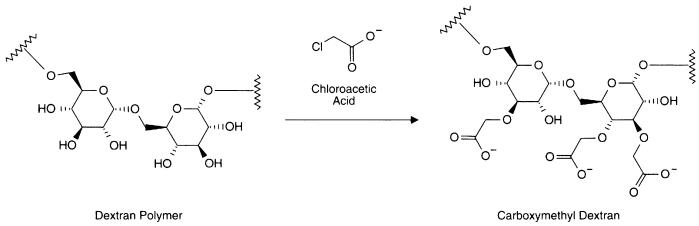
(REACTION 3.38)



(REACTION 3.39)

(REACTION 3.40)

4.5. Enzymatic Oxidation

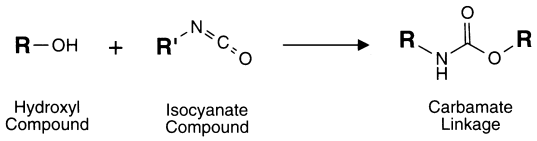


Certain enzymes may be used to oxidize hydroxyl-containing carbohydrates to create aldehyde groups (Chapter 2, Section 4.4). For example, the reaction of galactose oxidase on terminal galactose or *N*-acetyl-D-galactose residues proceeds to form C-6 aldehyde groups on polysaccharide chains (Reaction 3.41). These groups can then be used for conjugation reactions with amine- or hydrazide-containing molecules.

(REACTION 3.41)

4.6. Alkyl Halogens

Reactive alkyl halogen compounds can be used to specifically modify hydroxyl groups in carbohydrates, polymers, and other molecules. Chloro- or bromo-derivatives of short alkyl chains containing an electron-withdrawing second functional group on their other end (typically a carboxylate group) can be used to form spacer arms useful for conjugation with another substance. Brunswick *et al*. (1988) used chloroacetic acid to modify the hydroxyl groups of dextran, forming the carboxymethyl derivative (Reaction 3.42). The carboxylates may then be coupled with amine-containing molecules using a carbodiimide reaction scheme. In a somewhat similar approach, Noguchi *et al*. (1992) prepared a carboxylate spacer arm by reacting 6-bromohexanoic acid with a dextran polymer (Chapter 18, Section 2.2).



(REACTION 3.42)

Modification of hydroxyl groups with such compounds can be performed in 3- to 10-*M* NaOH by reacting from 25°C to 40°C for 1.5 to 4h.

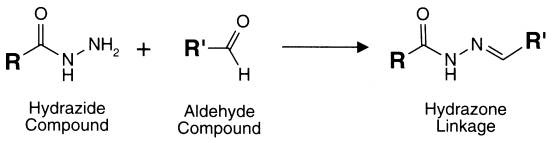
4.7. Isocyanates

Isocyanates can be formed from the reaction of an aromatic amine with phosgene (Rifai and Wong, 1986). They can also be created from acyl azides by treatment at 80°C in the presence of an alcohol (Chapter 10, Section 5). In the transformation, the acyl azide group rearranges to form an isocyanate that can react with hydroxyl-containing molecules to form a urethane (carbamate) linkage (Reaction 3.43). The reactivity of isocyanates is excellent, but for the same reason their stability can be a problem. In storage, moisture decomposes them, releasing CO_2 and leaving an aromatic amine in its place. In aqueous environments, the aromatic amine can react with another molecule of isocyanate to form a urea derivative (Annunziato *et al*., 1993).

(REACTION 3.43)

Isocyanate-containing reagents can be used to cross-link or label hydroxyl-containing molecules, including polysaccharides. Carbohydrate modification can be performed without the need for prior oxidation of sugar

residues with periodate to form reactive aldehydes, as is common in many protocols (Chapter 2, Section 4.4). The reaction occurs best at alkaline pH values (e.g., pH 8.5). Many coupling protocols avoid the hydrolysis problem by performing the reaction in organic solvent (i.e., DMSO).

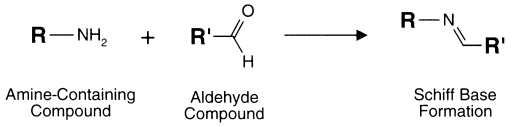


Annunziato *et al*. (1993) have reported on the synthesis and use of a novel heterobifunctional crosslinking reagent containing a hydroxyl-reactive isocyanate group on one end and a sulfhydryl-reactive maleimide group on the other end. The compound can be useful in labeling hydroxylic molecules for subsequent conjugation with thiol-containing molecules.

5. ALDEHYDE AND KETONE REACTIONS

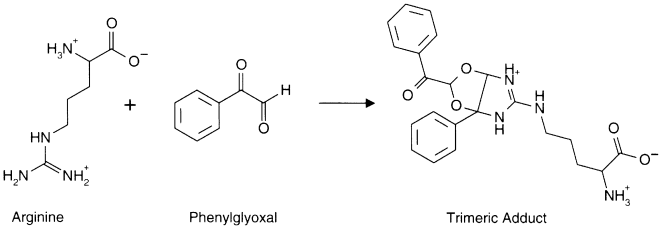
Aldehyde and ketone groups are important reactive sites in molecules for many bioconjugate strategies. Although some pharmacological agents contain ketones, these groups are not usually present in proteins and other biological macromolecules. Even when a molecule does not contain these functionalities, however, they may be created through a number of processes (Chapter 4, Section 4.4). The following sections discuss the major reactions that can be performed with aldehydes and ketones to modify or crosslink molecules containing them.

5.1. Hydrazine and Hydrazide Derivatives



Derivatives of hydrazine, especially the hydrazide compounds formed from carboxylate groups, can react specifically with aldehyde or ketone functional groups in target molecules. Reaction with either group creates a hydrazone linkage (Reaction 3.44)—a type of Schiff base. This bond is relatively stable if it is formed with a ketone, but somewhat labile if the reaction is with an aldehyde group. However, the reaction rate of hydrazine derivatives with aldehydes is typically faster than the rate with ketones. Hydrazone formation with aldehydes, however, results in much more stable bonds than the easily reversible Schiff base interaction of an amine with an aldehyde. To further stabilize the bond between a hydrazide and an aldehyde, the hydrazone may be reacted with sodium cyanoborohydride to reduce the double bond and form a secure covalent linkage.

(REACTION 3.44)

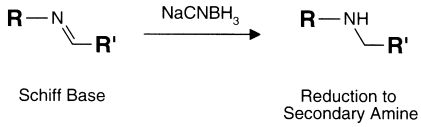


5.2. Schiff Base Formation

Aldehydes and ketones can react with primary and secondary amines to form Schiff bases, a dehydration reaction yielding an imine (Reaction 3.45). However, Schiff base formation is a relatively labile, reversible interaction that is readily cleaved in aqueous solution by hydrolysis. The formation of Schiff bases is enhanced at alkaline pH values, but they are still not stable enough to use for crosslinking applications unless they are reduced by reductive amination (see below).

(REACTION 3.45)

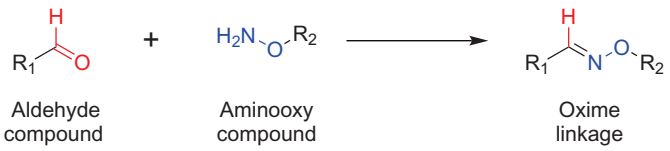
The reaction of dicarbonyl compounds, such as glyoxal or phenylglyoxal, with a guanidinyl group, such as that of an arginine residue, proceeds to yield a more stable linkage due to the formation of a cyclic derivative (Reaction 3.46).



(REACTION 3.46)

5.3. Reductive Amination

Reductive amination (or alkylation) may be used to conjugate an aldehyde- or ketone-containing molecule with an amine-containing molecule. Schiff base formation between aldehydes and amines occurs readily in aqueous solutions, especially at elevated pH. This type of linkage, however, is not stable unless reduced to secondary or tertiary amine bonds. A number of reducing agents can be used to specifically convert the Schiff base interaction into an alkylamine linkage (Reaction 3.47). Once reduced, the bonds are highly stable and will not readily hydrolyze in aqueous environments. The use of reductive amination to conjugate an aldehyde-containing molecule to an amine-containing molecule results in a zero-length crosslinking procedure where no additional spacer atoms are introduced between the molecules (Section 2.1.4). Reaction of ammonia or a diamine compound with an aldehyde by reductive amination is a

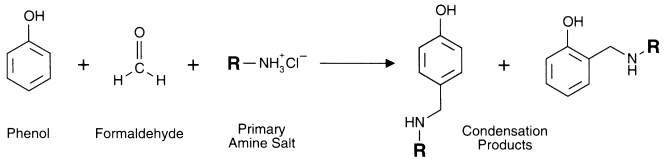


method of creating a primary amine functional group (Chapter 2, Section 4.3).

(REACTION 3.47)

5.4. Aminooxy Derivatives

Aminooxy groups (also called aminoxy or alkoxyamine) contain a terminal primary amine group next to oxygen (–ONH_2), wherein the oxygen atom can be attached to a linker arm of a bioconjugation reagent or attached to a solid phase such as a particle or surface. The chemoselective ligation reaction that occurs between an aldehyde group and an aminooxy group yields an oxime linkage (aldoxime) that has been used in many bioconjugation reactions, as well as in the coupling of ligands to insoluble supports including surfaces (see Chapter 15, Section 2.4) (Thumshirn *et al*., 2003; Poethko *et al*., 2004; Liu *et al*., 2007; Colombo and Bianchi, 2010). This reaction is also quite efficient with ketones to form an oxime called a ketoxime. The simplest form of this reaction has been known for over a century and occurs with aldehydes or ketones as they react with the small compound hydroxylamine (Reaction 3.48).



(REACTION 3.48)

Oxime linkages are very stable bonds that, unlike in the case of a hydrazone bond between a hydrazide group and an aldehyde, do not require further stabilization through reduction to eliminate leakage. The formation of the oxime can be further accelerated through the use of aniline as a catalyst. The aniline aryl amine group will first react with an aldehyde to form an intermediate Schiff base with the aldehyde, which then undergoes efficient attack by the aminooxy group to result in loss of aniline and formation of the oxime linkage. Additional information on the use of this reaction can be found in Chapter 15.

5.5. Mannich Condensation

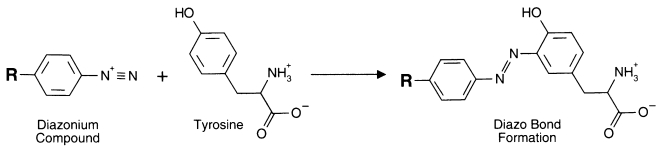
Aldehydes may participate in a condensation reaction with an amine compound and a substance containing a sufficiently active hydrogen, yielding an alkylated derivative that effectively crosslinks the two molecules through the carbonyl group of the aldehyde. Strictly speaking, the Mannich reaction consists of the condensation of formaldehyde (or sometimes another aldehyde) with ammonia, in the form of its salt, and another compound containing an active hydrogen. Instead of using ammonia, however, this reaction can be carried out with primary or secondary amines, or even with amides. An example is illustrated in the condensation of phenol, formaldehyde, and a primary amine salt (Reaction 3.49).

(REACTION 3.49)

The Mannich reaction provides an often superior alternative to diazonium conjugation (Section 6.1, this chapter), because of the disadvantages inherent in the instability of both the diazonium group and the resultant diazo linkage. By contrast, conjugations performed through the use of a Mannich condensation process result in stable covalent bonds.

The crosslinking scheme using this method can make use of the native ε- and N-terminal amines on proteins as the source of primary amine for the condensation reaction. Added to the conjugation reaction is formaldehyde and the desired molecule to be coupled containing an appropriately active hydrogen. The Mannich reaction should not be used for molecules containing both an amine and a reactive hydrogen, since polymerization may occur. It is especially useful for preparing hapten–carrier conjugates when the hapten contains no other available functionalities suitable for crosslinking, but does contain an active hydrogen (Chapter 19, Section 6.2).

A modification of the Mannich reaction was described by Joshi *et al*. (2004) which uses aniline in the reaction solution as a catalyst to accelerate the formation of the condensation product. This alternative reaction scheme is more fully described in Chapter 15, Section 2.7. The aniline catalyzed Mannich reaction may be used to specifically target tyrosine-containing peptides for covalent conjugation at the *ortho* position relative to its phenolic ring –OH group (see Figures 15.103 and 15.104 in Chapter 15).



6. ACTIVE HYDROGEN REACTIONS

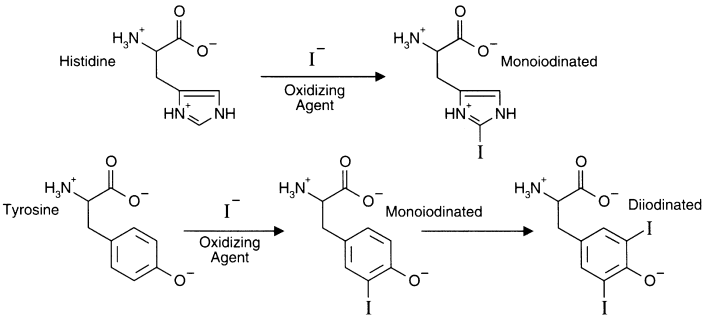
Many compounds contain reactive (or replaceable) hydrogens that are able to participate in conjugation

procedures using certain chemical reactions. These hydrogens typically are associated with aromatic systems wherein an electron donating group activates positions on the ring toward substitution reactions. At such carbons, the hydrogen is easily displaced by an attacking electrophilic group able to form a new covalent linkage. Several common modification reactions are used in bioconjugate chemistry to label or crosslink molecules at active hydrogen sites. The following three sections discuss these chemical reactions.

6.1. Diazonium Derivatives

Diazonium groups react with active hydrogen sites on aromatic rings to give covalent diazo bonds. Generation of a diazonium functional group is usually made from an aromatic amine by reaction with sodium nitrite under acidic conditions at 0°C (Chapter 2, Section 4.3, and Chapter 19, Section 6.1). The highly reactive and unstable diazonium is reacted immediately with an active hydrogen-containing compound at pH 8 to 10. In general, at pH 8.0 the diazonium group will react principally with histidinyl residues, attacking the electron rich nitrogens of the imidazole ring. At higher pH, the phenolic side chain of tyrosine groups can be modified (Reaction 3.50). The reaction proceeds by electrophilic attack of the diazonium group toward the electron-rich points on the target molecules. Phenolic compounds are modified at positions *ortho* and *para* to the aromatic hydroxyl group. For tyrosine side chains, only the *ortho* modification is available.

(REACTION 3.50)



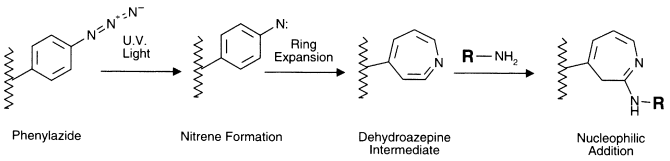
Crosslinking using diazonium compounds usually creates deeply colored products characteristic of the diazo bonds. Occasionally, the conjugated molecules may turn dark brown or even black. The diazo linkages are reversible by addition of 0.1-*M* sodium dithionite in 0.2-*M* sodium borate, pH 9.0. Upon cleavage, the color of the complex is lost.

6.2. Mannich Condensation

The Mannich reaction consists of the condensation of an active hydrogen-containing compound with an amine-containing compound in the presence of formaldehyde. See Section 5.5 (this chapter) for additional details.

6.3. Iodination Reactions

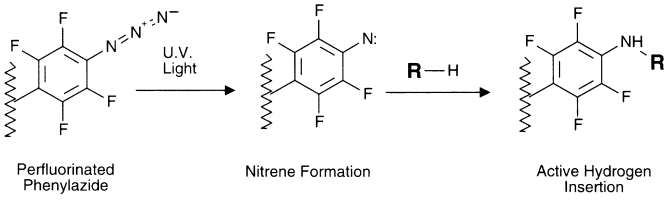
Radioiodination involves the substitution of radioactive iodine atoms for reactive hydrogen sites in target molecules. The process usually involves the action of a strong oxidizing agent to transform iodide ions into a highly reactive electrophilic iodine compound (typically I_2 or a mixed halogen species such as ICl). Formation of this electrophilic species leads to the potential for rapid iodination of aromatic compounds containing strong activating groups, such as aryl compounds. In particular, aromatic constituents that have electron-donating groups can sufficiently activate the carbons on the ring to undergo electrophilic substitution reactions. Therefore, phenols, aniline derivatives, or alkyl anilines that contain OH, NH_2, or NHR constituents, respectively, are very susceptible to being iodinated. In proteins, this translates into tyrosine side-chain phenolic groups and histidine side-chain imidazole groups (Reaction 3.51). See Chapter 12, Section 2, for further details on iodination reactions.



(REACTION 3.51)

7. PHOTOCHEMICAL REACTIONS

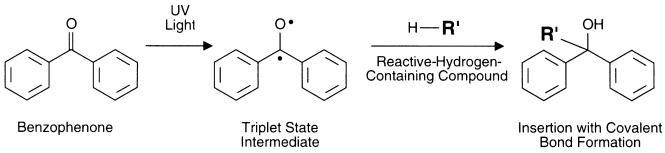
Photoreactive groups can be induced to couple with target molecules by exposure to UV light. Until they are photolyzed, photosensitive functional groups are relatively nonreactive in typical thermochemical processes. For this reason, reagents designed with a photoreactive group can be used in highly controlled reactions. The labeling reaction can be induced by a UV flash at predetermined points in an experimental protocol. For instance, covalent bond formation can be initiated after binding of photo-labeled ligands to receptors or after some other biochemical process has taken place. In this regard, photoreactive chemistry has become an important device for numerous bioconjugate applications. The following sections describe the major photosensitive groups that can be used in the design of modification or crosslinking reagents. Chapter 5, Section 5; Chapter 6, Sections 3–7; Chapter 7; and Chapter 11, Section 6.5, describe the reagents that utilize these functional groups.



7.1. Aryl Azides and Halogenated Aryl Azides

The most popular type of photosensitive functional group is the aryl azide derivative. Upon photolysis, phenyl azide groups form short-lived nitrenes that react rapidly with the surrounding chemical environment (Gilchrist and Rees, 1969). Nitrenes can insert nonspecifically into chemical bonds of target molecules, including undergoing addition reactions with double bonds and insertion reactions into active hydrogen bonds at C–H and N–H sites. Abundant evidence, however, indicates that the photolyzed intermediates of aryl azides principally undergo ring expansion to create nucleophile-reactive dehydroazepines. Instead of inserting non-selectively at active carbon–hydrogen bonds, dehydroazepines have a tendency to react preferentially with nucleophiles, especially amines (Reaction 3.52).

(REACTION 3.52)



However, some investigators have shown that aryl azides that possess a perfluorinated ring structure or are substituted completely with halogen atoms are quite efficient at forming the desired nitrene intermediate (Keana and Cai, 1990; Cai *et al*., 1993; Schnapp and Platz, 1993; Schnapp *et al*., 1993; Soundararajan *et al*., 1993; Yan *et al*., 1994). The ring substitution prevents ring expansion after nitrene formation, thus allowing the reactive intermediate to survive long enough to react with target molecules. Halogenated phenyl azides undergo the insertion reactions that were typically attributed to unsubstituted aryl azides in the past (Reaction 3.53).

(REACTION 3.53)

7.2. Benzophenones

A photoreactive group consisting of a benzophenone residue photolyzes upon exposure to UV light to give a highly reactive triplet-state ketone intermediate (Walling and Gibian, 1965). Similar to the reactive nitrene of photolyzed phenyl azides, the energized electron of an activated benzophenone can insert in hydrogen–carbon bonds and other active groups to give covalent linkages with target molecules (Reaction 3.54). Unlike phenyl azides, however, the decomposition or decay of the photoactivated species does not yield an inactive compound. Instead, benzophenones that have become deactivated without forming a covalent bond can once again be photolyzed to an active state. As a result of this multiple-activation characteristic, a benzophenone reagent has more than one chance to form a covalent bond with its intended target. Thus, it typically gives much higher yields of photo-crosslinking than comparable phenyl azide crosslinkers.

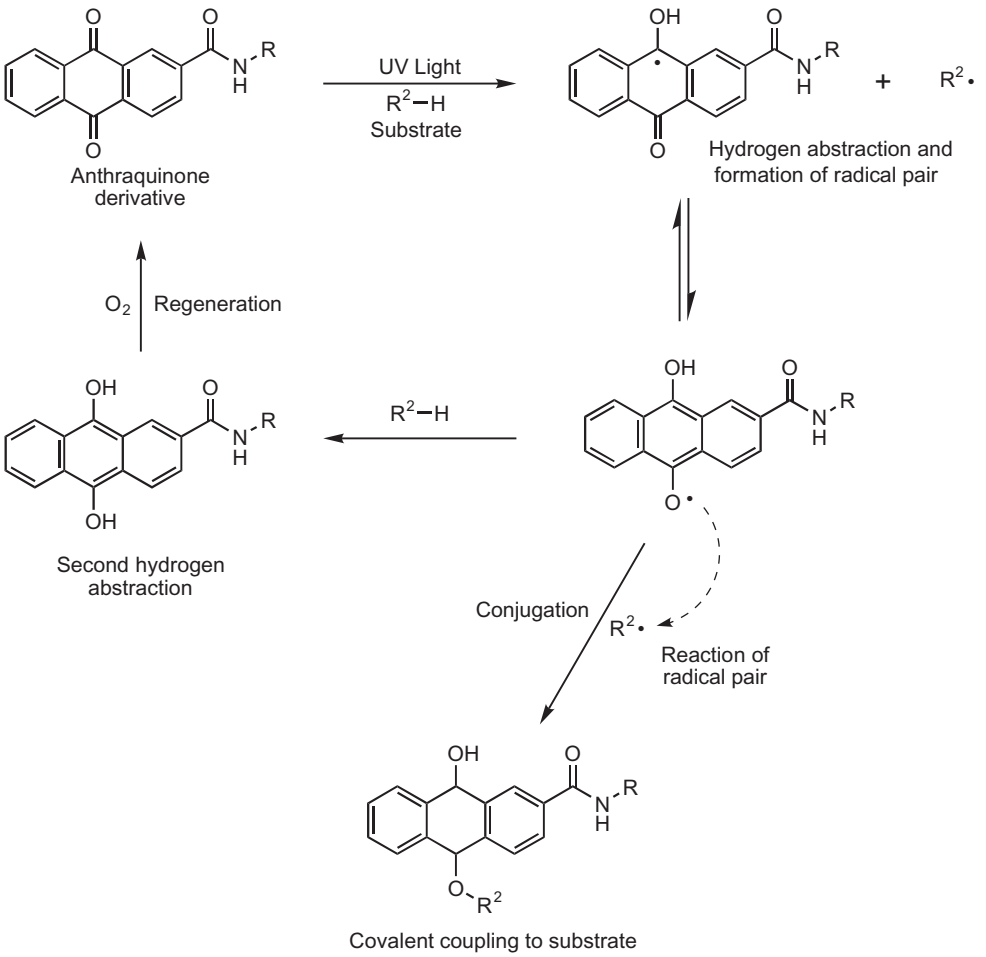
(REACTION 3.54)

The use of a benzophenone photoactivatable group in the design of bioconjugate reagents is rare. Two sulfhydryl-reactive ones incorporating a maleimide group and an iodoacetyl group opposite the benzophenone are described in Chapter 6, Sections 4.3, and 4.4. A newer benzophenone modification reagent containing a water soluble PEG spacer is described in Chapter 18, Section 1.3.

7.3. Anthraquinones

Anthraquinone groups are highly photoreactive by exposure to long UV light in the range of 340 to 360 nm. Unlike photoreactive groups that form intermediate nitrene or carbine precursors after photoactivation, anthraquinones react by a radical generation process, which is much more efficient in coupling to C–H substrates. Photoactivation results in a highly reactive, excited species that involves the formation of a triplet n,π*-state, which becomes a powerful electron acceptor. If an organic substrate is present containing a reactive C–H bond, then the excited anthraquinone is able to cause rapid proton abstraction, resulting in the formation of a reduced, phenoxy radical intermediate with a second radical formed on the hydrogen-donating substrate. This radical pair can then react to covalently link the anthraquinone group to the substrate, forming an ether linkage and effectively immobilizing the reagent to the substrate (Brennan and Beutel, 1969; Koch *et al*., 2000) (Figure 3.7).

Modification or crosslinking reagents containing an anthraquinone group can be made from the 2-carboxylic acid derivative (Kumar *et al*., 2004) (Exiqon). A spacer arm can be added to the carboxylate to terminate in a reactive group for bioconjugation or an affinity group (e.g., biotin) for interaction with other molecules.



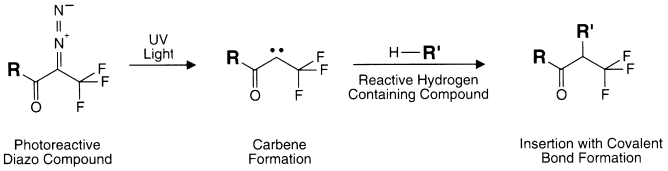


FIGURE 3.7 Anthraquinone derivatives can photoreactively couple to substrates by means of a free radical generation process. The reactive intermediate can also be regenerated back to the initial anthraquinone by proton abstraction and oxidation, resulting in the possibility of again being photolyzed and successfully coupled to the substrate.

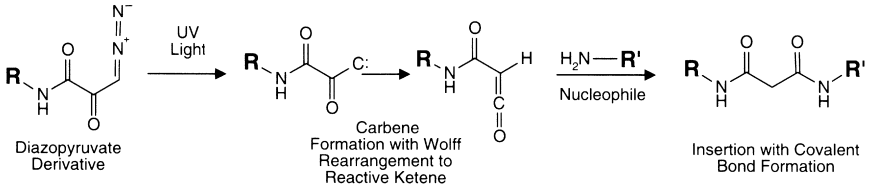
Anthraquinone photoreactive linking reagents can be used to modify any surfaces or particles containing C–H groups, including polymer-based microplates, slides, and particles. Inorganic surfaces can be modified with an organosilane compound (Chapter 13) and then further reacted using an anthraquinone compound; however, the benefit of this strategy may be negated by choice of the proper reactive group on the silane. Reactions with surfaces are usually performed with anthraquinone concentrations in aqueous buffers ranging from 100 ng/ml to about 2 µg/ml. Protect all photoreactive reagents and solutions from light until ready to photoactivate them.

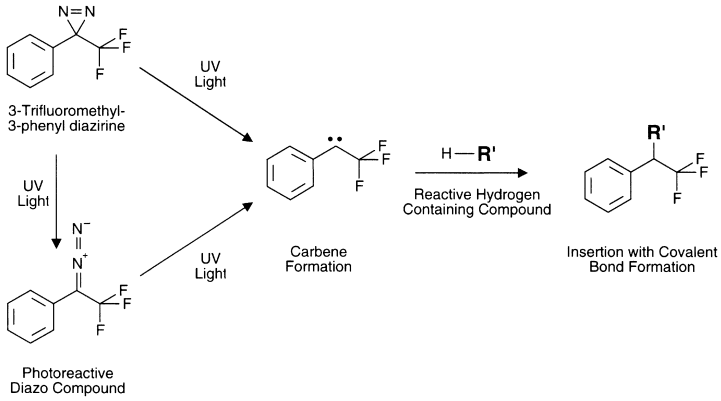


7.4. Certain Diazo Compounds

Certain diazo compounds can be photolyzed with UV light to generate highly reactive carbenes (Reaction 3.55). Similar to nitrenes, carbenes can insert into active C–H or N–H bonds or add to double bonds, forming covalent linkages with target molecules (Gilchrist and Rees, 1969). Few diazo photoreactive reagents have been synthesized, probably due to their tendency to react with water molecules after photoactivation, thus severely decreasing coupling yields with intended molecules. One heterobifunctional crosslinker, PNP–DTP, containing an amine-reactive end and a photosensitive diazotrifluoropropionate group is available (Chapter 6, Section 3.12).

(REACTION 3.55)

Diazopyruvates are another class of photoreactive diazo compounds that have a unique coupling mechanism (Chapter 6, Section 3.11). The diazo functional



(REACTION 3.56)

group can by photolyzed by exposure to irradiation at 300 nm, forming a highly reactive carbene, which can undergo a Wolff rearrangement to produce a ketene amide intermediate. In the presence a nucleophilic species on a target molecule, the ketene can undergo an acylation reaction to form a stable malonic acid derivative. The photolyzed product thus can couple to hydrazide- or amine-containing targets to form covalent linkages (Reaction 3.56).

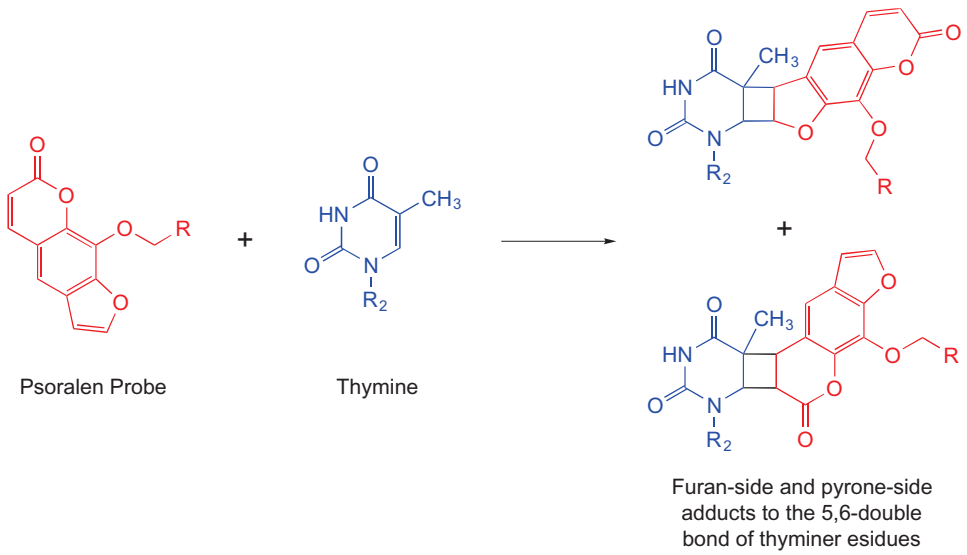
7.5. Diazirine Derivatives

Diazirine compounds are similar in their photoreactivity to diazo groups, forming highly reactive carbene intermediates upon exposure to UV light of about 360 nm (Reaction 3.57). Diazirines consist of a three-member ring system containing two nitrogen atoms connected through a double bond. First developed by Smith and Knowles (1973), the photosensitive diazirine is perhaps second in popularity to phenyl azides in the design of photoreactive crosslinking agents.

(REACTION 3.57)

Some diazirines, particularly the 3-trifluoromethyl-3-aryldiazirines, can rearrange upon photolysis to a linear diazo derivative, similar in structure to the photosensitive end of the crosslinker PNP–DTP (Chapter 6, Section 3.12). These isomerized products themselves can be photolyzed to the reactive carbene.

Carbene generation from photolysis of diazirine compounds leads to efficient insertion into C–H or N–H bonds and also causes addition reactions with points of unsaturation within target molecules. Diazirine-containing photoaffinity probes have been used to study numerous ligand–receptor interactions (Bergmann *et al.*, 1994). Heterobifunctional crosslinkers containing a diazirine photosensitive group has also been used to attach macromolecules to surfaces such as polystyrene and glass (Collioud *et al.*, 1993). In addition, diazirine-containing photoreactive amino acid analogs, photo-leucine and photo-methionine, have been developed to study protein interactions within cells (Suchanek *et al.*, 2005).



7.6. Psoralen Compounds

Psoralen, or derivatives of 9-methoxy-7*H*-furo [3,2-*g*]chromen-7-one tricyclic ring structures, are used as photoreactive groups in crosslinkers, biotinylation compounds, and nucleic acid probes. Psoralens have been used for many years as photochemotherapy agents for treatment of psoriasis and vitiligo (Smith and Barker, 2006). Psoralens react when exposed to UV light in the range of 320 to 400 nm to form an excited triplet state intermediate that can insert in certain double-bond structures, especially at the 5,6-double bond of thymine bases.

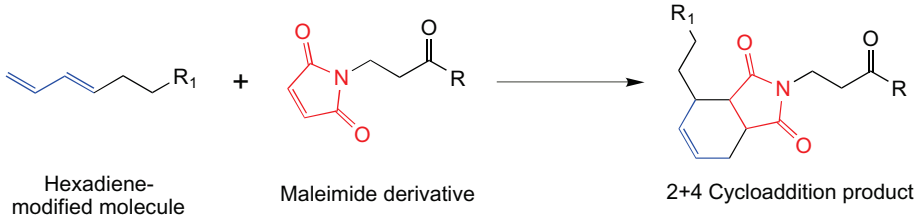
Psoralens can react by two different routes upon photoactivation (Parsons, 1980; Pathak, 1984). The first route is through the well-known photoreaction mechanism that principally involves intercalation within double-stranded DNA or RNA with the formation of adducts with adjacent thymine bases. The furan-side and pyrone-side rings in psoralen can both form cycloaddition products with the 5,6-double-bond of thymine to create a crosslink between two DNA strands (Reaction 3.58) or, to a lesser extent, within double-strand regions of RNA.

Psoralen can also undergo reactions with oxygen to produce reactive oxygen species, including the formation of singlet oxygen ($^1O_2$), superoxide anion ($O_2^{\cdot-}$), and hydroxyl radicals ($^{\cdot}OH$). The production of reactive oxygen species by psoralen derivatives can damage biological molecules and structures. See Chapter 2, Section 1.1, for additional information on the oxidation of amino acids.

Psoralen–biotin compounds have been used to label double-stranded DNA for detection using streptavidin reagents (Henriksen *et al.*, 1991; Wygrecka *et al.*, 2007). The compound psoralen–PEG_3–biotin is commercially available for this purpose (Thermo Fisher). Crosslinking

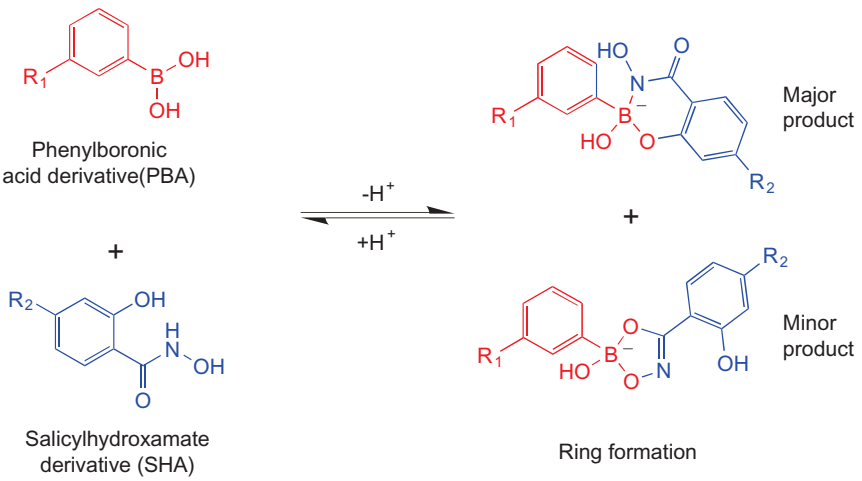
(REACTION 3.58)

agents can also be built using a photoreactive psoralen ring system at one end. The reagent succinimidyl-[4-(psoralen-8-yloxy)]butyrate (SPB) contains an NHS ester to covalently link a psoralen group to proteins or other amine-containing molecules (Thermo Fisher, Molecular Biosciences). Oser *et al*. (1988) created a lanthanide chelate with a psoralen group to label DNA with a time-resolved fluorescent probe. Psoralen derivatives can also be coupled to polymeric surfaces by a photoreaction process. Elsner and Mouritsen (1994) used psoralen linkers for modification of the surface of microplates to create sites for covalent binding of affinity molecules.



8. CYCLOADDITION REACTIONS

The following sections briefly describe three cycloaddition reactions that can be used to form bioconjugates. These reactions represent highly specific reactant pairs that have a chemoselective nature, meaning they mainly react with each other and not other functional groups, such as those found on biomolecules. For a complete discussion of chemoselective ligation reactions, see Chapter 17.



8.1. Diels–Alder Reaction

The Diels–Alder reaction consists of the covalent coupling of a diene with an alkene to form a six-membered ring complex. This process has been used extensively in organic synthesis, but only recently has it been applied to bioconjugation reactions (Hill *et al*., 2001). This reaction proceeds at room temperature or slightly elevated temperature conditions (30°C) to give the 2 + 4 cycloaddition product, a hexane ring containing a single double bond. The reaction can be performed using a maleimide group as the alkene derivative and a hexadienyl group as the diene (Reaction 3.59). The reaction process can give 90 to 95% yields in 1 to 18 h.

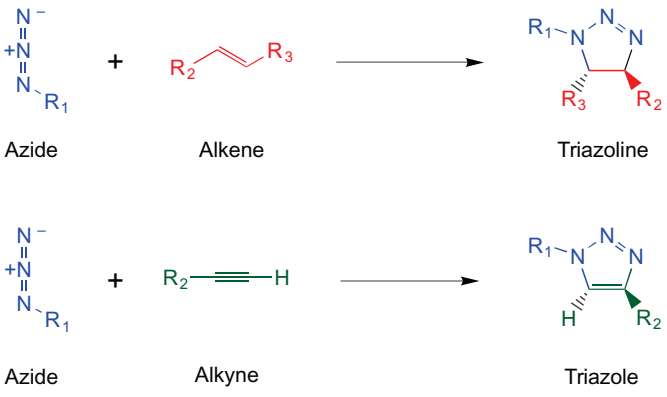
See Chapter 17, Section 1, for additional information concerning the use of the Diels–Alder reaction in bioconjugation applications.

(REACTION 3.59)

(REACTION 3.60)

8.2. Complex Formation with Boronic Acid Derivatives

Boronic acid derivatives are able to form ring structures with other molecules having neighboring functional groups consisting of 1,2- or 1,3-diols, 1,2- or 1,3-hydroxy acids, 1,2- or 1,3-hydroxylamines, 1-2- or 1,3-hydroxyamides, 1,2- or 1,3-hydroxyoximes, as well as various sugars containing these species (Weith at al., 1970; Rosenberg and Gilham, 1971; Rosenberg *et al.*, 1972; Pace and Pace, 1980; Singhal *et al.*, 1980). The products of these reactions are five- or six-membered heterocyclic rings, which in some cases are reversible with a change in pH or by the addition of a counter-ligand having competing functional groups.



Typically, the boronic acid group is part of an aminophenyl boronic acid derivative, and this group has been used for bioconjugation and affinity chromatography purposes (Burnett *et al.*, 1980; O'Shannessy and Quarles, 1987). A common partner for a phenyl boronic acid group in bioconjugation is the salicylhydroxamic acid (SHA) group (Chapter 17, Section 4) (Reaction 3.60).

8.3. Click Chemistry: Cu[1]-Promoted Azide–Alkyne [3 + 2] Cycloaddition

Click chemistry refers to the reaction between an azido functional group and an alkyne to form a [3 + 2] cycloaddition product, a five-membered triazole ring. This reaction has been used for many years in organic synthesis to form heterocyclic rings. Normally, the click reaction requires high temperatures, and this was the main reason that it was not used as a bioconjugation tool. However, it was discovered that in aqueous solutions and in the presence of Cu(I), the reaction kinetics are dramatically accelerated to provide high yields even at room temperature and ambient pressures (TornØe *et al.*, 2002; Rostovtsev *et al.*, 2002; Sharpless *et al.*, 2005).

The advantage of the click reaction for bioconjugation is that the reactant pair is not reactive with any other functional group encountered in biological systems. This property of bioorthogonality provides extreme selectivity for bringing together azide and alkyne derivatives to form triazoles even in complex biological samples.

Reaction 3.61 shows the reaction of an alkyne with an azide to form a triazole ring in the presence of a Cu(I) catalyst. See Chapter 17, Section 5, for additional details on the use of this conjugation reaction.

(REACTION 3.61)

CHAPTER

4

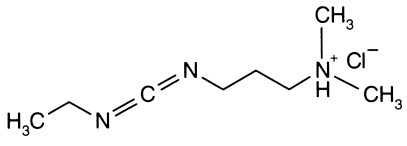
Zero-Length Crosslinkers

The smallest available reagent systems for bioconjugation are the so-called zero-length crosslinkers. These compounds mediate the conjugation of two molecules by forming a bond containing no additional atoms. Thus, one atom of a molecule is covalently attached to an atom of a second molecule with no intervening linker or spacer. In many conjugation schemes, the final complex is bound together by virtue of chemical components that add foreign structures to the substances being crosslinked. In some applications, the presence of these intervening linkers may be detrimental to the intended use. For instance, in the preparation of hapten–carrier conjugates the complex is formed with the intention of generating an immune response to the attached hapten. Occasionally, a portion of the antibodies produced by this response will have specificity for the crosslinking agent used in the conjugation procedure. Zero-length crosslinking agents eliminate the potential for this type of cross-reactivity by mediating a direct linkage between two substances.

The reagents described in this section can initiate the formation of three types of bonds: an amide linkage made by the condensation of a primary amine with a carboxylic acid, a phosphoramidate linkage made by the reaction of a organic phosphate group with a primary amine, and a secondary or tertiary amine linkage made by the reductive amination of a primary or secondary amine with an aldehyde group. Therefore, using these reagent systems, substances containing amines can be conjugated with other molecules containing phosphates or carboxylates. Alternatively, substances containing amines can be crosslinked to molecules containing formyl groups. All of the reactions are quite efficient, and, depending on the reagent chosen and the desired application, they may be performed in aqueous or nonaqueous environments.

1. CARBODIIMIDES

Carbodiimides are used to mediate the formation of amide linkages between carboxylates and amines or phosphoramidate linkages between phosphates and amines (Hoare and Koshland, 1966; Chu *et al.*, 1986; Ghosh *et al.*, 1990). They are probably the most popular type of zero-length crosslinker in use, being efficient in forming conjugates between two protein molecules, between a peptide and a protein, between an oligonucleotide and a protein, between a biomolecule and a surface or particle, or any combination of these with small molecules. There are two basic types of carbodiimides: water soluble and water insoluble. The water soluble ones are the most common choice for biochemical conjugations, because most macromolecules of biological origin are soluble in aqueous buffer solutions. Not only is the carbodiimide itself able to dissolve in the reaction medium, but the byproduct of the reaction, an isourea, is also water soluble, facilitating easy purification. Water-insoluble carbodiimides, by contrast, are used frequently in peptide synthesis and other conjugations involving molecules soluble only in organic solvents. Both the organic-soluble carbodiimides and their isourea byproducts are insoluble in water.



1.1. EDC

EDC (or EDAC; 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide hydrochloride) is the most popular carbodiimide used for conjugating biological substances containing carboxylates and amines. In fact, it may also be the most frequently used crosslinking agent of all. Its application in particle and surface conjugation procedures along with NHS (*N*-hydroxysulfosuccinimide) or sulfo-NHS is nearly universal (Chapter 14) and this fact makes it the most common bioconjugation reagent in use today. EDC is water soluble, which allows for its direct addition to a reaction without prior organic solvent dissolution. Both the reagent itself and the isourea formed as the byproduct of the crosslinking reaction are water soluble and may be removed easily by dialysis or gel filtration (Sheehan *et al.*, 1961, 1965). The reagent is, however, labile in the presence of water, especially in acidic solutions. In alkaline solutions,

Bioconjugate Techniques, Third Edition.
DOI: http://dx.doi.org/10.1016/B978-0-12-382239-0.00004-2

© 2013 Elsevier Inc. All rights reserved.

the reagent is more stable, but it reacts much more slowly. The bulk chemical should be stored desiccated at −20°C. Warm the bottle to room temperature before opening to prevent condensation occurring that will cause decomposition of the reagent over time. A concentrated solution of EDC in water may be prepared to facilitate the addition of a small molar amount to a reaction, but the stock solution should be dissolved rapidly and used immediately to prevent extensive loss of activity.

EDC
1-Ethyl-3-(3-dimethylaminopropyl)
Carbodiimide Hydrochloride
MW 191.7

A variety of chemical conjugates may be formed using EDC Chu *et al.*, 1976, 1977, 1982; Yamada *et al.*, 1981; Chase *et al.*, 1983, provided one of the molecules contains an amine and the other a carboxylate group. N-substituted carbodiimides can react with carboxylic acids to form highly reactive *O*-acylisourea intermediates (Figure 4.1). This active species can then react with a nucleophile such as a primary amine to form an amide bond (Williams and Ibrahim, 1981). Other nucleophiles are also reactive. Sulfhydryl groups may attack the active species and form thiol ester linkages, although these are not as stable as the bond formed with an amine. In addition, oxygen atoms may act as the attacking nucleophile, such as those in water molecules. In aqueous solutions, hydrolysis by water is the major competing reaction, cleaving off the activated ester intermediate, forming an isourea, and regenerating the carboxylate group (Gilles *et al.*, 1990).

Nakajima and Ikada (1995) investigated the reactions of EDC amide bond formation in aqueous solution using hydrogels of acrylic acid- or maleic acid-containing polymers or other carboxylate molecules to contribute the activatable groups and ethylenediamine or benzylamine as the amine functional groups to be conjugated. Their results indicate that carboxylate activation occurs most effectively with EDC at pH 3.5 to 4.5, while amide bond formation occurs with highest yield in the range of pH4 to 6. However, EDC hydrolysis occurs maximally at acidic pH values with increasing stability of the carbodiimide in solution at or above pH 6.5. When working with proteins and peptides, experience indicates that EDC-mediated amide bond formation effectively occurs between pH 4.5 and 7.5. Beyond this pH range, however, the coupling reaction occurs more slowly with lower yields.

An EDC-mediated reaction to form an amide bond in aqueous solution involves a number of potential side reactions that can occur in addition to the desired conjugation product. The preferred reaction route is facilitated first by protonation of one of the nitrogens on the imide group of EDC, which results in the formation of an intermediate carbocation on the central carbon

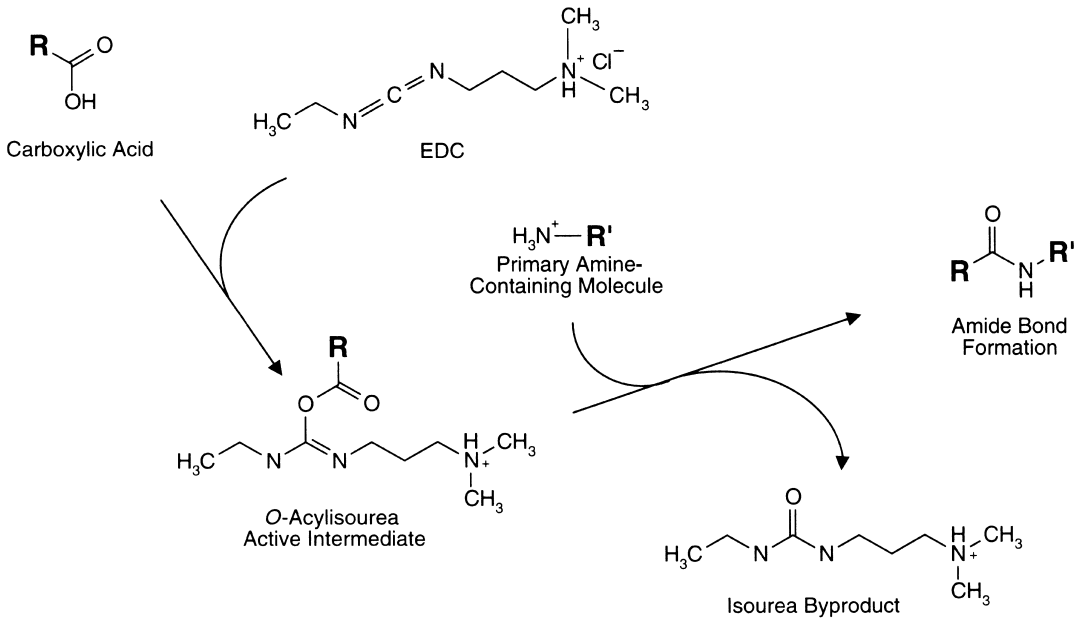


FIGURE 4.1 EDC reacts with carboxylic acids to create an active-ester intermediate. In the presence of an amine nucleophile, an amide bond is formed with release of an isourea byproduct.

atom. At this point, the modified carbodiimide can itself hydrolyze to form an inactive isourea that no longer can participate in the reaction process. It can also react with an available ionized carboxylate group to create the desired *O*-acylisourea reactive ester intermediate (Figure 4.2). This ester again can accept another proton to form a second carbocation on the central carbon atom, and it is this form of the reactive ester that can go on to react with an amine to create an amide bond. However, this intermediate also can undergo a hydrolysis event to yield the same undesired isourea derivative, which again inactivates the compound. Therefore, there are two stages in the reaction sequence in which hydrolysis can occur and inhibit the desired product formation (Nakajima and Ikada, 1995). If hydrolysis does not occur, there are at least three subsequent reactions that can happen, including the desired amide bond formation. If a neighboring carboxylate group is in close proximity to the *O*-acylisourea ester, it may react with it and form an anhydride intermediate. This especially can occur in polymers containing repeating carboxylate groups, such as in polymethacrylate, where the primary intermediate reactive group formed from EDC may be anhydrides (Wang *et al.*, 2011). Fortunately, an anhydride is also reactive with amine groups, so the desired amide bond formation can still occur with at least one of the two carboxylates making up the anhydride. Indeed, anhydride formation may result in higher yields of amide bond formation in certain instances (Nakajima and Ikada, 1995). In addition, if EDC is in large excess over the amount of carboxylates present, then the intermediate ester may exist for a longer period and potentially it can rearrange by reacting with the neighboring secondary amines in the carbodiimide and thus form an *N*-acylisourea derivative, which is inactive and permanently attaches the EDC derivative to the carboxylate compound. Finally, the EDC-reactive ester can also react with the desired amine-containing molecule and form an amide bond. Given this degree of potential side reactions, it is amazing that EDC-mediated amide bond formation can be done with reproducibility, especially when scaling up reactions in production processes. The propensity for EDC to undergo side reactions may be a reason that high variability has been reported using the carbodiimide for particular conjugation reactions (Young *et al.*, 2004).

To complicate matters even further, the presence of both carboxylates and amines on one of the molecules to

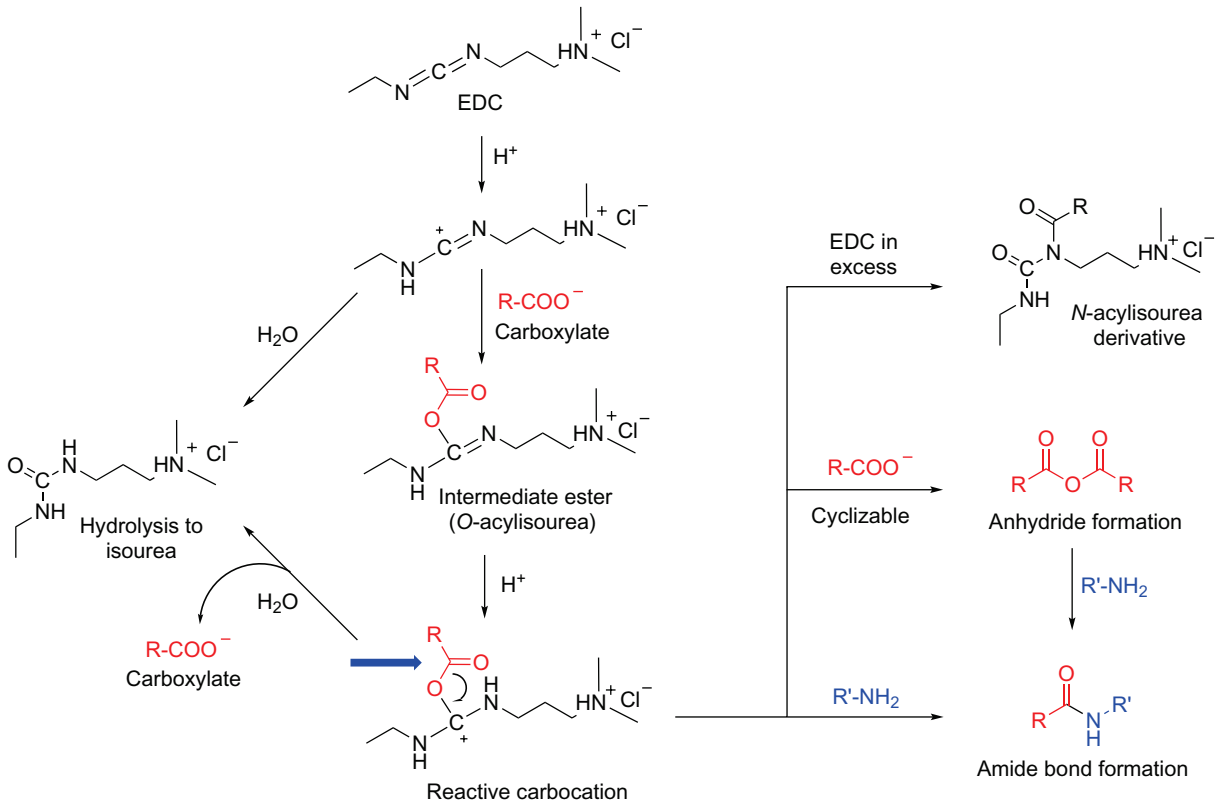

FIGURE 4.2 EDC can undergo a number of potential side reactions that compete with amide bond formation. In aqueous solution, hydrolysis may occur at two points in the reaction path to decrease the yield of the desired conjugate in addition to the possible formation of a permanent EDC complex to create an *N*-acylisourea derivative. This complex reaction pathway often makes EDC conjugations difficult to reproduce in large-scale conjugations.

be conjugated with EDC may result in self-polymerization, because the substance can then react with another molecule of its own kind instead of the desired target. For instance, when conjugating peptides to carrier proteins using EDC, the peptide usually contains both a carboxylate and an amine. The result typically is peptide polymerization in addition to coupling to the carrier (see Chapter 19, Section 3). For this type of immunogen conjugation, polymerization is not usually detrimental to its use, because polymerized peptide is also immunogenic. However, for other crosslinking applications where it may be more desirable to avoid oligomer formation, the use of a carbodiimide may not be the best choice of reagent, especially if one of the molecules being conjugated contains both a carboxylate and an amine.

EDC has been used extensively in the conjugation of amine-containing molecules to carboxylate particles, including small microparticles and nanoparticles (Chapter 14). Most references to the use of EDC describe the optimal reaction medium to be at a pH from 4.7 to 6.0. However, the carbodiimide reaction occurs effectively up to at least pH 7.5 without significant loss of yield. Conjugations performed under mildly alkaline pH conditions (e.g., pH 8.5) can also be carried out to limit the polymerization of proteins, while still facilitating the coupling of a carboxylate-containing molecule at a lower substitution level per protein. See Chapter 19, Section 3, for additional information on the properties of EDC conjugation using small peptides coupled to carrier proteins.

Some procedures recommend the use of water as the solvent in an EDC reaction, while the pH is maintained constant by the addition of HCl. Buffered solutions are more convenient, because the pH does not have to be monitored during the course of the reaction. For acidic pH conjugations, MES [2-(*N*-morpholino)ethane sulfonic acid] buffer at 0.1-*M* works well. When carrying out neutral pH reactions, a phosphate buffer at 0.1-*M* is appropriate. Any buffers may be used that do not interfere with the reaction, but avoid amine- or carboxylate-containing buffer salts or other components in the medium that may react with the carbodiimide.

There are some additional side reactions that may occur when using EDC with proteins. In addition to reacting with carboxylates, EDC itself can form a stable complex with exposed sulfhydryl groups (Carraway and Triplett, 1970). Tyrosine residues can react with EDC, most likely through the phenolate ionized form of its side chain (Carraway and Koshland, 1968). The imidazolyl group of histidine may react with sulfo-NHS esters, resulting in an active carbonyl imidazole group which subsequently hydrolyzes (Cuatrecasas and Parikh, 1972). Finally, EDC may promote unwanted polymerization due to the usual abundance of both amines and carboxylates on protein molecules.

The following protocol is a generalized description of how to conjugate a small amine- or carboxylate-containing molecule to a protein. The protocol may be modified by changing the pH, buffer salts, and ratios of reactants to obtain the desired product. Specific protocols utilizing EDC in selected conjugation applications may be found in Chapters 8, 14, 15, 19, 21, and 23. In some cases, the parameters of this generalized protocol may have to be modified to retain solubility or activity of the resulting conjugate. For instance, coupling hydrophobic molecules to the surface of proteins often causes partial or complete precipitation. This problem may be somewhat alleviated by decreasing either the amount of EDC or the amount of the hydrophobic molecule added to the reaction, thus resulting in a lower density of substitution. Protocols on the use of EDC to couple proteins or other molecules to carboxylated nanoparticles and microparticles may be found in Chapter 14 and Chapter 10, Section 10.

Protocol

1. Dissolve the protein to be modified at a concentration of 10 mg/ml in one of the following reaction media: (a) water; (b) 0.1-*M* MES, pH 4.7 to 6.0; or (c) 0.1-*M* sodium phosphate, pH 7.3. NaCl may be added (i.e., 0.15-*M*) if desired. If lower or higher concentrations of the protein are used, adjust the amounts of the other reactants added as necessary to maintain the correct molar ratios. For the preparation of a peptide–protein immunogen conjugate, a 200 µl solution of the carrier protein at a concentration of 10 mg/ml in 0.1-*M* MES, pH 4.7, usually works well.
2. Dissolve the molecule to be coupled in the same buffer used in step 1. For small molecules, add them to the reaction in at least a 10-fold molar excess to the amount of protein present. If possible, the molecule may be added directly to the protein solution in the appropriate excess. Alternatively, dissolve the molecule in the buffer at a higher concentration, and then add an aliquot of this stock solution to the protein solution. In the example of preparing a peptide–protein conjugate, dissolve the peptide in 0.1-*M* MES, pH 4.7, at a concentration of up to 2 mg/500 µl.
3. Add the solution prepared in step 2 to the protein solution to obtain at least a 10-fold molar excess of small molecule-to-protein. In the case of the peptide–protein immunogen conjugate, add the 500 µl of peptide solution to the 200 µl of protein solution.
4. Add EDC (Thermo Fisher) to the above solution to obtain at least a 10-fold molar excess of EDC to the protein. Alternatively, a 0.5- to 0.1-*M* EDC concentration in the reaction mixture usually works well. To make it easier to add the correct quantity of EDC, a higher concentration stock solution may

be prepared if it is dissolved and used immediately. To prepare the peptide–protein conjugate, add the solution from step 3 to 10 mg of EDC in a test tube. Mix to dissolve. If this ratio of EDC to peptide or protein results in precipitation, then scale back the amount of carbodiimide addition until a soluble conjugate is obtained. For some proteins, as little as 0.1 times this amount of EDC may have to be used to maintain solubility.

5. React for 2 h at room temperature.
6. Purify the conjugate by gel filtration or dialysis using the buffer of choice (for many conjugates 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, is appropriate). If some turbidity has formed during the conjugation procedure, it may be removed by centrifugation or filtration. When using EDC to prepare immunogen conjugates, the presence of some precipitated material is usually not of concern, because precipitated immunogens are often more immunogenic than soluble proteins.

1.2. EDC Plus Sulfo-NHS

The water soluble carbodiimide EDC may be used to form active ester functionalities with carboxylate groups using the water soluble compound *N*-hydroxysulfosuccinimide (sulfo-NHS) (Thermo Fisher). Sulfo-NHS esters are hydrophilic reactive groups that couple rapidly with amines on target molecules (Staros, 1982; Denney and Blobel, 1984; Kotite *et al.*, 1984; Jennings and Nicknish, 1985; Ludwig and Jay, 1985; Beth *et al.*, 1986; Donovan and Jennings, 1986; Anjaneyulu and Staros, 1987). Unlike many non-sulfonated NHS esters that can be relatively water insoluble and must first be dissolved in organic solvent before being added to aqueous solutions, sulfo-NHS esters typically are water soluble and longer lived and don't hydrolyze quite as quickly in water. However, in the presence of amine nucleophiles that can attack at the carbonyl group of the ester, the sulfo-NHS group rapidly leaves, creating a stable amide linkage with the amine. Sulfhydryl and hydroxyl groups will also react with such active esters, but the products of such reactions, thioesters and esters, are relatively unstable compared to an amide bond.

The advantage of adding sulfo-NHS to EDC reactions is to increase the solubility and stability of the active intermediate, which ultimately reacts with the attacking amine. EDC reacts with a carboxylate group to form an active ester (*O*-acylisourea) leaving group. Unfortunately, this reactive complex is slow to react with amines and can hydrolyze in aqueous solutions, having a rate constant measured in seconds (Chapter 14, Section 4) (Hoare and Koshland, 1967). If the target amine does not find the active carboxylate before it hydrolyzes, the desired coupling cannot occur. This is especially a problem when the target molecule is in low concentration compared to water, as in the case of protein molecules. In addition, Nakajima and Ikada (1995) found that if a carboxylate-containing compound can form an anhydride from the *O*-acylisourea intermediate reactive ester, then the yield of amide bond formation is increased. In a similar approach, forming a sulfo-NHS ester intermediate from the reaction of the hydroxyl group on sulfo-NHS with the EDC active-ester complex dramatically increases the resultant amide bond formation. Since the concentration of added sulfo-NHS usually is much greater than the concentration of target molecule, the reaction preferentially proceeds through the more efficient sulfo-NHS ester intermediate. However, the final product of this two-step reaction is identical to that obtained using EDC alone: The activated carboxylate reacts with an amine to give a stable amide linkage (Figure 4.3).

EDC/sulfo-NHS coupled reactions are highly efficient and usually increase the yield of conjugation significantly over that obtainable solely with EDC. Staros *et al.* (1986) showed that the addition of just 5-m*M* sulfo-NHS to the EDC coupling of glycine to keyhole limpet hemocyanin increased the yield of derivatization about 20-fold as compared to using EDC alone. This technique can also be used to create activated proteins containing sulfo-NHS esters (Grabarek and Gergely, 1990). A protein can be incubated in the presence of EDC/sulfo-NHS, the active ester form isolated and then mixed with a second protein or other amine-containing molecule for conjugation. This two-step process allows the active species to form on only one protein, thus gaining greater control over the conjugation reaction (Figure 4.4).

In addition to the potential side reactions of EDC as mentioned previously (Section 1.1, this chapter), the additional efficiency obtained by the use of a sulfo-NHS intermediate in the process may cause other problems. In some cases, the conjugation actually may be too efficient to result in a soluble or active complex. Particularly when coupling some peptides to carrier proteins, the use of EDC/sulfo-NHS often causes severe precipitation of the conjugate. Scaling back the amount of EDC/sulfo-NHS added to the reaction may be performed to solve this problem. However, eliminating the addition of sulfo-NHS altogether may have to be done in some instances to preserve the solubility of the final product.

An EDC/sulfo-NHS reaction using carboxylated particles to couple amine-containing ligands has the added advantage of creating an intermediate negatively charged particle surface, which helps maintain strong repulsion between particles and prevents aggregation during the reaction. Many types of carboxylated particles have been used in this procedure to couple biomolecules in high yield (Bartczak and Kanaras, 2011).

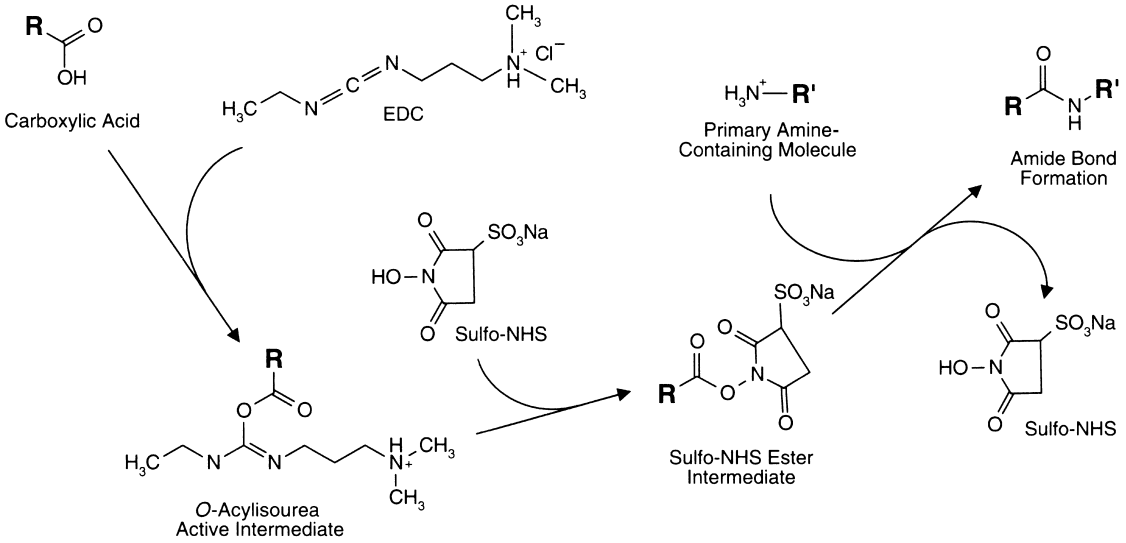

FIGURE 4.3 The efficiency of an EDC-mediated reaction may be increased through the formation of a sulfo-NHS ester intermediate. The sulfo-NHS ester is more effective at reacting with amine-containing molecules. Thus, higher yields of amide bond formation may be realized using this two-step process as opposed to using a single-step EDC reaction.

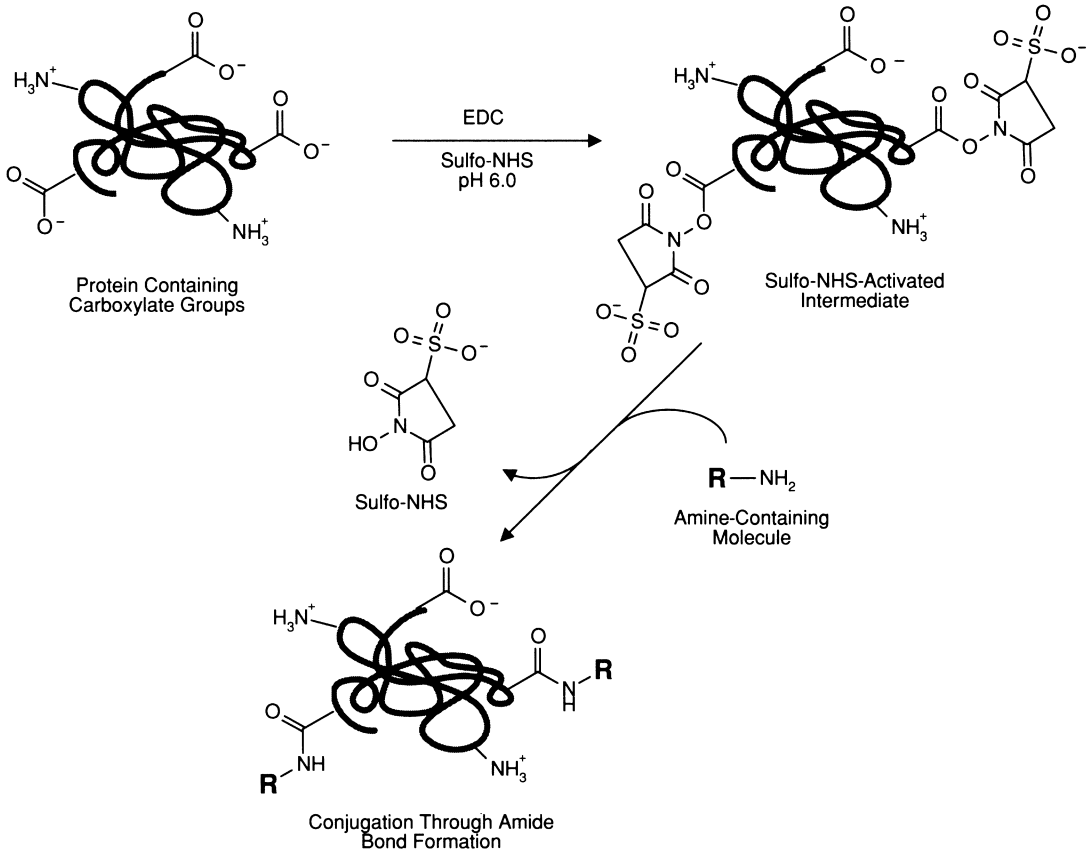

FIGURE 4.4 EDC may be used in tandem with sulfo-NHS to create an amine-reactive protein derivative containing active ester groups. The activated protein can couple with amine-containing compounds to form amide bond linkages.

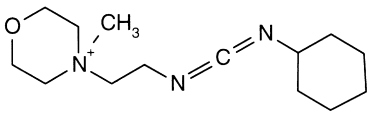
The following protocol is a generalized description of how to incorporate sulfo-NHS ester intermediates in EDC conjugation procedures. For specific applications of this technology, the amount of each reagent and unconjugated species may have to be adjusted to obtain an optimal conjugate. See also Chapter 14 and Chapter 10, Section 10, for protocols using EDC/sulfo-NHS in the coupling of proteins to particles and quantum dots, respectively.

Protocol

1. Dissolve the protein to be modified at a concentration of 1 to 10 mg/ml in 0.1-*M* sodium phosphate, pH 7.4. NaCl may be added to this buffer if desired. For the modification of keyhole limpet hemocyanin (KLH; Thermo Fisher) as described by Staros *et al.* (1986), include 0.9-*M* NaCl to maintain the solubility of this high-molecular-weight protein. If lower or higher concentrations of the protein are used, adjust the amounts of the other reactants as necessary to maintain the correct molar ratios.
2. Dissolve the molecule to be coupled in the same buffer used in step 1. For small molecules, add them to the reaction in at least a 10-fold molar excess over the amount of protein present. If possible, the molecule may be added directly to the protein solution in the appropriate excess. Alternatively, dissolve the molecule in the buffer at a higher concentration, and then add an aliquot of this stock solution to the protein solution.
3. Add the solution prepared in step 2 to the protein solution to obtain at least a 10-fold molar excess of small molecule to protein.
4. Add EDC (Thermo Fisher) to the above solution to obtain at least a 10-fold molar excess of EDC over the amount of protein present. Alternatively, a 0.05- to 0.1-*M* EDC concentration in the reaction usually works well. Also, add sulfo-NHS (Thermo Fisher) to the reaction to bring its final concentration to 5-m*M*. To make it easier to add the correct quantity of EDC or sulfo-NHS, higher concentration stock solutions may be prepared if they are dissolved and used immediately. Mix to dissolve. If this ratio of EDC/sulfo-NHS to peptide or protein results in precipitation, scale back the amount of addition until a soluble conjugate is obtained.
5. React for 2 h at room temperature.
6. Purify the conjugate by gel filtration or dialysis using the buffer of choice (for many conjugates 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, is appropriate). If some turbidity has formed during the conjugation procedure, it may be removed by centrifugation or filtration.



A modification of a two-step protocol (Grabarek and Gergely, 1990) for the activation of proteins with EDC/sulfo-NHS and subsequent conjugation with amine-containing molecules is given below. The variation in the pH of activation from that described above provides greater stability for the active ester intermediate. At pH 6.0, the amines on the protein will be protonated and therefore be less reactive toward the sulfo-NHS esters that form. In addition, the hydrolysis rate of the esters is dramatically slower at slightly acid pH. Thus, the active species may be isolated in a reasonable time frame without significant loss in conjugation potential. To quench the unreacted EDC, 2-mercaptoethanol is added to form a stable complex with the remaining carbodiimide, according to Carraway and Triplett (1970). In the following protocol, sulfo-NHS is used instead of NHS so that active ester is more water soluble and ester hydrolysis is slowed (Anjaneyulu and Staros, 1987; Thelen and Deuticke, 1988).

Protocol

1. Dissolve the protein to be activated in 0.05-*M* MES, 0.5-*M* NaCl, pH 6.0 (reaction buffer), at a concentration of 1 mg/ml.
2. Add to the solution in step 1 a quantity of EDC and sulfo-NHS (Thermo Fisher) to obtain a concentration of 2-m*M* EDC and 5-m*M* sulfo-NHS. To aid in aliquoting the correct amount of these reagents, they may be quickly dissolved in the reaction buffer at a higher concentration, and then a volume immediately pipetted into the protein solution to obtain the proper molar quantities.
3. Mix and react for 15 min at room temperature.
4. Add 2-mercaptoethanol to the reaction solution to obtain a final concentration of 20-m*M*. Mix and incubate for 10 min at room temperature. Note: If the protein being activated is sensitive to this level of 2-mercaptoethanol, instead of quenching the reaction chemically the activation may be terminated by desalting (step 5).
5. If the reaction was quenched by the addition of 2-mercaptoethanol, the activated protein may be added directly to a second protein or other amine-containing molecule for conjugation. Alternatively, or if no 2-mercaptoethanol was added, the activated protein may be purified from reaction by-products by gel filtration using a desalting resin. The desalting operation should be performed rapidly to minimize hydrolysis and recover as much active ester functionality as possible. The use of centrifugal spin columns of some sort may afford the greatest speed in purification (Thermo Fisher). After purification, add the activated protein to the second molecule for conjugation. The second protein or other

amine-containing molecule should be dissolved in 0.1-*M* sodium phosphate, pH 7.5. This will bring the pH of the coupling medium above pH 7.0 to initiate the active ester reaction.

6. React for at least 2 h at room temperature.
7. Remove excess reactants by gel filtration or dialysis.

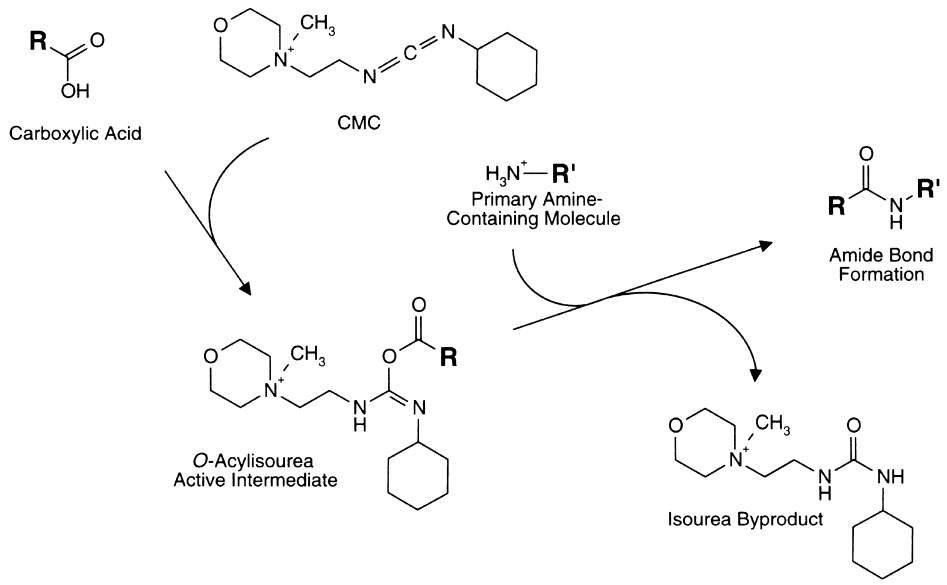
CMC
1-Cyclohexyl-3-(2-morpholinoethyl)carbodiimide
MW 423.58
(as the metho-p-toluene sulfonate salt)

1.3. CMC

CMC, or 1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide (usually synthesized as the metho *p*-toluene sulfonate salt) (Aldrich), is a water soluble reagent used to form amide bonds between one molecule containing a carboxylate and a second molecule containing an amine. The presence of the positively charged morpholino group creates its water solubility. Along with EDC (Section 1.1, this chapter), CMC is the only other water soluble carbodiimide commonly available for biological conjugations. It was first utilized in peptide synthesis (Sheehan and Hlavka, 1956) and found to be superior to other coupling agents used at the time (Ondetti and Thomas, 1965). It has also been used for the quantitative modification and estimation of total carboxyl groups in protein molecules (Hoare and Koshland, 1967) and for investigating the secondary structure of nucleic acids (Metz and Brown, 1969). Another early application area of CMC relates not to solution-phase crosslinking of two molecules but to coupling of ligands to insoluble support materials for use in affinity chromatography (Lowe and Dean, 1971; Marcus and Balbinder, 1972; Schmer, 1972). It has also been used to conjugate antibodies to quantum dots (East *et al.*, 2011).

CMC reacts with carboxylate groups by addition of the carboxyl across one of its diimide bonds, resulting in the characteristic active ester, *O*-acylisourea intermediate common to all carbodiimide mechanisms. Nucleophilic attack on this intermediate yields the acylated product—usually an amide bond, resulting from the reaction with a primary amine (Figure 4.5). However, carbodiimide chemistry does create several potential side-reactions. Sulfhydryl groups may react with CMC to form a stable covalent complex unreactive toward further conjugation. The reagent may also react with phenols, alcohols, and other nucleophiles to quench the crosslinking reaction. In aqueous solutions, hydrolysis of the carbodiimide and the active ester are by far the most frequent side-reactions. Reaction of the ester with water molecules regenerates the carboxylate and releases a soluble isourea by-product.

CMC should be able to participate in the two step reaction using a sulfo-NHS ester intermediate similar to EDC, however there are no reports in the literature to this effect. Protocols for the use of this reagent in biological crosslinking applications should be essentially the same as those given previously for EDC, except substituting a molar equivalent quantity of CMC. See Section 1.1 and 1.2 in this chapter for additional information concerning carbodiimide reactions.



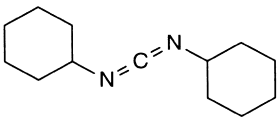


FIGURE 4.5 The water soluble carbodiimide CMC reacts with carboxylates to form an active-ester intermediate. In the presence of amine-containing molecules, amide bond formation can take place with release of an isourea byproduct.

1.4. DCC

DCC (dicyclohexyl carbodiimide) is one of the most frequently used coupling agents, especially in organic synthesis applications. It has been used for peptide synthesis since 1955 (Sheehan and Hess, 1955) and continues to be a popular choice for creating peptide bonds (Barany and Merrifield, 1980). DCC is water-insoluble, but it has been used in 80% DMF for the immobilization of small molecules onto carboxylate-containing chromatography supports for use in affinity separations (Larsson and Mosbach, 1971; Gutteridge and Robb, 1973; Lowe *et al.*, 1973). In addition to forming amide linkages, DCC has been used to prepare active esters of carboxylate-containing compounds using NHS or sulfo-NHS (Staros, 1982). Unlike the EDC/sulfo-NHS reaction described in Section 1.2 (this chapter), active ester synthesis with DCC typically is carried out in organic solvent and therefore does not have the hydrolysis problems of water soluble EDC-formed esters. Thus, DCC is most often used to synthesize active ester containing crosslinking and modifying reagents and not to perform biomolecular conjugations.

DCC
N,N'-Dicyclohexyl carbodiimide
MW 206.32

DCC is a waxy solid that is often difficult to remove from a bottle. Its vapors are extremely hazardous to inhalation and to the eyes. It should always be handled in a fume hood. The isourea byproduct of a DCC-initiated reaction, dicyclohexyl urea (DCU) (Figure 4.6), is also water insoluble and must be removed by organic solvent washing. For synthesis of peptides or affinity supports on insoluble matrices this is not a problem, because washing of the support material can be performed without disturbing the conjugate coupled to the support. For solution-phase chemistry, however, reaction products must be removed by solvent washings, precipitations, or recrystallizations.

A potential undesirable effect of DCC coupling reactions is the spontaneous rearrangement of the *O*-acylisourea to an inactive *N*-acylurea (Stewart and Young, 1984) (Figure 4.7). The rate of this rearrangement is dramatically increased in aprotic organic solvents, such as DMF. Another potential problem with using DCC to create active ester, such as in the synthesis of NHS esters, is a side reaction that can occur with NHS to create a bifunctional crosslinking agent in solution (Chapter 15, Section 2.1) (Wilchek and Miron, 1987). If a reaction involving the carbodiimide DCC with added NHS is used to create the NHS ester groups on a carboxylate support under nonaqueous conditions, as is also typical for synthesizing most NHS ester-containing bioconjugation reagents, the formation of a *bis*-NHS derivative of β-alanine can be created at the same time that NHS esters are being formed with the carboxylate spacers on the matrix. This side reaction results from the initial interaction of DCC with the hydroxyl on NHS to

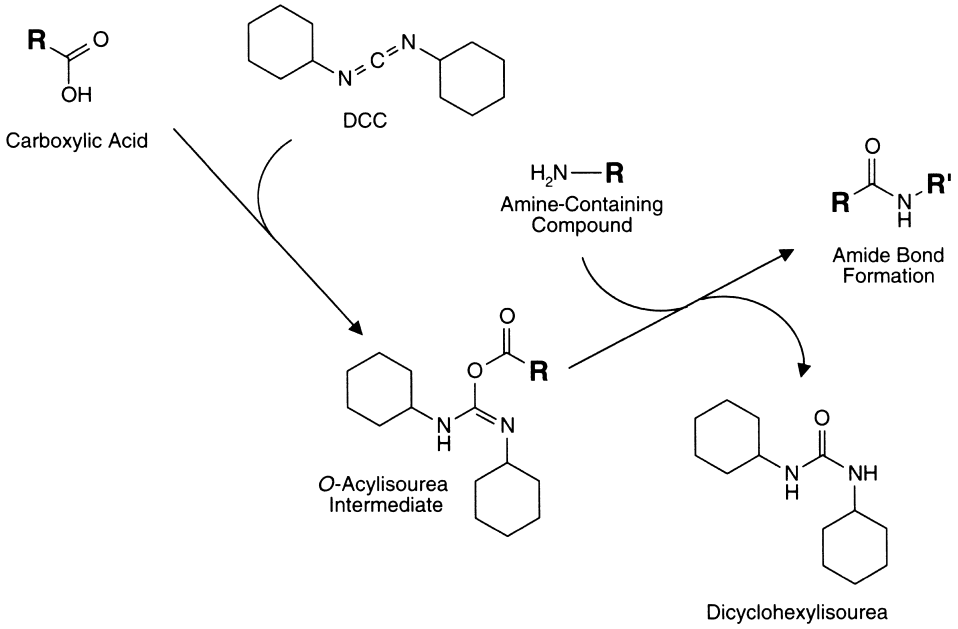

FIGURE 4.6 The organic-soluble carbodiimide DCC is often used to create amide bonds, especially between water-insoluble compounds.

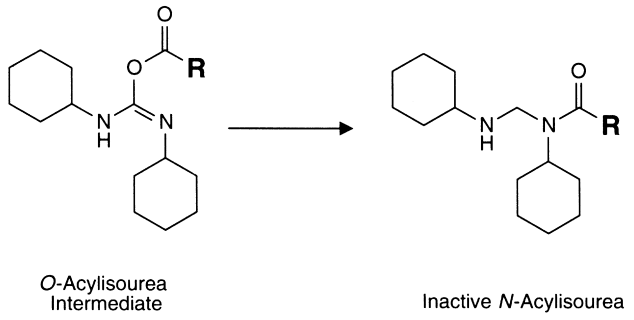

FIGURE 4.7 The active-ester intermediate formed from the reaction of DCC with a carboxylate group may undergo rearrangement to an inactive *N*-acylisourea product.

form a carbodiimide-activated NHS group. This ability of carbodiimides to react with hydroxyl groups correlates to the reported activation of hydroxyls on chitosan using the carbodiimide EDC (Chiou and Wu, 2004).

The activation efficiency of DCC is extraordinarily high, especially in anhydrous solutions that do not have competing hydrolysis problems. *O*-Acylisourea-activated carboxylates may undergo two side reactions that form other active groups. If DCC is added to an excess of a carboxylate-containing molecule without the presence of an amine-containing target, then the activated carboxylate may react with another carboxylic acid to form a symmetrical anhydride (Figure 4.8). The formation of an anhydride intermediate may be a frequent mechanism an route to the creation of an amide bond with an amine, especially under anhydrous conditions (Rebek and Feitler, 1974; Nakajima and Ikada, 1995). In addition, a DCC-activated carboxylate may react with an amino acid to form an azlactone (Figure 4.9) (Coleman *et al.*, 1990). Both the anhydride and the azlactone will react with amines to form covalent amide linkages. However, the ring-opening reaction of an azlactone will form a different product than the zero-length crosslinking result of coupling directly to an amine-containing molecule (Figure 4.10) (Chapter 15, Section 2.1). Finally, if DCC is used in the presence of NHS under anhydrous conditions, a bifunctional crosslinking product may result from a series of reactions that activate and then open up the NHS ring and form amine-reactive groups at both ends of a beta-alanine cross-bridge. See Chapter 15, Figure 15.42, for an illustration of this reaction.

1.5. DIC

DIC, or diisopropyl carbodiimide, is another water-insoluble amide bond-forming agent that has advantages over DCC (Section 1.4, this chapter). It is a liquid at room temperature and is therefore much easier to dispense than DCC. The byproducts of

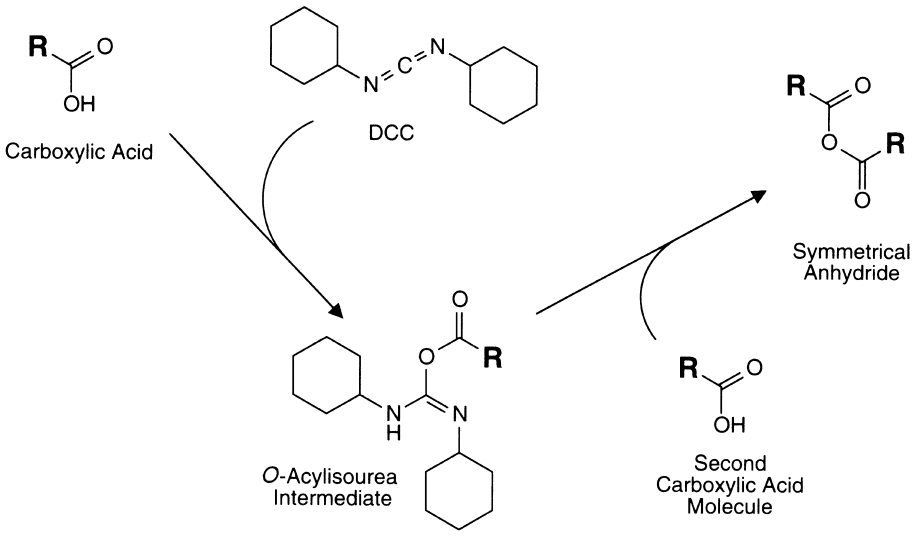

FIGURE 4.8 The reaction of DCC with a carboxylate compound in excess may create anhydride products in the absence of nucleophiles.

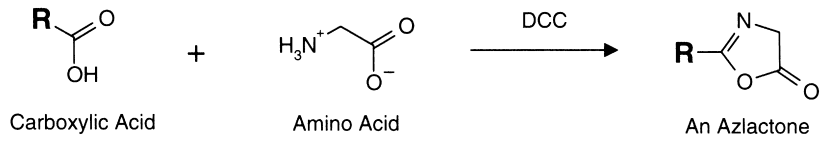

FIGURE 4.9 A DCC-mediated reaction with a carboxylate group in the presence of a small amino acid may form azlactone rings.

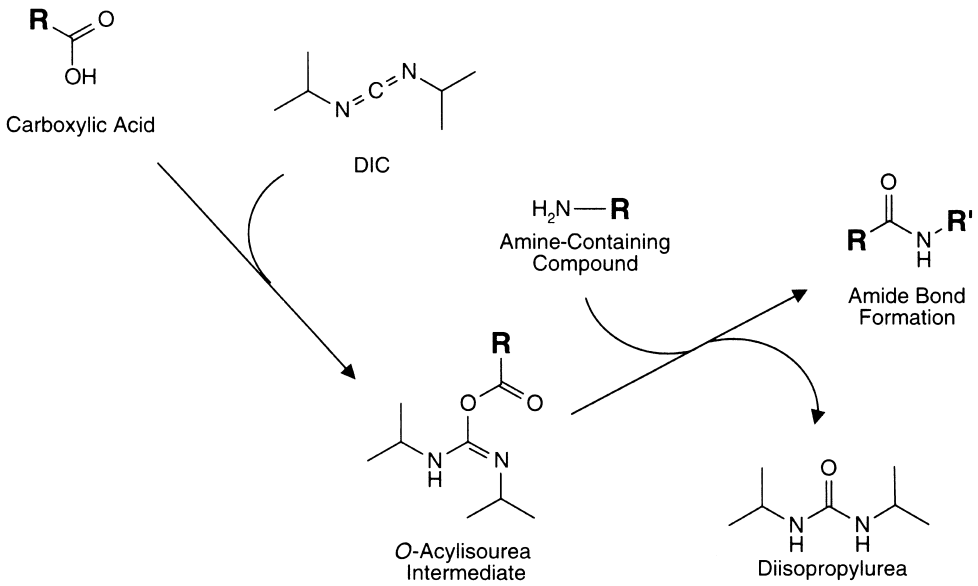
FIGURE 4.10 An azlactone reacts with an amine group through a ring-opening process, creating an amide bond linkage with the attacking nucleophile.



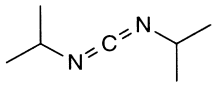


FIGURE 4.11 The symmetrical carbodiimide DIC reacts with carboxylates to form active-ester intermediates able to couple with amine-containing compounds to form amide bond linkages.

its activation reaction with a carboxylate, diisopropylurea and diisopropyl-*N*-acylurea, are more soluble in organic solvents than the DCU byproduct of a DCC reaction. DIC reacts similarly to DCC, forming an active *O*-acylisourea intermediate with a carboxylic acid group (Figure 4.11). This active species may then react with a nucleophile such as an amine to form an amide bond. Presumably, all the possible side reactions that DCC may undergo are also possible with DIC, although it is not well documented.

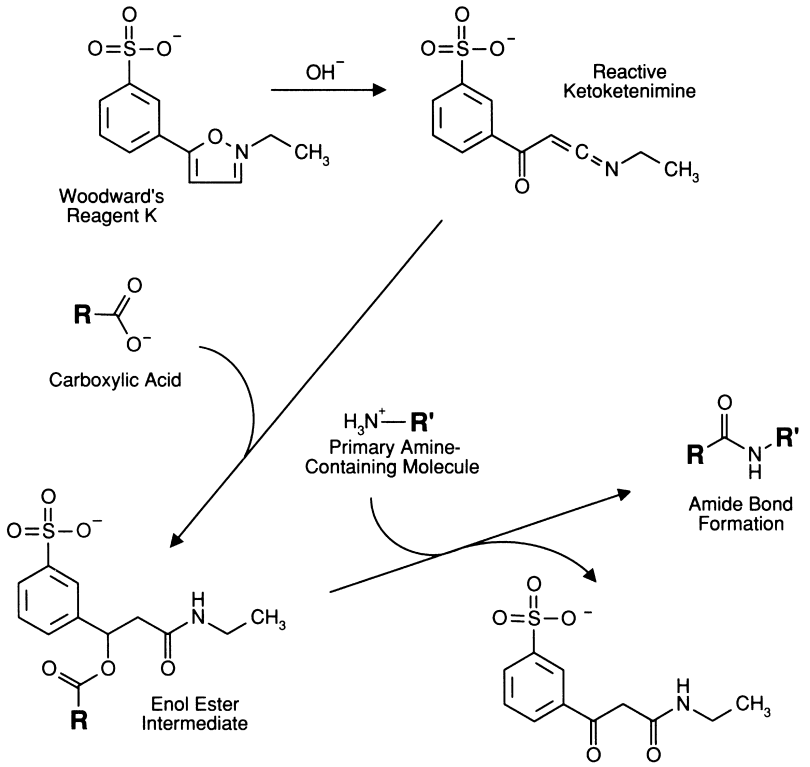
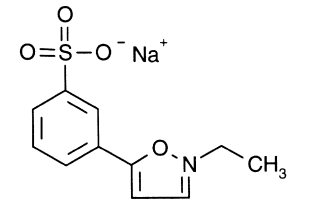
2. WOODWARD'S REAGENT K

Woodward's reagent K is *N*-ethyl-3-phenylisoxazolium-3′-sulfonate, a zero-length crosslinking agent able to cause the condensation of carboxylates and amines to form amide bonds (Woodward *et al.*, 1961; Woodward and Olofson, 1961). The reaction mechanism involved in activating a carboxylate includes the conversion of the reagent under alkaline conditions to a reactive ketoketenimine. This intermediate then reacts with a carboxylate to create an enol ester. The enol ester is highly susceptible to nucleophilic attack. The reaction with an amine proceeds to amide bond formation with loss of the inactive diketo derivative (Figure 4.12). In aqueous solution, the major side reaction is hydrolysis, which occurs rapidly (Dunn and Affinsen, 1974). Although Woodward's reagent K has been used successfully for conjugation applications with proteins and other molecules to form amide linkages (Boyer, 1986; Pikuleva and Turko, 1989), its mechanism of reaction was called into question by Johnson and Dekker (1996), who found that the compound reacted with cysteine and histidine groups in *E. coli* L-threonine dehydrogenase, not the available aspartate or glutamate groups. Woodward's reagent K is available from Fluka.





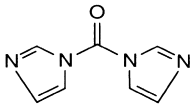


FIGURE 4.12 Woodward's reagent K undergoes a rearrangement in alkaline solution to form a reactive ketoketenimine. This active species can react with a carboxylate group to create another active group, an enol ester derivative. In the presence of amine nucleophiles, amide bond formation takes place.

to form amide bonds or with hydroxyl groups to form ester linkages (Figure 4.13). Both reaction mechanisms have been used successfully in peptide synthesis (Paul and Anderson, 1960, 1962). In addition, activation of a styrene/4-vinylbenzoic acid copolymer with CDI was used to immobilize the enzyme lysozyme through its available amino groups to the carboxyl groups on the matrix (Bartling *et al.*, 1973). Other carboxylate-containing polymers have also been activated with CDI to form bioconjugates useful even in therapeutic applications (Peng *et al.*, 2011).

3. N, N′-CARBONYL DIIMIDAZOLE

CDI, or *N,N′*-carbonyl diimidazole, is a highly active carbonylating agent that contains two acylimidazole leaving groups (Aldrich). The result is that CDI can activate carboxylic acids or hydroxyl groups for conjugation with other nucleophiles, creating either zero-length amide bonds or one-carbon-length *N*-alkyl carbamate linkages between the crosslinked molecules. Carboxylic acid groups react with CDI to form *N*-acylimidazoles of high reactivity. The active intermediate forms in excellent yield due to the driving force created by the liberation of carbon dioxide and imidazole (Anderson, 1958). The active carboxylate can then react with amines

CDI functions as a zero-length crosslinker if the activated species is a carboxylic acid, because the attack of another nucleophile liberates the imidazole leaving group. However, if CDI is used to activate a hydroxyl functional group, the reaction proceeds quite differently. The active intermediate formed by the reaction of CDI with an OH group is an imidazolyl carbamate

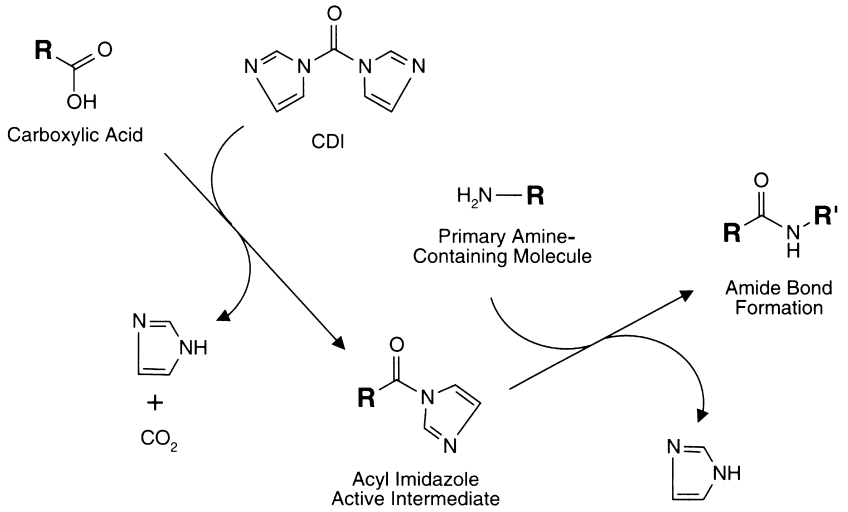

FIGURE 4.13 CDI reacts with carboxylate groups to form an active acylimidazole intermediate. In the presence of an amine nucleophile, amide bond formation can take place with release of imidazole.

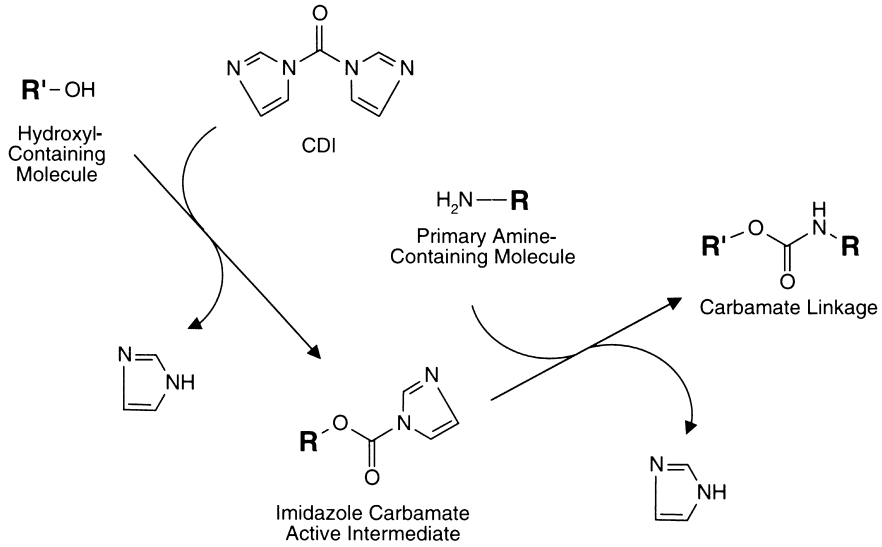

FIGURE 4.14 CDI reacts with hydroxyl groups to form an active imidazole carbamate intermediate. In the presence of amine-containing compounds, a carbamate linkage is created with loss of imidazole.

(Figure 4.14). Attack by an amine releases the imidazole, but not the carbonyl. Thus, a hydroxyl-containing molecule may be coupled to an amine-containing molecule with the result of a one-carbon spacer and formation of a stable urethane (*N*-alkyl carbamate) linkage. This coupling procedure has been applied to the activation of hydroxyl-containing chromatography supports for the immobilization of amine-containing affinity ligands (Chapter 15, Section 2.1; Chapter 14, Section 4.2) (Bethell *et al.*, 1979; Hearn *et al.*, 1979, 1983; Hermanson *et al.*, 1992) and also to the activation of polyethylene glycol for the modification of amine-containing macromolecules (Chapter 18, Section 2.1) (Beauchamp *et al.*, 1983).

CDI-activated hydroxyls may also undergo a side reaction to form active carbonates. This occurs when an imidazolyl carbamate reacts with another hydroxyl group before the second hydroxyl has had a chance to get activated with CDI. Particularly with adjacent hydroxyls on the same molecule, this can be a problem if a defined reactive species is desired. Any carbonates formed, however, are still reactive toward amines to create carbamate linkages.

Formation of the activated species, whether with a carboxylate or a hydroxyl, must take place in non-aqueous environments due to the rapid breakdown of CDI by hydrolysis. Even in solvents containing small amounts of water, CDI quickly hydrolyzes to

CO_2 and imidazole. It is best to use solvents with less than 0.1% water to prevent extensive CDI breakdown. Characteristic bubble formation is an indication of reagent hydrolysis, although CO_2 also is released upon reaction with a carboxylic acid. Activation of carboxylates or hydroxyls may be performed in dry organic solvents such as acetone, dioxane, DMSO, THF, DMAC, or DMF. If an excess of CDI is used during the activation step, it should be removed before adding the active intermediate to an amine-containing molecule for conjugation. Alternatively, equal molar quantities of CDI and the molecule to be activated may be mixed to form the active species. After about an hour of activation, add an equivalent molar quantity of the amine-containing target molecule to be conjugated.

Aqueous reaction conditions that result in the best conjugation yields using CDI usually reflect the relative pK_a of the nucleophilic amine being coupled. Proteins are best coupled to CDI-activated supports or molecules in an environment at least one pH unit above their pI values. Frequently, the greatest coupling yields occur in alkaline buffers within the range of pH 8.0 to 10.0. In aqueous solutions, CDI-activated carboxylates or hydroxyls will hydrolyze and slowly lose activity. *N*-Acylimidazoles hydrolyze by loss of imidazole and regenerate the original carboxylate. The imidazole carbamate active species hydrolyzes by loss of CO_2 and imidazole, regenerating, in this case, the original hydroxyl group. CDI-activated carboxylic acids hydrolyze faster in aqueous solutions than CDI-activated hydroxyls; however, both reactive intermediates undergo increasing hydrolysis with increasing pH.

Conjugation or immobilization reactions using CDI may also be performed in organic solutions (Chapter 15, Section 2.1). This is a distinct advantage if the reactants are not very soluble in aqueous environments. In addition, organic coupling will not result in concomitant loss of activity due to hydrolysis as water-based reactions, thus nonaqueous reactions will usually provide greater yields.

A protocol for the use of CDI in the activation of poly(ethylene glycol) is discussed in Chapter 18, Section 2.1, while CDI activation procedures for particles are described in Chapters 14 and 15.

4. SCHIFF BASE FORMATION AND REDUCTIVE AMINATION

Aldehydes and ketones can react with primary and secondary amines to form Schiff bases. A Schiff base is a relatively labile bond that is readily reversed by hydrolysis in aqueous solution. The formation of Schiff bases is enhanced at alkaline pH values, but they are still not completely stable unless reduced to secondary

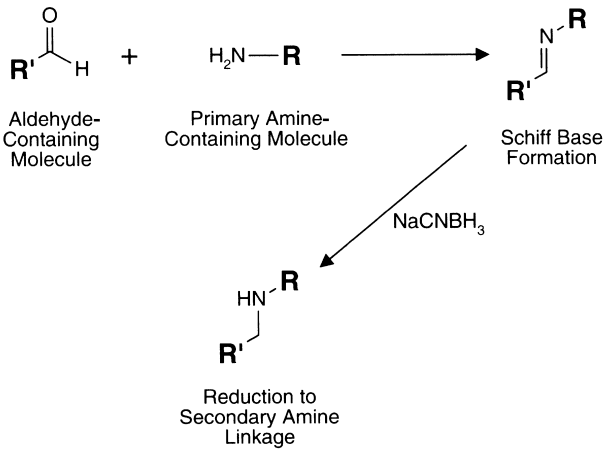

FIGURE 4.15 Carbonyl groups such as in aldehydes and ketones can react with amine nucleophiles to form reversible Schiff base intermediates. In the presence of a suitable reductant, such as sodium cyanoborohydride, the Schiff base is stabilized to a secondary amine bond.

or tertiary amine linkages (Figure 4.15). A number of reducing agents can be used to convert specifically the Schiff base into an alkylamine linkage. Once reduced, the bonds are highly stable. The use of reductive amination to conjugate an aldehyde-containing molecule to an amine-containing molecule results in a zero-length crosslink where no additional spacer atoms are introduced between the molecules.

Reductive amination (or alkylation) may be used to conjugate an aldehyde- or ketone-containing molecule with an amine-containing molecule. The reduction reaction is best facilitated by the use of a reducing agent such as sodium cyanoborohydride, because the specificity of this reagent is toward the Schiff base structure and will not affect the original aldehyde groups. By contrast, sodium borohydride is also used in this reaction, but its strong reducing power rapidly converts any aldehydes not yet reacted into nonreactive hydroxyls, effectively eliminating them from further participation in the conjugation process. Borohydride may also affect the activity of some sensitive proteins, whereas cyanoborohydride is gentler, successfully preserving the activity of even some labile monoclonal antibodies. Cyanoborohydride has been shown to be at least five times milder than borohydride in reductive amination processes with antibodies (Peng *et al.*, 1987). Other reducing agents that have been explored for reductive amination include various amine boranes and ascorbic acid (Cabacungan *et al.*, 1982; Hornsey *et al.*, 1986).

Immobilization by reductive amination of amine-containing biological molecules onto aldehyde-containing solid supports has been used for quite some time (Sanderson and Wilson, 1971). The reaction proceeds with excellent efficiency (Domen *et al.*, 1990). The

optimum pH for the reaction is alkaline, although good yield can be realized from pH 7 to 10. At the high end of this range (pH 9–10), the formation of the Schiff bases is more efficient, and the yield of conjugation or immobilization reactions can be dramatically increased (Hornsey *et al.*, 1986) (see Chapter 15, Section 2.1).

The introduction of aldehyde functional groups into proteins and other molecules can be accomplished by a number of methods (Chapter 2, Section 4.4). Glycoproteins may be oxidized at their carbohydrate residues using sodium periodate or by using a specific sugar oxidase. Amine groups may be modified to produce a formyl group by reacting with NHS–aldehyde compounds (Chapter 17, Section 2) or *p*-nitrophenyl diazopyruvate. The following generalized protocol assumes that the requisite groups are present on the two molecules to be conjugated.

Protocol

1. Dissolve the amine-containing protein to be conjugated at a concentration of 1 to 10 mg/ml in a buffer having a pH between 7 and 10. Higher pH reactions will result in greater yield of conjugate formation. Suitable buffers include 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2; 0.1-*M* sodium borate, pH 9.5; or 0.05-*M* sodium carbonate, 0.1-*M* sodium citrate, pH 9.5. Avoid amine-containing buffers like Tris.
2. Add a quantity of the aldehyde-containing molecule to the solution in step 1 to obtain the desired molar ratio for conjugation. For instance, if the amine-containing protein is an antibody and the aldehyde-containing protein is an enzyme such as horseradish peroxidase (HRP), a typical molar ratio for the reaction might be 2 to 4 moles of HRP per mole of antibody.
3. Add 10 µl of 5-*M* sodium cyanoborohydride in 1-*N* NaOH (Aldrich) per ml of the conjugation solution volume. *Caution: Highly toxic compound. Use a fume hood and be careful to avoid skin contact with this reagent.*
4. React for 2 h at room temperature.
5. To block unreacted aldehyde sites, add 20 µl of 3-*M* ethanolamine (pH adjusted to desired value with HCl) per ml of the conjugation solution volume. React for 15 min at room temperature.
6. Purify the conjugate by dialysis or gel filtration using a buffer suitable for the nature of the proteins being crosslinked.

CHAPTER

5

Homobifunctional Crosslinkers

The first crosslinking reagents used for modification and conjugation of macromolecules consisted of bireactive compounds containing the same functionality at both ends (Hartman and Wold, 1966). Most of these homobifunctional reagents were symmetrical in design with a carbon chain spacer connecting the two identical reactive ends (Figure 5.1). Like molecular rope, these reagents could tie one protein to another by covalently reacting with the same common groups on both molecules. Thus, the lysine ε-amines or N-terminal amines of one protein could be crosslinked to the same functionalities on a second protein simply by mixing the two together in the presence of the homobifunctional reagent.

The ability to so easily link two proteins or other molecules having different binding specificities or catalytic activities opened the potential for creating a new universe of unique and powerful reagent systems for use in assay and targeting applications. The variety and reactivity of homobifunctional reagents multiplied dramatically throughout the 1970s and 1980s. Today, there are dozens of commercially available crosslinkers possessing almost every length and reactivity desired.

The main disadvantage, however, of using simple homobifunctional reagents is the potential for creating a broad range of poorly defined conjugates (Avramease, 1969). When crosslinking two proteins, for example, the reagent may react initially with either one of the proteins, forming an active intermediate. This activated protein may form crosslinks with the second protein or react with another molecule of the same type. It also may react intramolecularly with other functional groups on part of its own polypeptide chain. In addition, other crosslinking molecules may continue to react with these intermediates to form various mixed oligomers, including severely polymerized products that may even precipitate (see Chapter 2, Section 1.2).

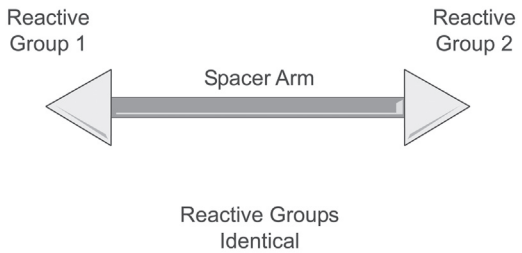

FIGURE 5.1 The general design of a homobifunctional crosslinking agent. The two reactive groups are identical and typically are located at the ends of an organic spacer arm. The length of the spacer may be designed to accommodate the optimal distance between two molecules to be conjugated.

The problem of poorly defined conjugation products is exacerbated in single-step reaction procedures using homobifunctional reagents. Single-step procedures involve the addition of all reagents at the same time to the reaction mixture. This technique provides the least control over the crosslinking process and invariably leads to a multitude of products, only a small percentage of which represent the desired conjugate. Excessive conjugation may cause the formation of insoluble complexes that consist of very high-molecular-weight polymers. For example, one-step glutaraldehyde conjugation of antibodies and enzymes (Chapter 20, Section 1.2) often results in significant oligomers and precipitated conjugates. To overcome this shortcoming, two-step reaction procedures have been developed using homobifunctional reagents. Controlled, two-step conjugation protocols somewhat alleviate the polymerization problem with homobifunctional reagents, but can never totally avoid it.

In two-step protocols, one of the proteins to be conjugated is reacted with the homobifunctional reagent and excess crosslinker and byproducts are removed. In the second stage, the activated protein is mixed with the other protein or molecule to be conjugated, and the final conjugation process occurs (Figure 5.2).

One potential problem of such two-step procedures is hydrolysis of the activated intermediate before addition of the second molecule to be conjugated. For instance, *N*-hydroxysuccinimide (NHS) ester homobifunctional reagents hydrolyze in aqueous buffers and may degrade before the second stage of the crosslinking is initiated. In addition, the use of homobifunctional reagents in

Bioconjugate Techniques, Third Edition.

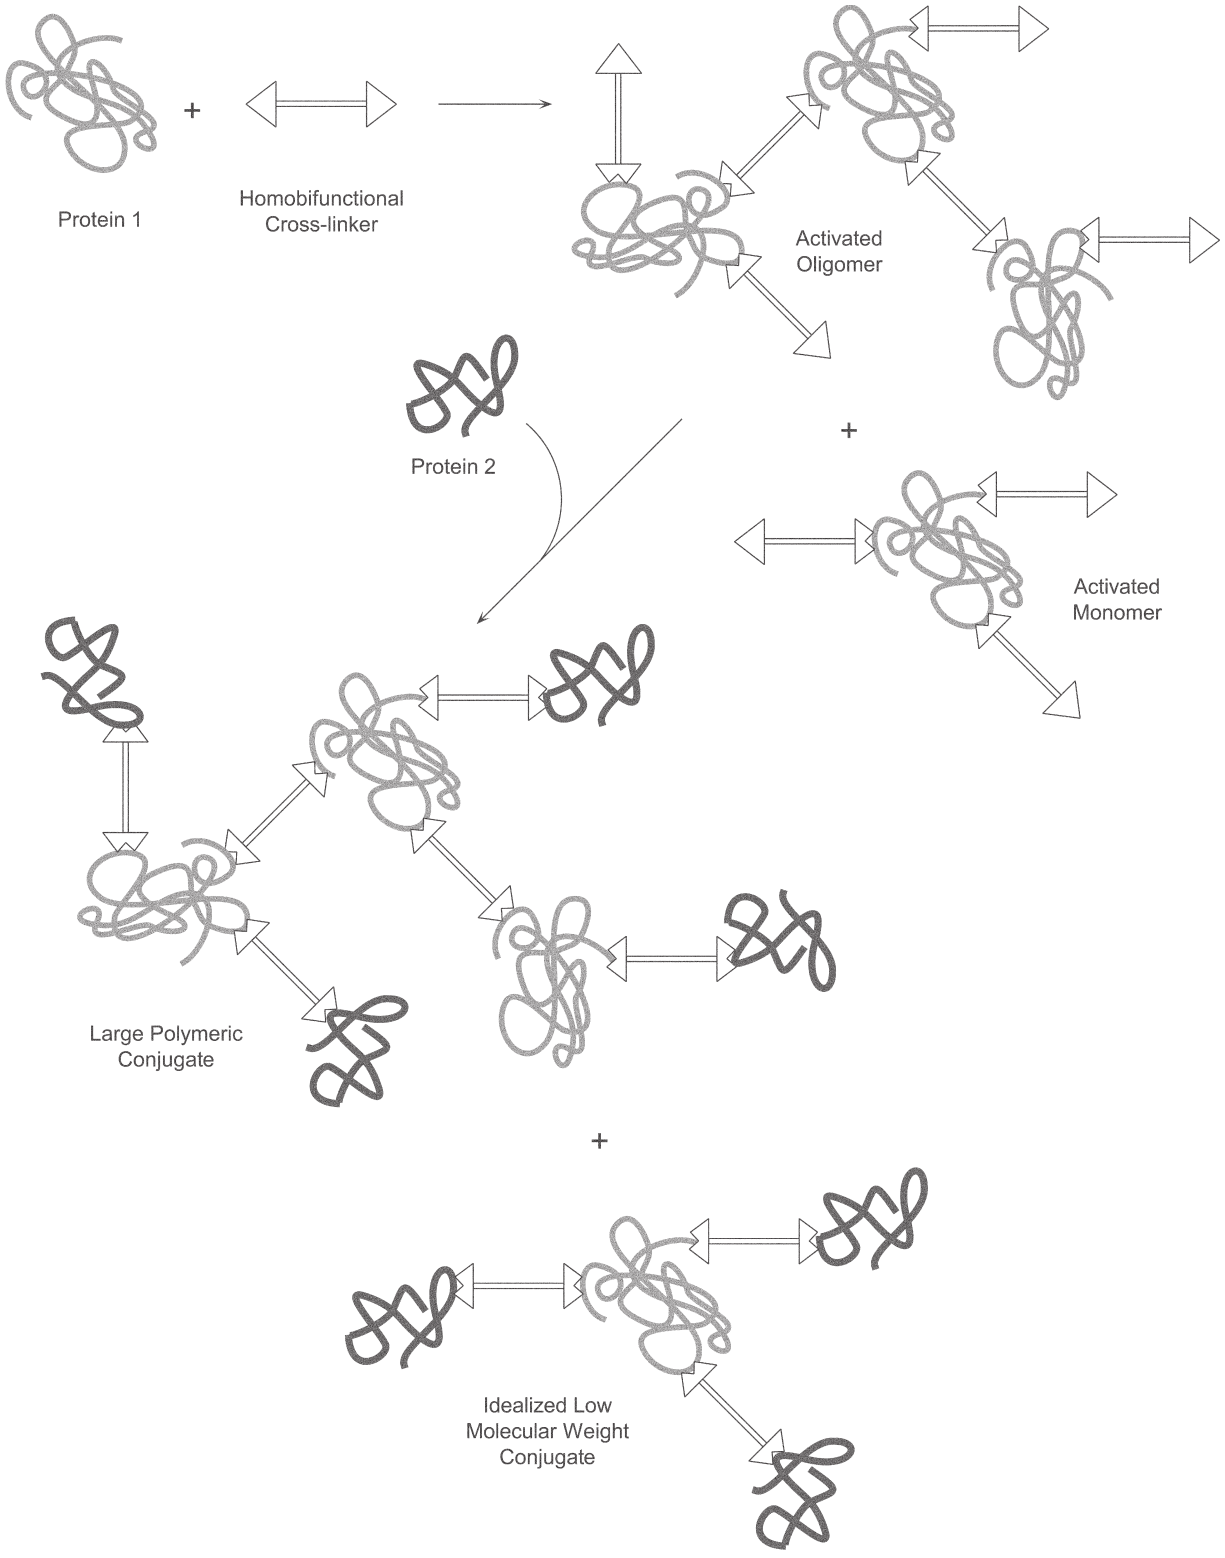

FIGURE 5.2 Homobifunctional crosslinkers may be used in a two-step process to conjugate two proteins or other molecules. In the first step, one of the two proteins is reacted with the crosslinker in excess to create an active intermediate. After removal of remaining crosslinker, a second protein is added to effect the final conjugate. Two-step reaction schemes somewhat limit the degree of polymerization obtained when using homobifunctional reagents, but can't entirely prevent it.

two-step protocols still produces many of the problems associated with single-step procedures, because the first protein can crosslink and polymerize with itself long before the second protein is added. Since the first protein to be activated has target functional groups on every molecule that can couple with both reactive groups of the crosslinker, both ends of the reagent potentially can react. This inherent capacity to polymerize uncontrollably is unfortunately a characteristic of all homobifunctional reagents, even in multi-step protocols.

Although their shortcomings in this regard are clearly recognized, homobifunctional reagents continue to be popular choices for all kinds of conjugation applications, including in the preparation of immobilized antibodies used for biosensor surfaces (Hansberry and Clark, 2012) and in the generation of complex bispecific antibodies (Ellerman and Scheer, 2011). The fact is, in many crosslinking functions, they work well enough to form effective conjugates. Even glutaraldehyde-mediated antibody–enzyme conjugates are still commonly utilized in everything from research to diagnostics.

The particular crosslinkers discussed in this section are the types most often referred to in the literature or are commercially available. Many other forms of homobifunctional reagents containing almost every conceivable chain length and reactivity are mentioned in the scientific literature.

1. HOMOBIFUNCTIONAL NHS ESTERS

Carboxylate groups activated with *N*-hydroxysuccinimide (NHS) esters are highly reactive toward amine nucleophiles. In the mid-1970s, NHS esters were introduced as reactive ends of homobifunctional crosslinkers (Bragg and Hou, 1975; Lomant and Fairbanks, 1976). Their excellent reactivity at physiological pH quickly established NHS esters as viable alternatives to the imidoesters predominating at the time (Section 2, this chapter).

Unfortunately, many NHS ester-containing crosslinkers are insoluble in aqueous buffers. Most protocols involve dissolving the compound at a relatively high concentration in an organic solvent and transferring the required quantity into the reaction medium. Prior dissolution helps to maintain at least some solubility in the buffered crosslinking environment. Most of the time, however, the addition of an organic-solvent-solubilized crosslinker into a buffered solution will result in a microprecipitate that slowly goes into solution during the course of reaction.

In the early 1980s, Staros prepared a derivative of NHS that aids in the water solubility of NHS ester crosslinkers (Staros, 1982). *N*-Hydroxysulfosuccinimide (sulfo-NHS) esters possess a negatively charged sulfonate group on

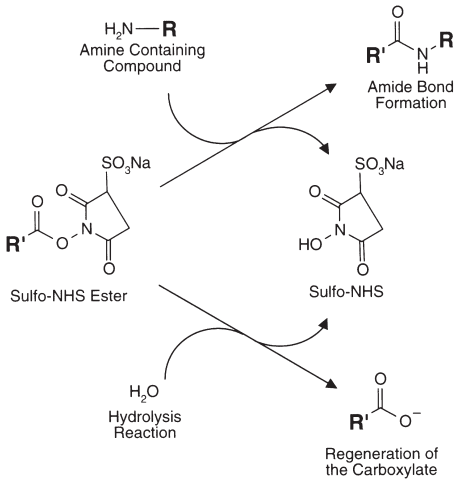

FIGURE 5.3 In aqueous solution, a sulfo-NHS ester can either couple to an amine group to form an amide bond or react with water to hydrolyze back to a carboxylate. Both processes release the sulfo-NHS leaving group.

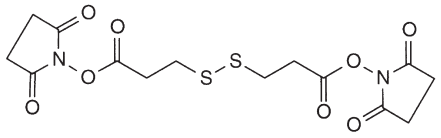
carbon number 2 or 3 of the succinimido ring (Figure 5.3). Crosslinking reagents containing sulfo-NHS esters have half-lives of hydrolysis of the order of hours, sometimes even better than their NHS ester analogs (Anjaneyula and Staros, 1987). The sulfo-NHS ester often lends enough charge and polarity to a crosslinker to provide water solubility and thus eliminate the need for organic solvent dissolution. In addition, sulfo-NHS crosslinkers may be used for surface-only modification of membranes and cells, since they are more hydrophilic and will not penetrate the lipid environment of the membrane (Robertson *et al.*, 1986). By contrast, many of the more hydrophobic NHS ester crosslinkers can be used to traverse the cell membrane and modify intracellular components.

NHS- or sulfo-NHS ester-containing homobifunctional crosslinkers react with nucleophiles to release the NHS or sulfo-NHS leaving group and form an acylated product. The reaction of such esters with a sulfhydryl or hydroxyl group is possible but does not yield stable conjugates, as it forms thioesters and ester linkages which may hydrolyze in aqueous environments. Histidine side-chain nitrogens of the imidazolyl ring also may be acylated with an NHS ester reagent, but they too hydrolyze rapidly (Cuatrecasas and Parikh, 1972). Reaction with primary and secondary amines, however, creates stable amide and imide linkages, respectively, that don't readily break down. In protein molecules, NHS ester crosslinking reagents primarily react with the α-amines at the N-terminals and the abundant ε-amines of lysine side chains.

NHS ester crosslinking reactions in aqueous solutions offer the potential for hydrolysis as well as the desired amide bond formation. Crosslinkers containing NHS esters have fairly good stability in aqueous solutions,

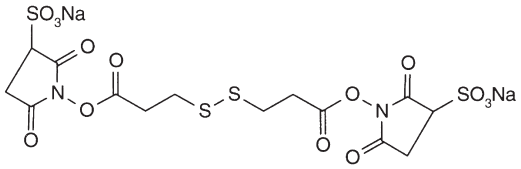
despite their susceptibility to attack and breakdown by water. Studies done on the NHS ester-containing homobifunctional reagent, dithiobis(succi-nimidylpropionate) (DSP), indicate that the activated carboxylates have half-lives on the order of hours at physiological pH. However, hydrolysis and amine reactivity both increase with increasing pH. At 0°C at pH 7.0, the half-life of the crosslinking reagent DSP is 4 to 5 h (Lomant and Fairbanks, 1976). At pH 8.0 at 25°C it falls to about 1 h (Staros, 1988), and at pH 8.6 and 4°C the half-life is only 10 min (Cuatrecasas and Parikh, 1972).

The rate of hydrolysis may be monitored by measuring the increase in absorption at 260 nm as the NHS leaving group is cleaved. The molar extinction coefficient of the NHS group in solution is $8.2 \times 10^3\,M^{-1}\,cm^{-1}$ in Tris buffer at pH 9.0 (Carlsson *et al.*, 1978), but somewhat decreases to $7.5 \times 10^3\,M^{-1}\,cm^{-1}$ in potassium phosphate buffer at pH 6.5 (Partis *et al.*, 1983). Unfortunately, the sensitivity of assay using absorption usually does not allow for measuring the rate of reaction in an actual crosslinking procedure.



To maximize the modification of amines and minimize the effects of hydrolysis, maintain a high concentration of protein or other target molecule. By adjusting the molar ratio of crosslinker to target molecule(s), the level of modification and conjugation may be controlled to create an optimal product.

The reaction buffer chosen for the conjugation reaction should be free of extraneous amines. Avoid Tris or glycine buffers. Also, avoid imidazole buffers, since the nitrogens of the imidazole ring may react with the active ester and then quickly hydrolyze. The effect is that imidazole only acts to catalyze the hydrolysis process. The pH of the reaction should be in the range of 7 to 9 to promote the unprotonated state of primary amines, which is the nucleophilic species that most effectively attacks the activated carbonyl group. Dissolve NHS ester crosslinkers that are insoluble in water in an organic solvent such as DMF or DMSO prior to addition to the reaction medium. Sulfo-NHS crosslinkers may be added directly to the reaction mixture or pre-dissolved in buffer at a higher concentration before adding an aliquot to the reaction. Aqueous stock solutions should be used immediately to prevent extensive hydrolysis of the active esters.



NHS ester crosslinking reagents also may be used in organic solvent-based reactions without the competing hydrolysis problem provided the target molecules are soluble and stable in such environments. In this case, both molecules to be conjugated must be soluble in the solvent. DMF, DMSO, acetone, and dioxane are examples of solvents that can be utilized as the reaction medium. Refer to any published solubility data on the crosslinking reagent of choice to see which solvents are most appropriate.

1.1. DSP and DTSSP

Lomant's reagent [(dithiobis(succinimidylpropionate), or DSP]) is a homobifunctional NHS ester crosslinking agent containing an eight-atom spacer 12 Å in length (Lomant and Fairbanks, 1976) (Thermo Fisher). It is symmetrically constructed around a central disulfide group that is cleavable after conjugation with typical disulfide reducing agents (Chapter 2, Section 4.1).

DSP
Dithiobis(succinimidylpropionate)
MW 404.42
12 Å

DTSSP
3,3'-Dithio*bis*(sulfosuccinimidylpropionate)
Water Soluble
MW 608.51
12 Å

DSP is water insoluble and must be pre-dissolved in an organic solvent before addition to a conjugation reaction. Concentrated stock solutions may be prepared in DMF or DMSO and an aliquot added to a buffered reaction medium. The NHS ester reaction occurs most efficiently at pH 7 to 9, with hydrolysis of the active species accelerating the greater the pH. The crosslinking buffers should be free of amine-containing components other than the target molecules to be conjugated. Avoid Tris or glycine buffers. A reaction buffer consisting of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 to 7.5 works well for most applications involving the crosslinking of two purified proteins. The relatively high concentration of sodium phosphate is used to prevent pH drift downward during the course of the reaction. For *in vitro* crosslinking of cellular components such as membrane proteins, a more dilute PBS buffer containing isotonic saline is more appropriate. Since DSP is a hydrophobic reagent, it is able to penetrate the cell membrane and conjugate membrane components. For this reason, it has become quite popular for use in investigating the interactions of membrane proteins.

DSP reacts with ε-amine groups on the side chains of lysine residues or the α-amine at the N-terminal of proteins to form amide linkages. Amine-containing macromolecules may be reversibly crosslinked with this reagent and later cleaved with dithiothreitol (DTT) or 2-mercaptoethanol (Figure 5.4). For reductive cleavage of conjugated molecules, add 10- to 50-m*M* DTT, and incubate

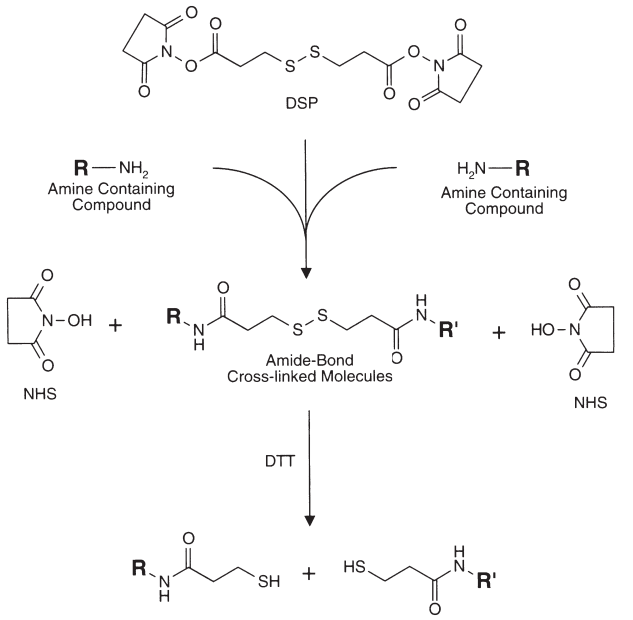


FIGURE 5.4 The reaction of DSP with amine-containing molecules yields amide bond crosslinks. The conjugates may be cleaved by reduction of the disulfide bond in the cross-bridge with DTT.

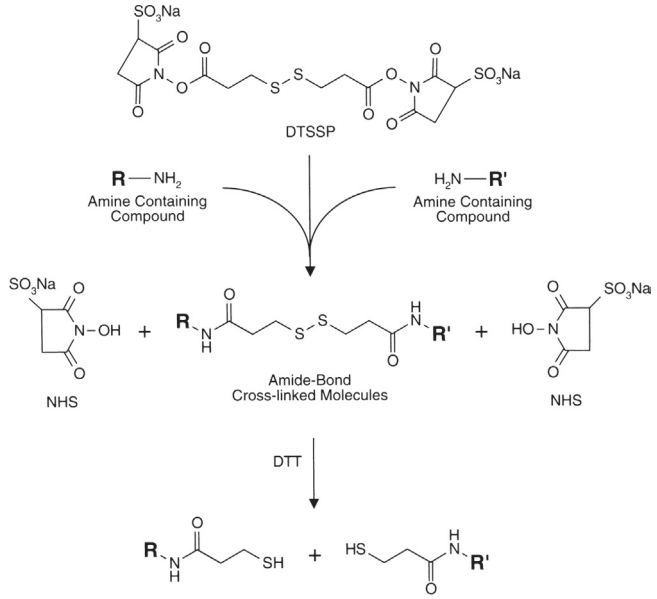

FIGURE 5.5 DTSSP can form crosslinks between two amine-containing molecules through amide linkages. The conjugates may be cleaved by disulfide reduction using DTT.

at 37°C for 30 min. Alternatively, the conjugate may be reduced prior to electrophoresis using SDS sample buffer with 5% 2-mercaptoethanol at elevated temperatures.

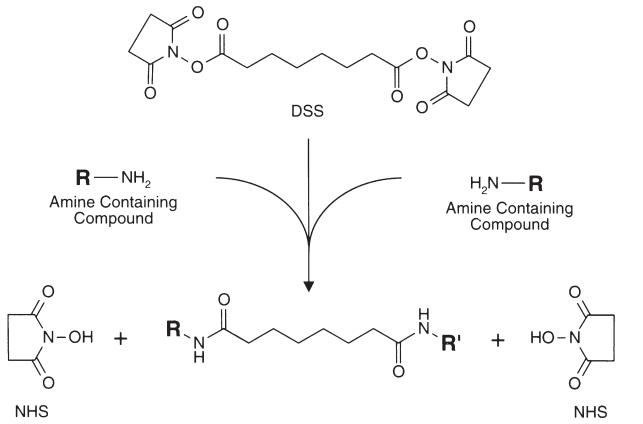
Lomant's reagent is one of the most popular of all crosslinking agents, especially for the investigation of protein interactions. Hordern *et al.* (1979) used it to investigate the spatial relationships in the capsid polypeptides of the *Mengo* virion. It has been used to study the interactions of proteins involved with active transport (dePont *et al.*, 1980; Joshi and Burrows, 1990), to identify crosslinks involving cytochrome P-450 (Baskin and Yang, 1982), to characterize cell-surface receptors for colony-stimulating factor (Park *et al.*, 1986), to determine various membrane antigens by crosslinking to specific monoclonal antibodies (Hamada and Tsuro, 1987), to study prothrombin self-association (Tarver *et al.*, 1982), to investigate chemotaxis in *E. coli* (Chelsky and Dahlquist, 1980), for the molecular identification of receptors for vasoactive intestinal peptide in rat intestinal epithelium (Laburthe *et al.*, 1984), to study the crosslinking of the affinity purified CCAAT transcription factor α-CP1 (Kim and Sheffrey, 1990), and to fix tissue for immunostaining procedures (Xiang *et al.*, 2004). The dithiol bridge in DSP has also been used to activate metal surfaces or metal particles through dative bonding (Grubor *et al.*, 2004). The presence of the disulfide group creates two dative bonds in each linker, which significantly increases the stability of the surface bonds. DSP's two NHS ester groups then can be used to couple amine-containing molecules to the metallic surface. See Chapter 3, Section 2.8, for additional information.

The sulfo-NHS version of DSP, dithiobis(sulfosuccinimidylpropionate) or DTSSP, is a water soluble analog of Lomant's reagent that can be added directly to aqueous reactions without prior organic solvent dissolution (Staros, 1982). DTSSP still contains the disulfide center portion that is cleavable with the proper reducing agents, and the sulfo-NHS ends have virtually the same reactivity as DSP (Figure 5.5). Due to its hydrophilicity, however, DTSSP will not penetrate cellular membranes as does its more hydrophobic analog, DSP. It is therefore an excellent choice for the crosslinking of cell-surface components without affecting intracellular substances.

DTSSP reportedly has been used to crosslink the extracytoplasmic domain of the anion exchange channel in human erythrocytes (Staros and Kakkad, 1983), for the characterization of a ribosomal complex in *B. subtilis* (Caufield *et al.*, 1984), to investigate ascites hepatoma cytokeratin filaments (Knoller *et al.*, 1991), to study the B lymphocyte Fc receptor for IgE (Waugh *et al.*, 1989), and to crosslink platelet glycoproteins (Jung and Moroi, 1983). Both DSP and DTSSP have been used extensively to study protein interactions and to investigate the oligomeric state of many proteins within cells (Sampathkumar *et al.*, 2012).

1.2. DSS and BS^3

Disuccinimidyl suberate (DSS) is an amine-reactive, homobifunctional, NHS ester, crosslinking reagent that produces an eight-atom bridge (11.4 Å) between conjugated molecules (Figure 5.6) (Thermo Fisher). Its hydrocarbon



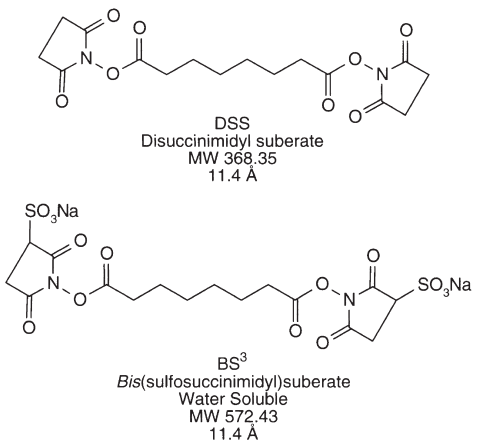


FIGURE 5.6 DSS reacts with two amine-containing molecules to form amide bond crosslinks. The crossbridge is noncleavable.

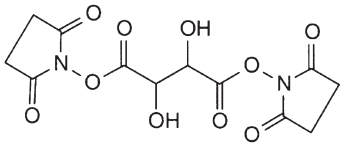
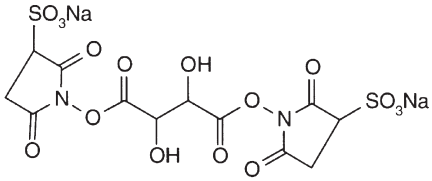
chain is non-cleavable, so crosslinks formed are irreversible. Many of the reported applications of DSS involve investigations of receptor–ligand binding on cell surfaces using radiolabeled molecules. The crosslinker is hydrophobic and must be solubilized in organic solvent prior to addition to a conjugation reaction. Pre-dissolving in dry dioxane, DMF, or DMSO may be done at higher concentration and then an aliquot added to the aqueous reaction medium as needed. The final concentration of the organic solvent in the buffered reaction should not exceed 10% to avoid precipitation of biomolecules. Stock solutions should be prepared fresh. DSS is membrane permeable and is therefore useful for intracellular and intramembrane conjugations. The optimum conditions for the crosslinking reaction are a pH range of 7 to 9 using buffers and other salts which contain no amines. Avoid the use of Tris or glycine. A phosphate buffer (PBS) at physiological pH works well. See Section 1 for additional information on NHS ester reactions.

Reported applications of DSS include crosslinking the A and B subunits of ricin (Montesano *et al.*, 1982), studying human somatotropin and the components of the lactogenic binding sites of rat liver (Caamano *et al.*, 1983), crosslinking CSF-1 to its cell-surface receptor (Morgan and Stanley, 1984), studying angiotensin II interactions with its receptor (Petruzzelli *et al.*, 1985), crosslinking of vasoactive intestinal peptide to its receptor on human lymphoblasts (Wood and O'Dorisio, 1985), investigating insulin-dependent protein kinases (Petruzzelli *et al.*, 1985), identifying a cellular receptor for TNF (Kull *et al.*, 1985), affinity crosslinking of atrial natriuretic factor in aorta membranes (Vandelen *et al.*, 1985), studying the receptor for human interferon (Rashidbaigi *et al.*, 1986), crosslinking of endorphin to membranes rich in opioid receptors (Helmeste *et al.*, 1986), immunoprecipitation studies of the crosslinked complex of parathyroid hormone with its receptor (Wright *et al.*, 1987), binding of human interferon Y to its receptor (Novick *et al.*, 1987), identifying the erythropoietin receptor on Friend virus-infected erythroid cells (Sawyer *et al.*, 1987), and binding of the p75 peptide to an interleukin 2 receptor (Tsudo *et al.*, 1987).



Bis(sulfosuccinimidyl) suberate (BS^3) is an analog of DSS that contains sulfo-NHS esters on both carboxylates. The affect of the negative charges provided by the sulfonate groups lends water solubility to the compound. Prior organic solvent dissolution (before addition to a reaction) is not necessary. The hydrophilicity of BS^3 also makes it membrane impermeable. Therefore, cell labeling with BS^3 results in hydrophilic-region modification and crosslinking, targeting surface functionalities, whereas DSS is capable of targeting hydrophobic regions within the membrane structure itself. As with DSS, BS^3 is non-cleavable, and thus all crosslinks formed are irreversible. The reactivity of the sulfo-NHS esters is identical to NHS esters, being highly reactive toward amines in the pH range of 7 to 9.

Reported applications of BS^3 include crosslinking of the β-endorphin–calmodulin interaction (Staros, 1982), crosslinking of the extracellular domain of intact human erythrocytes' anion exchange channel (Staros and Kakkad, 1983), crosslinking of hepatoma cytokeratin filaments (Ward *et al.*, 1985), investigating the β-lymphocyte Fc receptor for IgE (Lee and Conrad, 1985; Staros *et al.*, 1987), crosslinking of the tripeptide Arg–Gly–Asp to an adhesion receptor on platelets (Souza *et al.*, 1988), crosslinking of the large and small subunits of cytochrome b_{559} (Knoller *et al.*, 1991), and for general receptor–ligand crosslinking (Waugh *et al.*, 1989). See also Dihazi and Sinz (2003), Koller *et al.* (2004), and Law *et al.* (2002) for additional applications of BS^3 in proteomic applications. Also see Ishmael *et al.* (2005) and Longshaw *et al.* (2004) for additional applications involving DSS in studying protein interactions.



Both DSS and BS^3 continue to be used extensively to investigate protein interactions and the structure of individual proteins within cellular systems (Fioramonte *et al.*, 2012).

1.3. DST and Sulfo-DST

Disuccinimidyl tartarate (DST) is a homobifunctional NHS ester crosslinking reagent that contains a central diol that is susceptible to cleavage with sodium periodate (Thermo Fisher). DST forms amide linkages with α-amines and ε-amines of proteins or other amine-containing molecules (Figure 5.7). The reagent is fairly insoluble in aqueous buffers, but it may be pre-dissolved in THF, DMF, or DMSO prior to addition of an aliquot to a reaction. Optimal conditions for reactivity include a pH range of 7 to 9 with no extraneous amines present that may cross-react with the NHS esters. Avoid Tris, glycine, or imidazole buffers. Subsequent to conjugating proteins with DST, the crosslinks may be broken for analysis by treatment with 0.015-*M* sodium periodate.

DST
Disuccinimidyl tartarate
MW 344.24
6.4 Å

Sulfo-DST
Disulfosuccinimidyl tartarate
Water Soluble
MW 548.34
6.4 Å

Reported applications of DST include the crosslinking of ubiquinone cytochrome *c* reductase (Smith *et al.*, 1978), characterization of the cell-surface receptor for colony-stimulating factor (Park *et al.*, 1986), investigation of the Ca^{+2}, Mg^{+2} activated ATP of *E. coli* (Bragg and Hou, 1980), and characterization of human properdin polymers (Farries and Atkinson, 1989).

Disulfosuccinimidyl tartarate (sulfo-DST) is an analog of DST that contains sulfo-NHS esters. The negatively charged sulfonate groups contribute enough hydrophilicity to provide water solubility for the reagent without the need for organic solvent dissolution before adding it to a crosslinking reaction. The conditions for conjugation are otherwise identical to DST. DST and sulfo-DST also have been used to study protein–lipid complexes (Predescu *et al.*, 2001), to investigate the binding protein of corticotropin-releasing factor (Jahn *et al.*, 2002), and to investigate the acidic C-terminal domain of Rna1p (Haberland *et al.*, 1997).

DST and sulfo-DST also have been used to stabilize fragile cells by crosslinking membrane proteins (Deng, 2011).

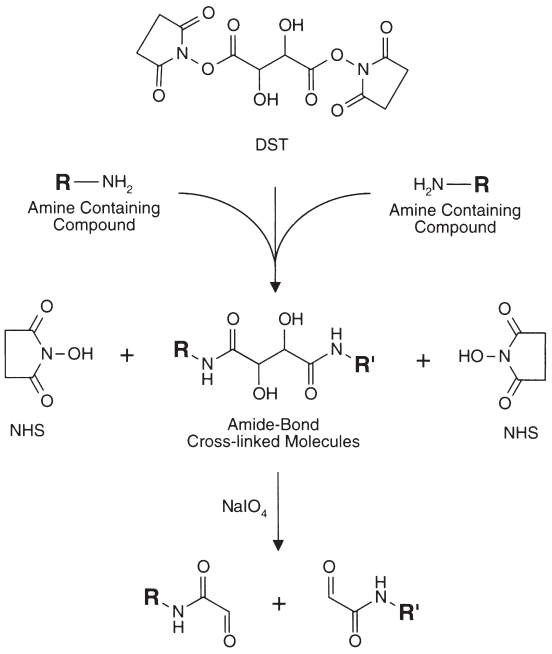


FIGURE 5.7 DST may be used to crosslink amine-containing molecules, forming amide bond linkages. The central diol of the cross-bridge is cleavable by treatment with sodium periodate.

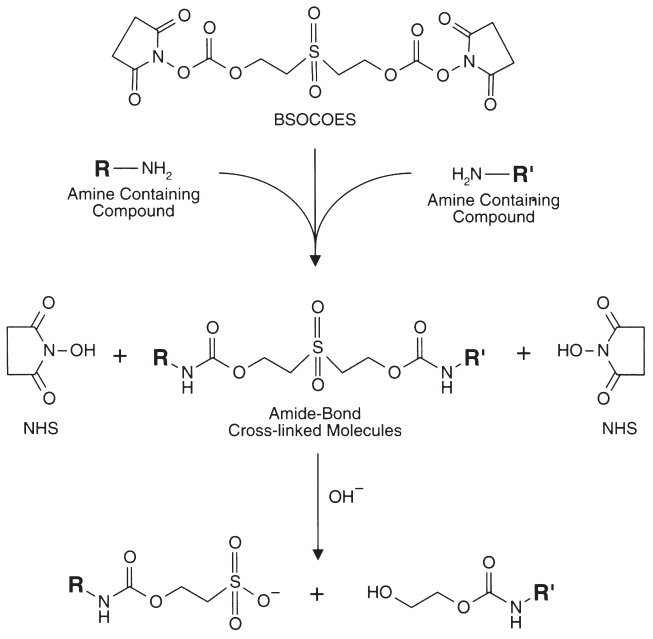

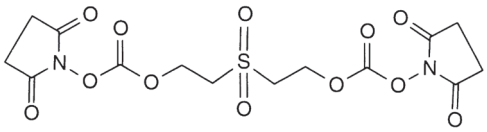

FIGURE 5.8 BSOCOES reacts with amine-containing molecules to create amide bond crosslinks. The internal sulfone group is cleavable under alkaline conditions.

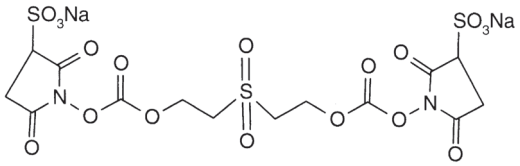
1.4. BSOCOES and Sulfo-BSOCOES



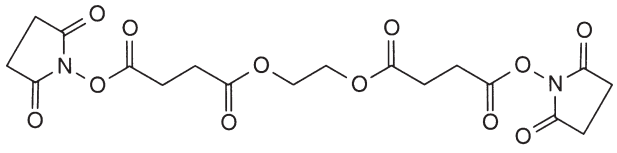
BSOCOES [*bis*[2-(succinimidyloxycarbonyloxy)ethyl] sulfone] is a water-insoluble, homobifunctional NHS ester crosslinking reagent that contains a central sulfone group, which is cleavable under alkaline conditions (Figure 5.8)

(Thermo Fisher). The two NHS ester ends are reactive with amine groups in proteins and other molecules to form stable amide linkages. Once proteins are crosslinked using this reagent, they may be dissociated for analysis by raising the pH to 11.6 and incubating for 2h at 37°C. The sulfone group is base labile under these conditions, and the conjugate cleaves at the center of the bridge.

BSOCOES is a hydrophobic crosslinker and therefore must be dissolved in organic solvent prior to its addition to an aqueous reaction medium. Preparing a stock solution in DMF or DMSO and then adding an aliquot to the crosslinking reaction is recommended. Do not exceed a concentration of more than 10% organic solvent in the buffered reaction to avoid protein precipitation.

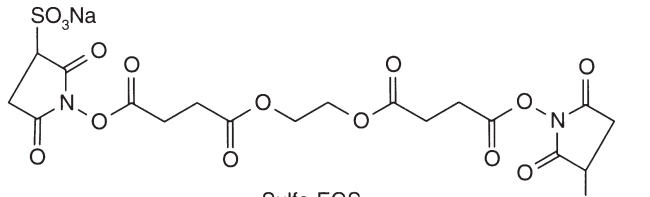
BSOCOES
Bis[2-(succinimidooxycarbonyloxy)ethyl]sulfone
MW 436.36
13 Å

Sulfo-BSOCOES
Bis[2-(sulfosuccinimidooxycarbonyloxy)ethyl]sulfone
Water Soluble
MW 640.46
13 Å



Reported applications of BSOCOES include studying the polypeptide antigens on lymphocyte cell surfaces (Zarling *et al.*, 1980), crosslinking labeled β-endorphin to its opioid receptors (Howard *et al.*, 1985), and isolation and characterization of calcitonin receptors in rat kidney (Bouizar *et al.*, 1986).

A water soluble version of this reagent is also available. Sulfo-BSOCOES [*bis*[2-(sulfosuccinimidooxycarbonyloxy) ethyl]sulfone] is built on the same chemical structure as BSOCOES, but contains the negatively charged sulfonate groups on both of its succinimido rings. The presence of the sulfonates provides enough charge and hydrophilicity to lend water solubility to the entire reagent. Thus, it may be added directly to aqueous reactions at concentrations of up to 10-m*M*. Prior dissolution in organic solvent, however, may provide solubility at greater concentrations in aqueous solutions.



Additional applications of BSOCOES and sulfo-BSOCOES include the study of factors influencing lysosomal membrane permeabilization (Zhao *et al.*, 2012), the study of nanotopography-induced changes in mesenchymal stem cells (Yim *et al.*, 2010), investigations of the cellular and subcellular distribution of the type II vasopressin receptor (Fenton *et al.*, 2007) and TNF-alpha (Grinberg *et al.*, 2005), and studying mechanisms in the control of plasmid replication (Das *et al.*, 2005).

1.5. EGS and Sulfo-EGS

Ethylene glycolbis(succinimidylsuccinate) (EGS) is a homobifunctional crosslinking agent that contains NHS ester groups on both ends (Thermo Fisher). Its central bridge is constructed from an ethylene glycol group esterified on either side with succinic acid, the terminal carboxylates of which are activated by forming *N*-hydroxysuccinimide esters. The two NHS esters are amine reactive, forming stable amide bonds between crosslinked molecules within a pH range of about 7 to 9. Avoid amine-containing buffers such as Tris or glycine, since they will cross-react with the NHS esters. Imidazole also should be avoided, because it has the effect of catalyzing the hydrolysis of the NHS ester groups. The internal structure of EGS provides two cleavable ester sites that may be broken at pH 8.5 by incubation with 1-*M* hydroxylamine for 3 to 6h at 37°C (Abdell *et al.*, 1979) (Figure 5.9). Thus, conjugates produced from the EGS crosslinking of the specific interaction of proteins or other molecules subsequently may be cleaved with hydroxylamine for analysis.

EGS
Ethylene glycolbis(succinimidylsuccinate)
MW 456.37
16.1 Å

Sulfo-EGS
Ethylene glycolbis(sulfosuccinimidylsuccinate)
MW 660.47
16.1 Å

EGS is not very water insoluble and must be dissolved in an organic solvent prior to its addition to an aqueous reaction. Prepare a concentrated solution of EGS in DMF or DMSO and add an aliquot of the stock solution to the reaction. Do not exceed a concentration of more than about 10% organic solvent in the aqueous reaction buffer or precipitation of buffer salts or protein may occur.

Reported applications of EGS include crosslinking studies of cytochrome P-450 (Baskin and Yang, 1980), studies of the conjugation of tumor necrosis factor with lymphotoxin (Browning and Ribolini, 1989),

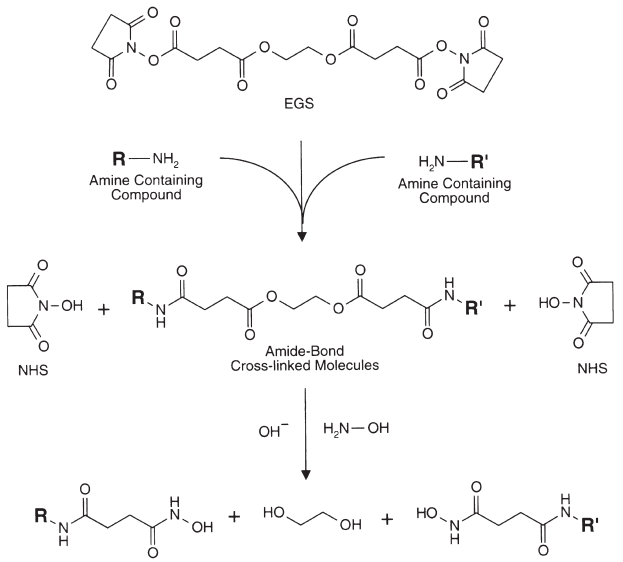


FIGURE 5.9 EGS reacts with amine-containing molecules to form amide-linked conjugates. The ester groups within its crossbridge are cleavable under alkaline conditions using hydroxylamine.

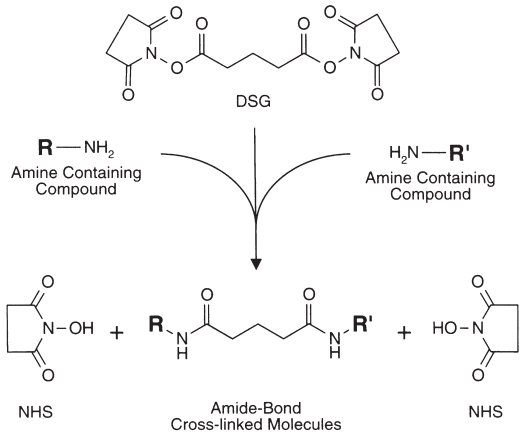
the conversion of a gonadotropin-releasing hormone antagonist to an agonist (Conn *et al.*, 1982a), preparation of a conjugate of gonadotropin-releasing hormone with an agonist (Conn *et al.*, 1982b), covalent crosslinking of vasoactive peptide to its lymphoblast receptors (Wood and O'Dorisio, 1985), and study of bombesin receptors in Swiss 3T3 cells (Millar and Rozengur, 1990).

A water soluble analog of EGS is also available commercially (Thermo Fisher). Sulfo-EGS, or ethylene glycolbis (sulfosuccinimidylsuccinate), contains negatively charged sulfonate groups on its NHS rings. The resultant charge and hydrophilicity of this modification provide water solubility to the entire compound so that prior dissolution in organic solvent is not necessary.

EGS and sulfo-EGS also have been used to study the surface loop motion in FepA (Scott *et al.*, 2002), to characterize the high-affinity copper transporter in *Saccharomyces cerevisiae* (Pena *et al.*, 2000) to study of protein interactions and large protein complexes (Petrotchenko *et al.*, 2005), and to study the activation of Syk through dimerization (Hughes *et al.*, 2010).

1.6. DSG

Disuccinimidyl glutarate (DSG) is a water-insoluble, homobifunctional crosslinker containing amine-reactive NHS esters at both ends (Thermo Fisher). The active esters react with amino groups in protein molecules in the pH range of 7 to 9 to form amide linkages. DSG is a non-cleavable reagent, forming stable five-carbon bridges between amine-containing molecules (Figure 5.10).



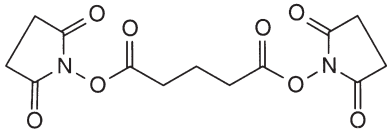


FIGURE 5.10 DSG is a noncleavable crosslinker that can react with two amine-containing molecules to form amide bonds.

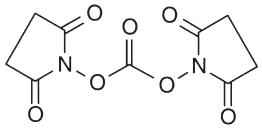
DSG should be dissolved in an organic solvent prior to addition to an aqueous reaction medium. Suitable solvents include DMF and DMSO. To initiate a reaction, add an aliquot of the organic solution to the buffered medium containing the molecules to be crosslinked. Reaction buffers should not contain any competing amine compounds such as Tris or glycine, as these will cross-react with the active esters. Avoid imidazole-containing buffers, also, since they catalyze the hydrolysis of NHS esters.



DSG
Disuccinimidyl glutarate
MW 326.26
7.7 Å

The reported applications of DSG include receptor–ligand studies by covalent crosslinking of their complexes (Waugh, 1989); the capture of protein interactions on protein array surfaces by DSG crosslinking (MacBeath, 2007); studying TorT, a member of a periplasmic binding protein family (Baraquet *et al.*, 2006); in the investigation of left-helical conformation of L-DNA for analyzing biomarkers (Hauser *et al.*, 2006); and studying the covalently bound terminal proteins at the 5′ ends of telomeres of *Streptomyces* linear plasmids (Tsai *et al.*, 2011).

1.7. DSC

N,N′-Disuccinimidyl carbonate (DSC) is the smallest homobifunctional NHS ester crosslinking reagent available (Aldrich). It is, in essence, merely a carbonyl group containing two NHS esters. The compound is

highly reactive toward nucleophiles. In aqueous solutions, DSC will rapidly hydrolyze to form two molecules of *N*-hydroxysuccinimide (NHS) with release of CO_2. In nonaqueous environments, it can react with two amine groups to form a substituted urea derivative with loss of two molecules of NHS. The reagent also can be used in anhydrous organic solvents to activate a hydroxyl group to an amine-reactive succinimidyl carbonate derivative (Chapter 15, Section 2.1). This procedure is commonly used to activate poly(ethylene glycol) for conjugation with proteins and other molecules (Chapter 18, Section 2.1). In this sense, DSC-activated hydroxylic compounds can be used to conjugate with an amine-containing molecule to form a stable derivative (Figure 5.11). The linkage created from this reaction is a urethane derivative or a carbamate bond, displaying excellent stability.

N,N'-Disuccinimidyl
Carbonate (DSC)
MW 256.17

Activation of hydroxyl groups with DSC can be done in acetone or dioxane by reacting for 4 to 6 h at room temperature. Subsequent conjugation with amine-containing molecules is done in organic or aqueous solutions. For buffered reactions, the optimal conditions include a pH range of 7 to 9 using common buffer salts (avoid amine-containing components, such as Tris). React for at least 4 h at room temperature or up to overnight at 4°C.

DSC also is used to activate hydroxylic particles for coupling to amine-containing ligands (Miron and Wilchek, 1993). It also has been used to activate carboxylate-containing molecules for coupling to amine-containing dendrimers to make targeted detection agents (Biswas *et al.*, 2012). For methods involving particle conjugation using this homobifunctional compound, see Chapter 14, Section 4.2, and Chapter 15, Section 2.1.

2. HOMOBIFUNCTIONAL IMIDOESTERS

Crosslinking compounds containing imidoesters at both ends are among the oldest homobifunctional reagents used for protein conjugation (Hartman and Wold, 1966). The imidoester (or imidate) functionality is one of the most specific acylating groups available for the modification of primary amines, with minimal cross-reactivity toward other nucleophilic groups in proteins. The α-amines and ε-amines of proteins may be targeted and crosslinked by reacting with homobifunctional imidoesters at a pH of 7 to 10 (optimal pH 8–9). The product of this reaction, an imidoamide (or amidine) (Figure 5.12), is protonated and thus carries a positive charge at physiological pH (Kiehm and Ji, 1977; Liu, *et al.*, 1977; Ji, 1979; Wilbur, 1992). The result is no alteration of the charge characteristics of the crosslinked proteins, since the amines being modified were themselves protonated and originally contributed to the overall positive charge of the molecule.

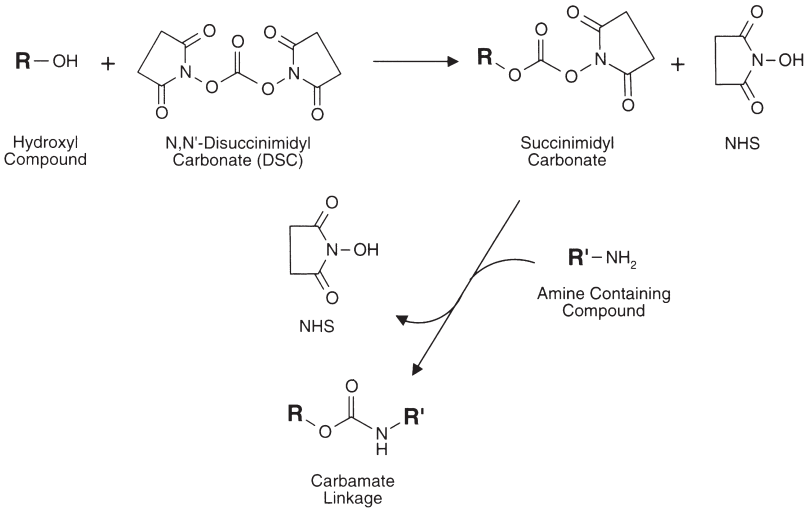


FIGURE 5.11 DSC can react with hydroxyl groups to create a succinimidyl carbonate intermediate that is highly reactive toward nucleophiles. In the presence of an amine-containing molecule, the active species can form stable carbamate linkages.

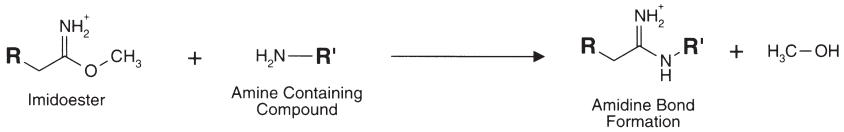

FIGURE 5.12 Imidoesters react with amine groups to form amidine bonds, which are positively charged at physiological pH.

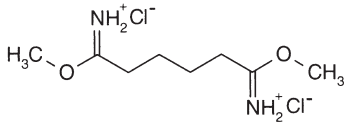
Imidoesters can therefore preserve the microenvironment within the vicinity of the crosslink bridge, possibly retaining native structure and activity better than reagents that modulate the net charge of a protein.



The amidine bond is quite stable at acid pH; however, it is susceptible to hydrolysis and cleavage at alkaline pH. Derivatized proteins may be assayed by amino acid analysis after acid hydrolysis without loss of imidate modifications.

Imidoester crosslinkers are highly water soluble, but undergo continuous degradation due to hydrolysis. The half-life of the imidate functionality is typically less than 30 min, especially in the alkaline conditions of the reaction medium (Hunter and Ludwig, 1962; Browne and Kent, 1975). Concentrated stock solutions may be prepared before addition of a small amount to a conjugation reaction, but they should be dissolved rapidly and used immediately.

The following list of homobifunctional imidoesters represent compounds that are commonly used for protein crosslinking and are currently available from commercial sources.

2.1. DMA

Dimethyl adipimidate (DMA) is a short-chain, homobifunctional crosslinking agent containing imidoesters at both ends (Thermo Fisher). After reaction with amine groups on target molecules, the compound creates a non-cleavable, six-atom bridge with terminal amidine bonds (Figure 5.13). DMA is water soluble and may be added directly to a crosslinking reaction or predissolved at higher concentration before addition of an aliquot to the reaction medium. Stock solutions should be used immediately to prevent breakdown by hydrolysis. Reaction buffers having a pH of 8 to 9 are optimal. Avoid buffers containing primary amines (glycine and Tris), since these will cross-react with the imidoester groups. Borate or bicarbonate buffers adjusted to the optimum pH range work well. The addition of (or the exclusive use of) 0.1- to 0.2-*M* triethanolamine is often carried out to help catalyze the coupling reaction.

DMA
Dimethyl adipimidate dihydrochloride
MW 245.15
8.6 Å

Reported applications of DMA include the crosslinking of bovine pancreatic ribonuclease A (Hartman and Wold, 1967), treatment of erythrocyte membranes to reduce the effects of sickle cell anemia (Waterman *et al.*, 1975), conjugation and analysis of the outer membrane proteins of *Neisseria gonorrhoeae* (Newhall *et al.*, 1980), protein structural studies of bovine α-crystalline (Siezen *et al.*, 1980), crosslinking of hemoglobin *S* (Pennathur-Das *et al.*, 1982), and forming S-carbomethoxyvaleramidine during hydrolysis of DMA (Mentzer *et al.*, 1982). The compound has also been used to study uranyl–antibody interactions by atomic force microscopy (Odorico *et al.*, 2007), to produce antibody–drug conjugates for the treatment of non-Hodgkin lymphoma (Polson *et al.*, 2007), to investigate the subcellular distribution of the type II vasopressin receptor in kidney (Fenton *et al.*, 2007), and to study protein–chromatin interactions (Tian *et al.*, 2011).

2.2. DMP

Dimethyl pimelimidate (DMP) is a homobifunctional crosslinking agent that has imidoester groups on either end (Thermo Fisher). The imidoesters are amine reactive to give stable amidine linkages with target molecules. The seven-atom bridge created by DMP crosslinks is non-cleavable and positively charged at physiological pH due to the protonated amidine bonds (Figure 5.14). The reagent is water soluble and may be reacted with

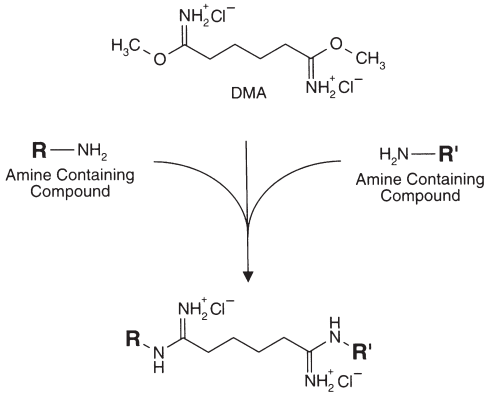


FIGURE 5.13 DMA can crosslink two amine-containing molecules to form charged amidine linkages.

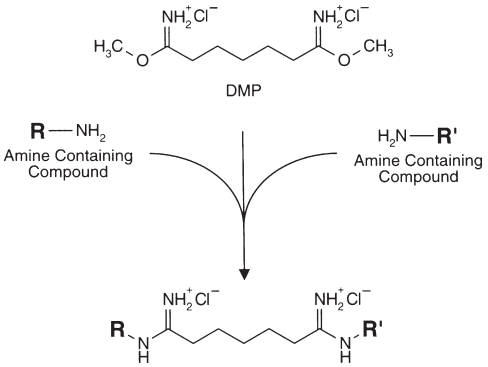

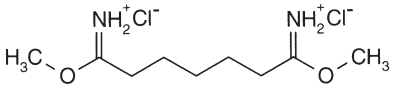

FIGURE 5.14 DMP reacts with amine-containing compounds to form amidine bonds.

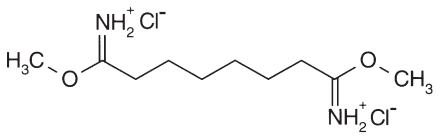
proteins or other amine-containing macromolecules at a pH of 8 to 9 in aqueous media. Use buffers that contain no amine groups that may cross-react with the imidoesters. Avoid glycine or Tris buffers.



DMP
Dimethyl pimelimidate dihydrochloride
MW 259.18
9.2 Å

In protein crosslinking studies, DMP has been used to examine the subunit structure of muscle pyruvate kinase (Davies and Kaplan, 1972), for the crosslinking of lactose synthetase (Brew *et al.*, 1975), and to conjugate a fluorescent derivative of α-lactalbumin to galactosyltransferase (O'Keefe *et al.*, 1980). The reagent has also found use in the immobilization of antibody molecules to insoluble supports containing bound protein A (Schneider *et al.*, 1982) or protein G (Tozawa *et al.*, 2012). The antibody molecules are first allowed to interact with the coupled protein A, orienting them with their antigen-binding sites facing away from the matrix. DMP is then added to covalently anchor the antibodies to the protein A, forming a permanent immunoaffinity matrix.

DMP also has been used to study the interaction between the endoplasmic reticulum and microtubules (Ogawa-Goto *et al.*, 2007), the conformational changes in the outer arm dynein of *Chlamydomonas* in response to calcium (Sakato *et al.*, 2007), and secretion of the adipocyte-specific secretory protein adiponectin (Wang *et al.*, 2007).

2.3. DMS

Dimethyl suberimidate, DMS, is a homobifunctional crosslinking agent containing amine-reactive imidoester groups on both ends. The compound is reactive toward the ε-amine groups of lysine residues and N-terminal α-amines in the pH range of 7 to 10 (pH 8–9 is optimal). The resulting amidine linkages are positively charged at physiological pH, thus maintaining the positive charge contribution of the original amine. DMS creates eight-atom bridges between conjugated molecules that are not cleavable (Figure 5.15).

DMS
Dimethyl suberimidate dihydrochloride
MW 273.2
11 Å

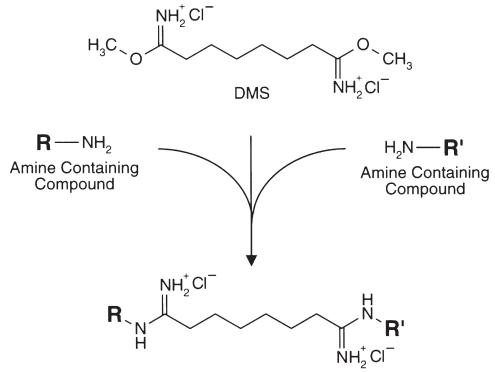


FIGURE 5.15 The reaction of DMS with amine-containing molecules yields amidine linkages.

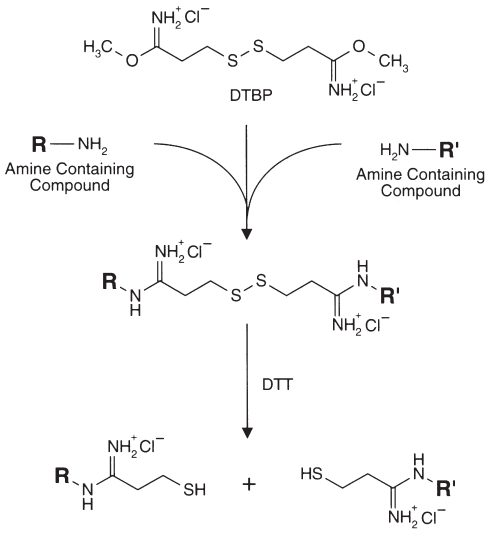
DMS reportedly has been used as a tissue fixative for light and electron microscopy (Hassell and Hand, 1974), to study the subunit structure of oligomeric proteins (Davies and Stark, 1970), to investigate ATPase activity (Adolfson and Moudrianokis, 1976), to study crosslinking ribonuclease A (Wang *et al.*, 1976), in binding studies of nerve growth factor to its receptor (Pulliam *et al.*, 1975), to study red cell shape (Mentzer and Lubin, 1979), to study crosslinking of glycogen phosphorylase *b* (Hajdu *et al.*, 1979), to study crosslinking of APO low-density lipoproteins (Ikai and Yanagita, 1980), to study the mechanism of binding of multivalent immune complexes to Fc receptors (Dower *et al.*, 1981), to investigate the quaternary structure of the pyruvate dehydrogenase multienzyme complex of *Bacillus stearothermophilus* (Packman and Perham, 1982), in crosslinking studies of the protein topography of rat liver microsomes (Baskin and Yang, 1982), in affinity crosslinking studies of the protein topography of rat liver microsomes (Pfeuffer *et al.*, 1985), and to study the quantitative chemical crosslinking of CAD protein (Lee *et al.*, 1985).

DMS also has been used to study the interaction between the *Helicobacter pylori* accessory proteins HypA and UreE (Benoit *et al.*, 2007) as well as to identify the interaction between the Ca^{2+}-binding protein S100A11 and the Ca^{2+}- and phospholipid-binding protein annexin A6 (Chang *et al.*, 2007) and the recognition of the 70S ribosome by the RNA degradosome (Tsai *et al.*, 2012).

2.4. DTBP

Dimethyl 3,3′-dithiobispropionimidate (DTBP) is a homobifunctional, reversible crosslinking agent containing imidoester groups on both ends (Thermo Fisher). The compound, commonly called Wang and Richards' reagent, is water soluble, and reacts with amines in the pH range of 7 to 10 (optimum pH 8–9) to produce amidine linkages (Wang, 1974; Wang and Richards, 1974). Conjugated molecules subsequently may be cleaved by



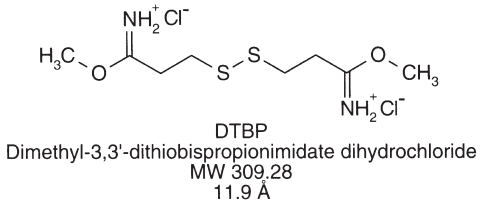


FIGURE 5.16 DTBP reacts with amine-containing molecules to form charged amidine bonds. The internal disulfide group can be cleaved with DTT to release the conjugate.

reduction of the internal disulfide group of the eight-atom bridge (Figure 5.16). Crosslinked molecules may be analyzed by one- or two-dimensional electrophoresis, making use of the easy reversibility of the disulfide bond.

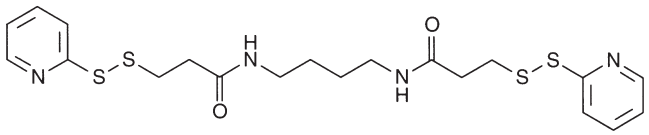
Reported applications include studying protein–protein interactions with paramyxoviruses (Markwell and Fox, 1980), inhibition of adenylate cyclase activity (Young, 1979), red cell shape (Mentzer and Lubin, 1979), crosslinking phytochrome to its putative receptor (Yu and Schweinberger, 1979), the subunit structure of Na, K-ATPase (DePont, 1979), Newcastle disease virus proteins (Nagai *et al.*, 1978), thylakoid membrane proteins (Novak-Hofer and Siegenthaler, 1978), glutamate dehydrogenase–amino transferase complexes (Fahien et al., 1978), vesicular stomatitis virus proteins (Mudd and Swanson, 1978), hemagglutinin of influenza virus (Wiley *et al.*, 1977), pig heart lactate dehydrogenase crystals (Bayne and Ottesen, 1977), beef heart mitochondrial coupling factor 1 (Baird and Hammes, 1977), chloroplast coupling factor 1 (Baird and Hammes, 1976), rabbit muscle skeletal sarcoplasmic reticulum protein (Louis *et al.*, 1977), human hemoglobin and erythrocyte membrane proteins (Wang and Richards, 1974, 1975; Miyakawa *et al.*, 1978), subunit interface of the E. coli ribosome (Cover *et al.*, 1981), rat liver 60S ribosomal subunits (Uchiumi *et al.*, 1980), proteins in avian sarcoma and leukemia viruses (Pepinsky *et al.*, 1980), outer membrane proteins of *Neisseria gonorrhoeae* (Dade and Johnston, 1980; Newhall *et al.*, 1980), monooxygenase enzymes (Baskin and Yang, 1980), cytochrome P-450 and reduced NAD phosphate-cytochrome P-450 reductase (Baskin and Yang, 1980b), crosslinking initiation factor IF2 to proteins in 70S ribosomes of E. coli (Heinmark *et al.*, 1976), sheep red blood cell membranes (Brandon, 1980), conjugation of F-actin to skeletal muscle myosin subfragment 1 (Labbe *et al.*, 1982), decreased staining of proteins after electrophoresis (Leffak, 1983), and the molecular association of IA antigens after T- and B-cell interaction (Shivdasani and Thomas, 1988).

DTBP also has been used to investigate the dimerization and actin-bundling properties of villin (George *et al.*, 2007), to study the interaction of the Mre11 complex with RPA (Olson *et al.*, 2007), to study gamma–secretase complex assembly (Spasic *et al.*, 2007), and to study the multi-protein assembly of Kv4.2, KChIP3, and DPP10 (Jerng *et al.*, 2005).

3. HOMOBIFUNCTIONAL SULFHYDRYL REACTIVE CROSSLINKERS

Crosslinking agents that contain homobifunctional sulfhydryl-reactive groups at either end fall into two general categories: those that form permanent bonds with available sulfhydryls and those that create reversible linkages. Reactive groups yielding permanent links with sulfhydryls usually form thioether bonds that are quite stable. Those that result in disulfide bonds can be cleaved with the use of a disulfide reducing agent like DTT (Chapter 2, Section 4.1). Mercurial-based coupling groups also can be reversed with reducing agents.

Many varieties of homobifunctional, sulfhydryl-reactive crosslinkers have been synthesized and described in the literature. Some have been based on *bis*-mercurial salts (Edelhoch *et al.*, 1953; Edsall *et al.*, 1954; Kay and Edsall, 1956; Singer *et al.*, 1960; Mandy *et al.*, 1961). Such mercurial reactive groups also have been used in reversible covalent chromatography applications to purify thiol-containing proteins (Cuatrecasas, 1970, 1972; Ruiz-Carrillo and Allfrey, 1973). Other homobifunctional sulfhydryl-reactive reagents have been based on forming a mixed disulfide active group with TNB (5-thio-2-nitrobenzoic acid). Reaction of the TNB active group with a sulfhydryl-containing macromolecule results in a reversible disulfide linkage (Gaffney *et al.*, 1983; Willingham and Gaffney, 1983). Active groups consisting of *bis*-thiosulfonates also have been used to create SH-reactive crosslinkers (Bloxham and Sharma, 1979; Bloxham and Cooper, 1982). The thiosulfonate groups react with available sulfhydryls to form disulfide linkages, in this case with loss of the sulfonate



groups. All of these disulfide crosslinks are cleavable with disulfide reducing agents.

A number of *bis*-alkyl halide-reactive groups have been used to create homobifunctional sulfhydryl-reactive crosslinkers (Husain and Lowe, 1968; Ozawa, 1967; Wilchek and Givol, 1977). These react with sulfhydryls to create stable, nonreversible thioether bonds. Similar thioether bond formation has been realized using various *bis*-maleimide derivatives (Moore and Ward, 1956; Kovacic and Hein, 1959; Tawney *et al.*, 1961; Fasold *et al.*, 1963; Simon and Konigsberg, 1966; Zahn and Lumper, 1968; Freedberg and Hardman, 1971; Chang and Flaks, 1972; Wells *et al.*, 1980; Heilmann and Holzner, 1981; Sato and Nakao, 1981; Moroney *et al.*, 1982; Partis, 1983; Chantler and Bower, 1988; Srinivasachar and Neville, 1989). Sulfhydryls add to the double bond of the maleimide to create a thioether linkage.

The differences within these families of reagents generally relate to the length of the spacer or bridging portion of the molecule. Occasionally, the cross-bridge portion itself is designed to be cleavable by one of a number of methods (Chapter 9). The great majority of homobifunctional, sulfhydryl-reactive crosslinkers mentioned in the literature are not readily available from commercial sources and would have to be synthesized to make use of them. The ones listed in this section are obtainable from Thermo Fisher.

3.1. DPDPB

DPDPB, or 1,4-di-[3′-(2′-pyridyldithio)propionamido] butane, is a homobifunctional crosslinking agent that contains sulfhydryl-reactive dithiopyridyl groups on both ends. These coupling groups are identical to the sulfhydryl-reactive end of the popular heterobifunctional crosslinking agent, SPDP (Chapter 6, Section 1.1). Available thiols on proteins and other molecules can react with the pyridyl disulfide groups to form disulfide linkages with release of pyridine-2-thione (Figure 5.17). Conjugation of two macromolecules with DPDPB results in a 14-atom spacer of approximately 16 Å in length. Release of two molecules of pyridine-2-thione during the crosslinking reaction may be followed by their characteristic absorbance at 343 nm ($\varepsilon = 8.08 \pm 0.3 \times 10^3 M^{-1} cm^{-1}$) (Stuchbury *et al.*, 1975).

DPDPB
1,4-di-[3'-(2'-pyridyldithio)propionamido]butane
MW 482.7
19.9 Å

DPDPB is insoluble in aqueous solutions and should be initially dissolved in an organic solvent prior to addition of a small aliquot to a buffered reaction medium. Preparation of a stock solution in DMSO at a concentration of 25 m*M* DPDPB works well. The addition of an aliquot of this stock solution to the conjugation reaction should not result in more than about 10% organic solvent by volume in the buffered mixture or protein precipitation may occur.

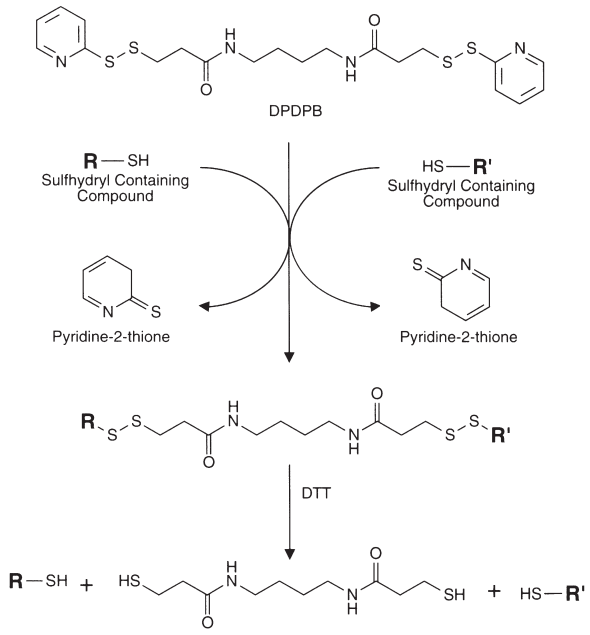


FIGURE 5.17 DPDPB is a sulfhydryl-reactive crosslinker that forms disulfide bonds with thiol-containing molecules. The conjugates may be disrupted using a disulfide reducing agent such as DTT.

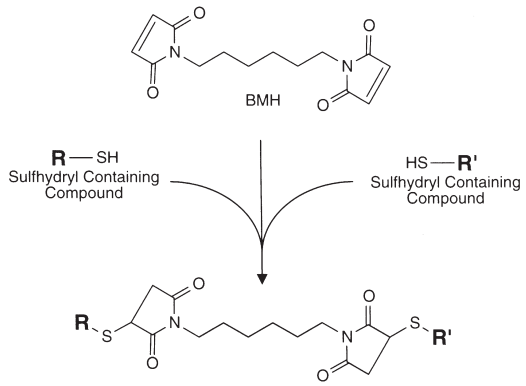
DPDPB has two absorbance maxima, one peak at 237 nm ($\varepsilon = 1.2 \times 10^4 M^{-1} cm^{-1}$) and another at 287 nm ($\varepsilon = 8.8 \times 10^3 M^{-1} cm^{-1}$) (Traut *et al.*, 1989; Zecherle, 1990;). Reduction of the pyridyldithio groups causes a shift in the absorbance characteristics of the molecule, such that the peak at 237 nm is shifted to 272 nm and the peak at 287 nm is shifted to 343 nm. This absorbance shift correlates to the release of the pyridine-2-thione groups.

DPDPB has been used to produce liposomal multilamellar vaccines (Moon *et al.*, 2012) and to study the endocytosis of cadherin from intracellular junctions (Troyanovsky *et al.*, 2006), the subunit arrangement in the flagellar rotor assembly (Lowder *et al.*, 2005), and the disease-associated mutations in myelin proteolipid protein in the ER (Swanton *et al.*, 2005). DPDPB can be used to conjugate reduced antibody molecules to β-D-galactosidase using essentially the same protocol as that described by O'Sullivan *et al.* (1979).

3.2. BMH

Homobifunctional crosslinking compounds containing maleimide groups on both ends have been used



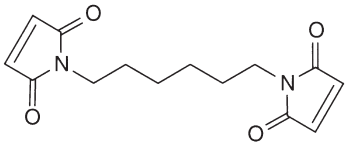


FIGURE 5.18 BMH contains two maleimide groups specific for crosslinking sulfhydryl-containing molecules. The thioether bonds that are formed are stable.

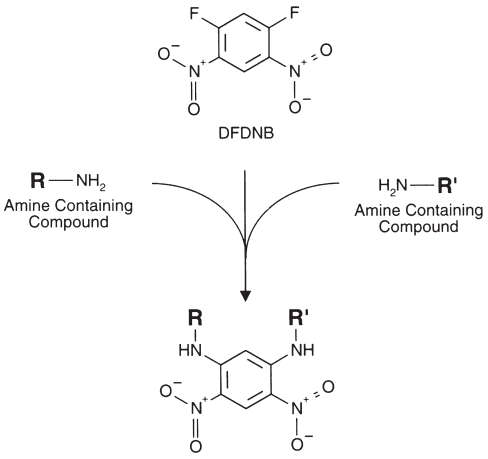
for quite some time (Moore and Ward, 1956; Kovacic and Hein, 1959; Tawney *et al.*, 1961; Fasold *et al.*, 1963; Simon and Konigsberg, 1966; Zahn and Lumper, 1968; Freedberg and Hardman, 1971; Chang and Flaks, 1972; Wells *et al.*, 1980; Heilmann and Holzner, 1981; Sato and Nakao, 1981; Moroney *et al.*, 1982; Partis, 1983; Chantler and Bower, 1988; Srinivasachar and Neville, 1989).

Bismaleimidohexane (BMH) is a homobifunctional reagent containing a non-cleavable, 6-atom spacer between terminal maleimides (Thermo Fisher). The maleimide groups can react with sulfhydryls to form stable thioether linkages (Figure 5.18). Crosslinks formed with this reagent create a 16.1-Å cross-bridge between conjugated macromolecules. The reaction takes place optimally from pH 6.5 to 7.5. Within this pH range, the reaction is very specific for sulfhydryls. At higher pH values, cross-reactivity with amino groups may occur (see Chapter 3, Section 2.2).

BMH has been used to study the initiation of Bak oligomerization (Dai *et al.*, 2011) and to study the binding of SUMO conjugating enzyme to the PR-Set7 histone methyltransferase (Spektor *et al.*, 2011).

4. DIFLUOROBENZENE DERIVATIVES

Difluorobenzene derivatives are small homobifunctional crosslinkers that react with amine groups.



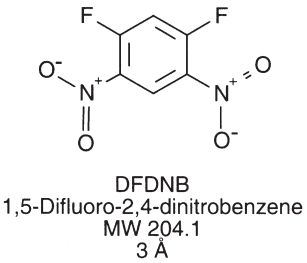


FIGURE 5.19 DFDNB is a small crosslinker able to form covalent bonds between amine-containing molecules. The aromatic fluorine atoms are readily displaced by nucleophiles.

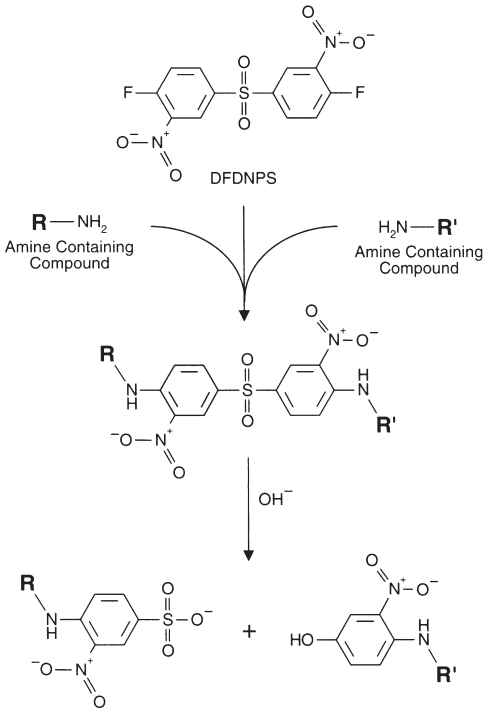
Conjugation using these compounds results in bridges only about 3 Å in length, potentially providing information concerning very close interactions between macromolecules.

4.1. DFDNB

DFDNB is the acronym for an aryl halide-containing compound having the structural names 1,5-difluoro-2,4-dinitrobenzene or 1,3-difluoro-4,6-dinitrobenzene (Thermo Fisher). The reagent contains two reactive fluorine atoms that can couple to amine-containing molecules, yielding stable arylamine bonds (Figure 5.19). However, the reactivity of aryl halides is not totally specific for amines. Thiol, imidazolyl, and phenolate groups of amino acid side chains also can react (Zahn and Meinhoffer, 1958). Conjugates formed with sulfhydryl groups, however, are reversible by cleaving with an excess of thiol (such as DTT) (Shaltiel, 1967). The compound is especially useful in crosslinking cellular membrane proteins, since it is able to penetrate the hydrophobic regions of the lipid bilayer.

Difluorobenzene reagents have been used for crosslinking phospholipids in human erythrocyte membranes (Berg *et al.*, 1965; Marfey and Tsai, 1975),



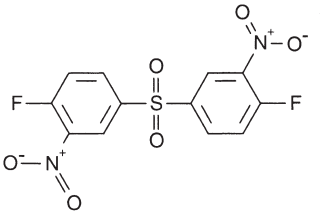


FIGURE 5.20 DFDNPS reacts with amine-containing molecules to form arylamine crosslinks. The central sulfone group in the cross-bridge can be cleaved under alkaline conditions.

conjugation of small peptides to the carrier protein albumin (Tager, 1976), studying the interaction of proteins in the myelin membrane (Golds and Braun, 1978), crosslinking cytochrome oxidase subunits (Kornblatt and Lake, 1980), and studying the conformational effects of calcium on troponin C (Kareva *et al.*, 1986). DFDNB also has been used to investigate the conformational changes in *Chlamydomonas* outer arm dynein in response to calcium ions (Sakato *et al.*, 2007), to study the dimerization properties of villin (George *et al.*, 2007), to characterize the intraflagellar transport complex B core (Lucker *et al.*, 2005), and to study peptide binding to human vascular endothelial growth factor (VEGF) (Marquez *et al.*, 2012).

4.2. DFDNPS

DFDNPS (4,4′-difluoro-3,3′-dinitrophenylsulfone) is a di-aryl halide reagent containing a central sulfone group (Figure 5.20). The aromatic fluorines are reactive with amines, sulfhydryls, phenolates, and imidazolyl groups of proteins (see previous section). The reaction with amines forms stable arylamine linkages. The reaction with sulfhydryl groups, however, is reversible by treatment with an excess of thiol. The central sulfone group provides cleavability through hydrolysis with base at pH 11 to 12 at 37°C (Wold, 1961, 1972; Zahling *et al.*, 1980).

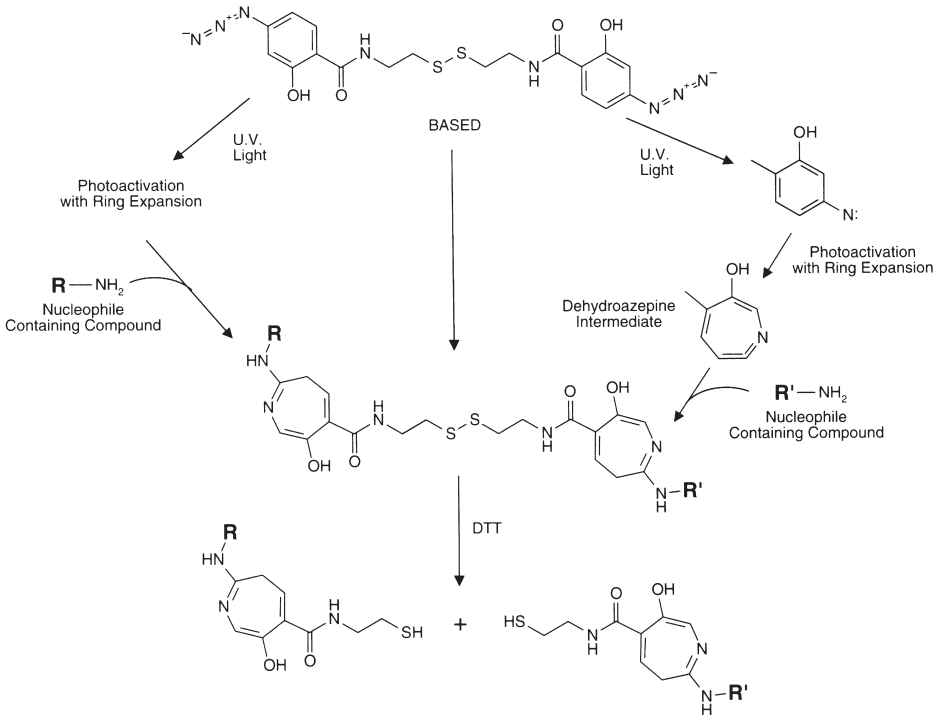
5. HOMOBIFUNCTIONAL PHOTOREACTIVE CROSSLINKERS

Although there are a number of photosensitive coupling chemistries that have been used in modification and conjugation reactions (Chapter 3, Section 7), it has been primarily aryl azides that have found application in homobifunctional crosslinkers. The photolysis reaction requires exposure of the phenyl azide to a bright light source at a wavelength of 265 to 275 nm (Ji, 1979). If the aromatic ring contains a nitro group *meta* to the azide functionality, then photolysis can occur at higher wavelengths (300–460 nm). The photolysis process initially forms a highly reactive aryl nitrene, but these quickly undergo ring expansion to create a dehydroazepine. This active species principally reacts with nucleophiles, rather than inserting in C–H or N–H bonds or adding to double bonds. Thus, instead of non-selective coupling into nearly any part of a molecular structure, aryl azides ultimately react with primary amines more than any other functionality (Schnapp *et al.*, 1993).

Reported structures for homobifunctional aryl azides include a biphenyl derivative and a naphthalene derivative (Mikkelsen and Wallach, 1976), a biphenyl derivative containing a central, cleavable disulfide group (Guire, 1976), and a compound containing a central 1,3-diamino-2-propanol bridge between phenyl azide rings that are nitrated (Guire, 1976). The only commercially available homobifunctional photoreactive crosslinker is BASED.

5.1. BASED

Bis-[β-(4-azidosalicylamido)ethyl]disulfide (BASED) is a homobifunctional photoreactive crosslinking agent containing phenyl azide groups at both ends (Thermo Fisher). Its central bridge contains a cleavable disulfide bond that may be broken after conjugation with the appropriate reducing agent (Chapter 2, Section 4.1). The aryl azides are salicylate derivatives that contain hydroxylic functions that activate the ring toward electrophilic reactions. Thus, the phenolic rings are modifiable with ^{125}I using traditional oxidative radioiodination reagents. Prior to the photoreactive conjugation step, the crosslinker may be iodinated with Iodogen or Iodobeads (Chapter 12, Sections 2.2 and 2.3).



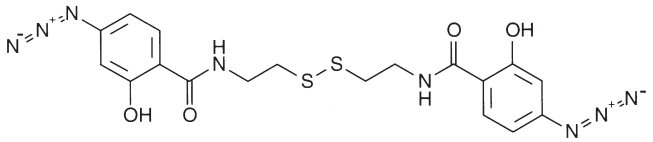


FIGURE 5.21 BASED can react with molecules after photoactivation to form crosslinks with nucleophilic groups, primarily amines. Exposure of its phenyl azide groups to UV light causes nitrene formation and ring expansion to the dehydroazepine intermediate. This group is highly reactive with amines. The crossbridge of BASED is cleavable using a disulfide reducing agent.

After two proteins are crosslinked, cleavage of the conjugate with DTT releases the link but maintains a radiolabel on each of the molecules (Figure 5.21).

MW 474.54

6. HOMOBIFUNCTIONAL ALDEHYDES

Numerous *bis*-aldehyde reagents have been used for the conjugation of biomolecules. Nearly every small organic compound containing two aldehyde groups has been at least tried in crosslinking reactions. The repertoire of available homobifunctional aldehydes ranges from the single-carbon formaldehyde (Section 6.1) through the two-carbon atom glyoxal (Brooks and Klamerth, 1968), the three-carbon malondialdehyde (Cater, 1963), the four-carbon succinaldehyde (Cater, 1963), the popular five-carbon glutaraldehyde (Section 6.2), the six-carbon adipaldehyde as well as its α-hydroxy derivative (Fein and Filachione, 1957; Seligsberger and Sadlier, 1957; Cater, 1963; Richard and Knowles, 1968; Hopwood, 1969), and several pyridoxal-polyphosphate derivatives that are internally cleavable with acid or base (Shimomura and Fukui, 1978; Benesch and Kwong, 1988).

By far, the two most popular *bis*-aldehyde reagents are formaldehyde and glutaraldehyde.

6.1. Formaldehyde

Formaldehyde is the smallest crosslinking reagent available that does not create a zero-length bridge between two molecules (Chapter 4). Although technically not a homobifunctional reagent, it undergoes crosslinking reactions as though it possessed two functional groups. In concentrated aqueous solutions, it can form the low-molecular-weight polymers typically observed in formalin preparations. In dilute solutions, it exists mainly in its monomeric state. Older solutions of formaldehyde may contain precipitated polymer that often can be resolubilized by heating. Commercial preparations of formaldehyde may be obtained as a 37% solution stabilized against polymerization by the addition of methanol.

Conjugation reactions using formaldehyde may proceed by one of two routes: the Mannich reaction or *via* an immonium cation intermediate. The Mannich reaction consists of the condensation of formaldehyde (or sometimes another aldehyde) with ammonia (in the form of its salt) and another compound containing an active hydrogen. For a review of this reaction mechanism, see Burns and Jacobsen (2011) and Adams *et al.* (1942). Instead of ammonia, however, this reaction can be performed with primary or secondary amines, or even with amides. An example of this is illustrated in

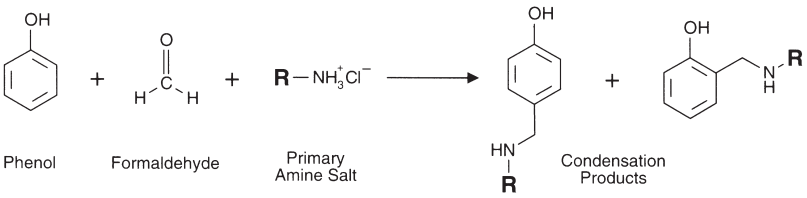

FIGURE 5.22 The Mannich reaction occurs between an active hydrogen-containing compound (phenol) and an amine-containing molecule in the presence of an aldehyde (formaldehyde). The condensation reaction forms stable crosslinks.

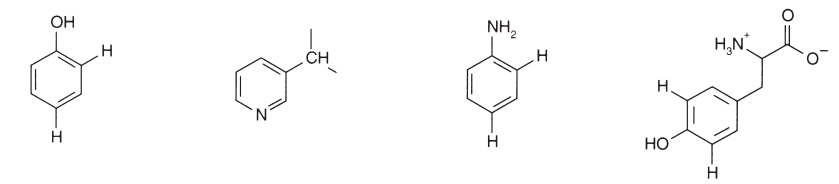

FIGURE 5.23 Examples of active hydrogen-containing compounds that can participate in the Mannich reaction. The points of reactivity are shown by the hydrogen atoms.

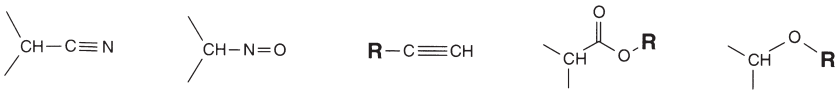

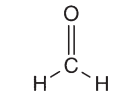

Figure 5.22 by the condensation of phenol, formaldehyde, and a primary amine salt (the active hydrogens are shown underlined). Figure 5.23 shows some active hydrogen-containing functional groups that can participate in the Mannich reaction.

Formaldehyde
MW 30

The Mannich reaction can be used for the immobilization of certain drugs, steroidal compounds, dyes, or other organic molecules that do not possess the typical nucleophilic groups able to participate in traditional coupling reactions (Chapter 15, Section 2.7) (Hermanson *et al.*, 1992). It also can be used to conjugate hapten molecules to carrier proteins when the hapten contains no convenient nucleophile for conjugation (Chapter 19, Section 6.2) (Liao *et al.*, 2011). In this case, the carrier protein contains the primary amines and the hapten contains at least one sufficiently active hydrogen to participate in the condensation reaction.

To obtain acceptable yields, the Mannich reaction must be done at elevated temperatures. Incubation at 37 to 57°C for at least 2 to 24h usually is required to complete the reaction. Addition of formaldehyde is done by adding an aliquot of a 37% solution to the reaction to obtain about a 10- to 100-fold molar excess over the amount of active hydrogen-containing compound to be conjugated. Thermo Fisher has designed a kit for the conjugation of haptens to carrier proteins using the Mannich reaction mechanism.

A secondary reaction pathway also is possible in formaldehyde-facilitated conjugations. Formaldehyde may react with a primary amine to form a quaternary ammonium salt. This intermediate spontaneously reacts to create a highly active immonium cation with loss of one molecule of water (Blass *et al.*, 1965; Ji, 1983). The immonium cation is reactive toward nucleophiles in proteins and other molecules, including amines, sulfhydryls, phenolic groups, and imidazole nitrogens. The reaction yields methylene bridges between two nucleophiles, binding macromolecules with a one-carbon linker (Figure 5.24).

It is obvious that the Mannich reaction pathway and the immonium ion mechanism may occur simultaneously, especially at conditions of room temperature or greater. Formaldehyde-facilitated crosslinking reactions between molecules that both contain nucleophiles probably occur primarily by the immonium ion pathway, since the Mannich reaction proceeds at a slower rate. In addition, the Mannich reaction will cause nondescript polymerization between molecules that possess both active hydrogens and amine groups. It is best to utilize the Mannich reaction only when one of the molecules contains no nucleophilic groups but at least one active hydrogen, and the other molecule contains a primary or secondary amine.

Formaldehyde also can be used to study protein interactions in cells or tissue sections by crosslinking and capturing protein complexes. Chapter 24, Section 1.3, describes this method and contains a protocol for use.

6.2. Glutaraldehyde

Glutaraldehyde is the most popular *bis*-aldehyde homobifunctional crosslinker in use today. However, a glance at glutaraldehyde's structure is not indicative of the complexity of its possible reaction mechanisms. Reactions with proteins and other amine-containing

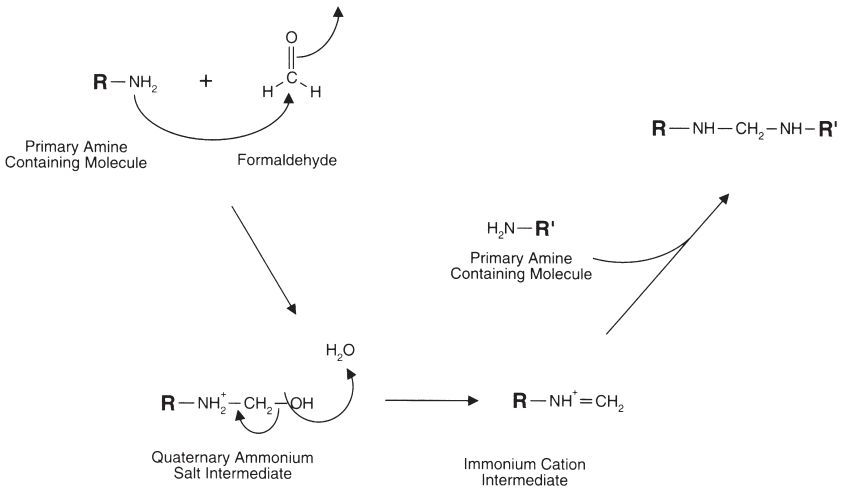

FIGURE 5.24 Two amine-containing molecules can be crosslinked by formaldehyde through formation of a quaternary ammonium salt with subsequent dehydration to an immonium cation intermediate. This active species then can react with a second amine compound to form stable secondary amine bonds.

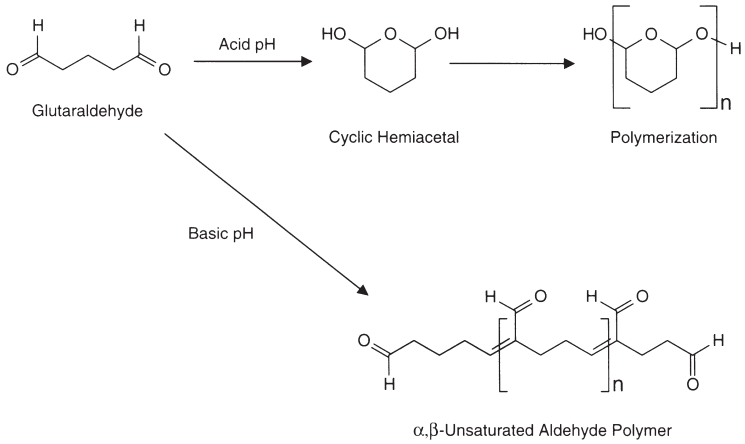

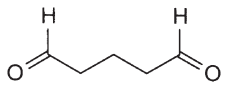

FIGURE 5.25 Glutaraldehyde in aqueous solution may polymerize at either acid or basic pH.

molecules would be expected to proceed through the formation of Schiff bases. Subsequent reduction with sodium cyanoborohydride or another suitable reductant would yield stable secondary amine linkages (Chapter 3, Sections 4.4 and 5.3). This reaction sequence certainly is possible, but other crosslinking reactions also occur.

Glutaraldehyde
MW 100.11

Glutaraldehyde in aqueous solutions can form polymers containing points of unsaturation due to aldol formation ((Figure 5.25) (Chapter 15, Section 2.1) (Hardy *et al.*, 1969, 1976; Monsan et al., 1975). Such α,β-unsaturated glutaraldehyde polymers are highly reactive toward nucleophiles, especially primary amines. Reaction with a protein results in alkylation of available amines, forming stable secondary amine linkages. These glutaraldehyde-modified proteins still may react with other amine-containing molecules either through the Schiff base pathway or through addition at other points of unsaturation (Figure 5.26). The proposed reaction mechanism of conjugation using these polymer conjugates may explain the stability of proteins crosslinked by glutaraldehyde that has not been reduced. Schiff base formation alone would not yield stable crosslinked products without reduction. In addition, a number of other potential reactions of glutaraldehyde in aqueous solution also can contribute to its stable crosslinking ability. These include reactions involving hemiacetal rings sometimes combined with aldol formation products, which can couple to amine groups without the formation of Schiff base linkages (see Chapter 15, Section 2.1, for an in-depth discussion of these reactions).

Crosslinking using glutaraldehyde polymers can be difficult to reproduce and scale up. Since the exact glutaraldehyde state in solution, including its potential polymer size and structure, is difficult to determine, the exact nature of the conjugates formed by this method may be indeterminable as well. The age of a

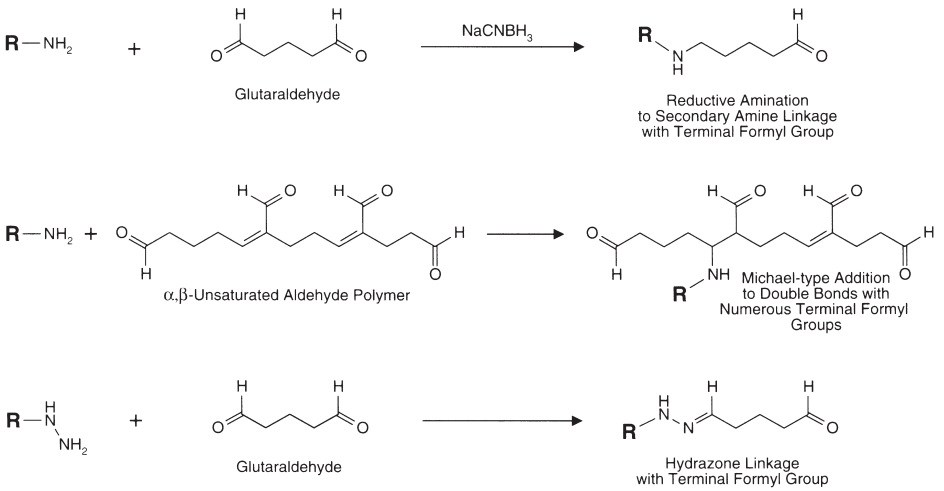

FIGURE 5.26 Glutaraldehyde may react by several routes to form covalent crosslinks with amine-containing molecules.

glutaraldehyde solution is another variable, because the older the solution the more polymer could be formed. Fresh glutaraldehyde often will not yield the same results as aged solutions. Some methods to control the glutaraldehyde activation and coupling process have been successfully carried out for the immobilization of affinity ligands (Chapter 15, Section 2.1); therefore, it also may be possible to use such methods to better control conjugate formation in solution.

A third method of using glutaraldehyde in conjugation reactions is through its ability to react rapidly with hydrazide groups. A molecule containing hydrazide functionalities or modified to contain them (Chapter 2, Section 4.5) can be conjugated with another molecule containing either amines or hydrazides. Glutaraldehyde will react with the hydrazide groups to form hydrazone linkages. When two macromolecules are crosslinked in solutions that contain multiple sites of conjugation, the multivalent hydrazone bonds will be strong enough to create a stable conjugate. If a small molecule is involved, however, reduction of the hydrazone with sodium cyanoborohydride is recommended to produce a leak-resistant bond.

Glutaraldehyde has been used extensively as a homobifunctional crosslinking reagent, especially for antibody–enzyme conjugations (Avrameas, 1969; Avrameas and Ternynck, 1971) and to produce vaccine immunogens (De Filette *et al.*, 2011; Chapter 19, Section 7). To help overcome its tendency to form large-molecular-weight polymers upon crosslinking two proteins, a two-step protocol often is employed. In this regard, one protein first is reacted with glutaraldehyde and purified away from excess reagent. The second protein then is added to effect the conjugate formation. See the introduction to this chapter and Chapter 2, Section 1.2 as well as Chapter 20, Section 1.2 for additional information on the use of glutaraldehyde and two-step crosslinking procedures.

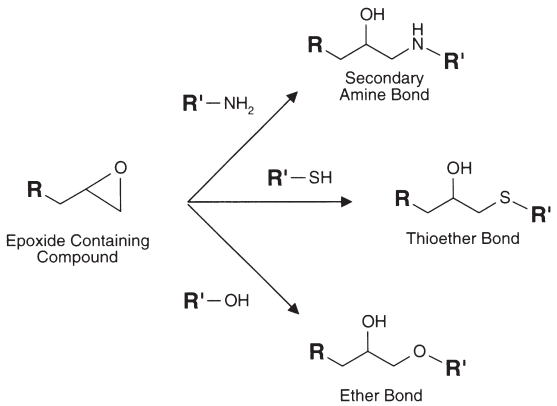

FIGURE 5.27 Epoxide groups are reactive toward sulfhydryls, amines, and hydroxyls.

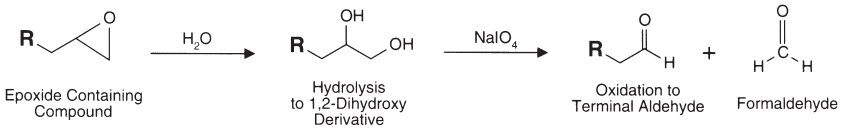
7. *BIS*-EPOXIDES

Homobifunctional compounds containing epoxide groups on both ends can be used to crosslink molecules containing nucleophiles, including amines, sulfhydryls, and hydroxyls. The reaction proceeds with epoxide ring opening to create secondary amine, thioether, or ether bonds with these functional groups (Figure 5.27). During the ring-opening process, a β-hydroxy group is created. Hydrolysis of the epoxy function without coupling to a nucleophile yields adjacent hydroxyls that can be oxidized with sodium periodate to create reactive aldehydes (Figure 5.28). Epoxide groups, however, are quite stable in aqueous environments around neutral pH or above. They are reactive at alkaline pH values toward other nucleophilic molecules, while they can be hydrolyzed to a diol at acid pH.

Certain *bis*-epoxide reagents have been used to activate hydroxylic matrices for coupling ligands containing amine, sulfhydryl, or hydroxyl groups for affinity chromatography purposes (Chapter 15, Section 2.3) (Hermanson *et al.*, 1992). Conjugation reactions involving proteins have



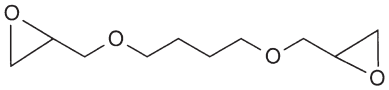


FIGURE 5.28 Hydrolysis of epoxy groups forms 1,2-dihydroxy derivatives that can be oxidized with periodate to create reactive aldehydes.

also been performed using epoxide crosslinkers, but not to the extent of their use in immobilization.

Bis-Epoxy compounds that have been used for crosslinking purposes vary mainly in their chain length, ranging from the 4-carbon bridge of 1,2:3,4-diepoxybutane (Kohn *et al.*, 1966; Skold, 1983), the 6-carbon spacer of 1,2:5,6-diepoxyhexane (Fearnley and Speakman, 1950), the 7-atom bridge of *bis*(2,3-epoxypropyl)ether (Kohn *et al.*, 1966), to the 12-atom spacer of the popular 1,4-(butanediol) diglycidyl ether (discussed below) (Sundberg and Porath, 1974; Porath, 1976). Longer-chain polymeric *bis*-epoxide compounds also have been utilized in collagen crosslinking experiments (Murayama, 1988).

7.1. 1,4-Butanediol Diglycidyl Ether

The most commonly used homobifunctional epoxide compound is 1,4-butanediol diglycidyl ether. The reagent can react with hydroxyls, amines, or sulfhydryl groups to produce ether, secondary amine, or thioether bonds, respectively. The reaction of the epoxide functionalities with hydroxyls requires high pH conditions, usually in the range of pH 11 to 12. Amine nucleophiles react at more moderate alkaline pH values, typically needing buffer environments of at least pH 9. Sulfhydryl groups are the most highly reactive nucleophiles with epoxides, requiring a buffered system in the range of only pH 7.5 to 8.5 for efficient coupling.

1,4-Butanediol Diglycidyl Ether
MW 202.25

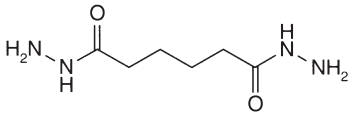
1,4-Butanediol diglycidyl ether is a viscous liquid having a density of 1.45 at 20°C. It is a hygroscopic, corrosive compound with a displeasing odor and should be handled with care in a fume hood. Aqueous solutions of the bis-epoxide usually possess a characteristic oily film on their surfaces, indicating the limited solubility of the reagent.

An example of the use of 1,4-butanediol diglycidyl ether for the activation of soluble dextran polymers is given in Chapter 18, Section 2.2. One end of the *bis*-epoxide reacts with the hydroxylic sugar residues of dextran to form ether linkages, which terminate in epoxy functionalities. The epoxides of the activated derivative then can be used to couple additional molecules containing nucleophilic groups to the dextran backbone.

bis-Epoxy compounds also have been used to couple affinity ligands to particles and chromatography supports. Amine- or hydroxyl-containing supports can be reacted with one end of 1,4-butanediol diglycidyl ether (in excess) to result in particles containing an available terminal epoxide group for further immobilization reactions ((Chapter 15, Section 2.3) (Goyal *et al.*, 2011).

8. HOMOBIFUNCTIONAL HYDRAZIDES

Homobifunctional crosslinking agents containing hydrazide groups at both ends can be used to conjugate molecules containing carbonyl or carboxyl groups. In one scheme, a *bis*-hydrazide compound can be reacted with the carboxylate groups of a protein in the presence of the water soluble carbodiimide 1-ethyl-3-[3-dimethylaminopropyl]carbodiimide hydrochloride (EDC), to yield acyl hydrazide linkages containing terminal alkyl hydrazides. The hydrazide-activated protein then can be used to conjugate with a glycoprotein that had been previously oxidized with sodium periodate to generate reactive aldehyde residues. The resulting hydrazone bonds can be further stabilized by reducing with sodium cyanoborohydride to give the secondary amine linkage.



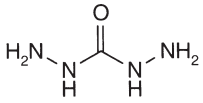
These techniques have been used to target, detect, or assay glycoproteins in solution or on cell surfaces by using hydrazide-activated enzymes, avidin, or streptavidin (Chapter 11, Section 5) (Bayer and Wilchek, 1990; Bayer *et al.*, 1987, 1990) and to form conjugates with glycoproteins.

bis-Hydrazide-containing molecules can also be used to activate soluble polymeric substances containing aldehyde groups. For instance, dextran may be periodate-oxidized to create numerous formyl functionalities on each molecule. Subsequent reaction with a homobifunctional hydrazide in large excess results in a hydrazide-activated polymer having multivalent binding capability toward aldehydes or ketones (Chapter 18, Section 2.2). Insoluble support matrices suitable for affinity chromatography have been activated in a similar fashion to create the hydrazide derivative (O'Shannessy and Wilchek, 1990).

8.1. Adipic Acid Dihydrazide

The dihydrazide derivative of adipic acid (Aldrich) is perhaps the most popular homobifunctional hydrazide compound in use. The reagent provides a 10-atom bridge between crosslinked molecules after conjugation. Adipic

dihydrazide (ADH) is a solid that is soluble in aqueous solutions, but may need to be moderately heated to create concentrated solutions. Aldehyde-containing substances may be modified with this reagent to form hydrazone bonds with alkyl hydrazide spacers suitable for reaction with other formyl-containing molecules (Figure 5.29). In this sense, affinity chromatography matrices have been activated with ADH to produce a hydrazide derivative for coupling to aldehyde-containing ligands (Chapter 15, Section 2.4) (O'Shannessy and Wilchek, 1990), enzymes have been modified at available carboxylate groups using an EDC-facilitated reaction to create hydrazide-activated derivatives appropriate for targeting oxidized glycoproteins (Bayer *et al.*, 1987), and the biotin-binding proteins avidin and streptavidin have been activated with *bis*-hydrazides to assay glycoconjugates using biotinylated enzymes (Bayer and Wilchek, 1990; Bayer *et al.*, 1990). The crosslinker has also been utilized to study the carbohydrate portion of yeast acid phosphatase (Kozulic *et al.*, 1984) and to prepare vaccine conjugates of the capsular polysaccharide of *Salmonella typhi* coupled to the carrier *Pseudomonas aeruginosa* recombinant exoprotein A (Kossaczka *et al.*, 2012).

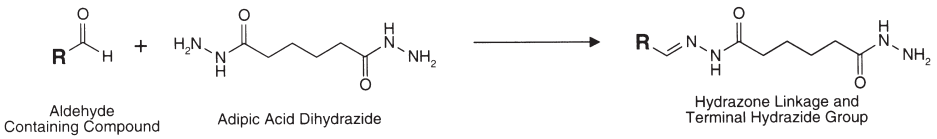


Adipic Acid Dihydrazide
MW 174.2

Protocols for the use of ADH in the modification of aldehyde or carboxylate functionalities can be found in Chapter 2, Section 4.5, and Chapter 11, Section 5.

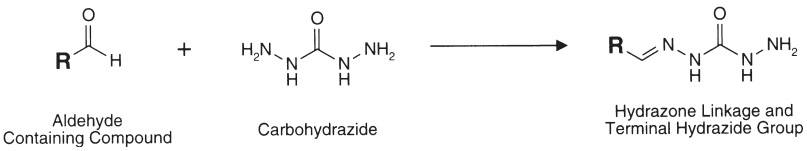
8.2. Carbohydrazide

Carbohydrazide (carbonic dihydrazide or 1,3-diaminourea) is a small homobifunctional reagent containing reactive hydrazide groups on both ends. Its lack of an internal aliphatic bridge, as found in adipic dihydrazide, gives the compound excellent solubility characteristics in aqueous solutions. Carbohydrazide is freely soluble in water, but practically insoluble in ethanol and other organic solvents. The two hydrazide functional groups of the molecule can react with aldehyde or ketone groups to form hydrazone linkages. When reacted in excess with a molecule containing carbonyl groups, carbohydrazide modification results in short derivatives terminating in available hydrazides (Figure 5.30). The compound has been used to modify microplate wells that have been graft polymerized with glycidyl methacrylate to form surfaces that would couple antibodies through their carbohydrate portions (Allmer *et al.*, 1990; Brillhart and Ngo, 1991) and also used to activate chromatography supports for the immobilization of aldehyde-containing ligands (Chapter 15, Section 2.4). In addition, carbohydrazide has been used as part of the linker arm to create a fucose-specific conjugation scheme for attaching glycan carbohydrates to a vascular-targeting monoclonal antibody (Zuberbuhler *et al.*, 2012). Although its use for protein modification has not been realized, carbohydrazide may be a superior alternative to adipic dihydrazide due to its hydrophilicity. Its only disadvantage may be in its shorter bridge (5-atom spacer as opposed to ADH's 10-atom bridge).



Carbohydrazide
MW 90.09

A protocol for the use of carbohydrazide in the modification of aldehyde or carboxylate functional groups can be found in Chapter 2, Section 4.5, and its potential use for the activation of particles or chromatography supports is described in Chapter 15, Section 2.4.



9. *BIS*-DIAZONIUM DERIVATIVES

Diazonium groups react with active hydrogens on aromatic rings to give covalent diazo bonds. Generation of a diazonium-reactive group is usually done from an aromatic amine by reaction with sodium nitrite under acidic conditions at 0°C (see Chapter 2, Section 4.3, and

Aldehyde Containing Compound

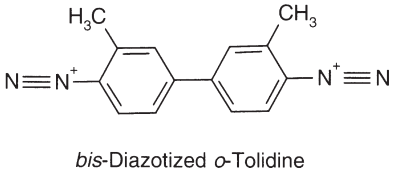

FIGURE 5.30 Carbohydrazide can be used to transform an aldehyde residue into a hydrazide group.

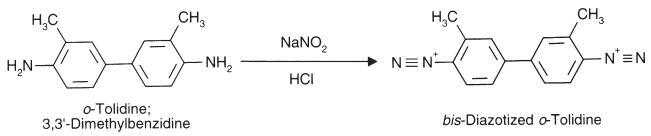
Chapter 3, Section 6.1). The highly reactive and unstable diazonium is reacted immediately with an active hydrogen-containing compound at pH 8 to 10. In general, at pH 8.0 the diazonium group will react principally with histidine residues, attacking the electron-rich nitrogens of the imidazole ring. At higher pH, the phenolic side chain of tyrosine groups can be modified. The reaction proceeds by electrophilic attack of the diazonium group toward the electron-rich points on the target molecules. Phenolic compounds are modified at positions *ortho* and *para* to the aromatic hydroxyl group. For tyrosine side chains, only the *ortho* modification is available and reactive.

bis-Diazonium compounds are useful in crosslinking molecules containing no other convenient functional groups such as amines, carboxylates, or sulfhydryls. Conjugations done using these compounds usually create deeply colored products characteristic of the diazo bonds. Occasionally, the conjugated molecules may turn dark brown or even black. The diazo linkages are reversible by addition of 0.1-*M* sodium dithionite in 0.2-*M* sodium borate, pH 9.0. Upon cleavage, the color of the complex is lost.

9.1. *o*-Tolidine, Diazotized

o-Tolidine, or 3,3′-dimethylbenzidine, is a *bis*-aromatic-amine-containing compound that can be readily diazotized to a homobifunctional diazonium crosslinker by reaction with sodium nitrite (Figure 5.31). The reagent is typically used in a one-step conjugation reaction wherein two active hydrogen-containing molecules are crosslinked through the addition of *o*-tolidine immediately after it has been diazotized under acidic conditions by reacting with sodium nitrite (Figure 5.32). pH adjustment to alkaline conditions after diazonium formation rapidly causes crosslinking to occur. The diazotized form of *o*-tolidine must be used quickly due to its instability in aqueous solutions. The reagent has been used to couple active hydrogen-containing haptens to carrier proteins to form immunogens suitable for the production of antibodies (Chapter 19, Section 6.1).

bis-Diazotized *o*-Tolidine



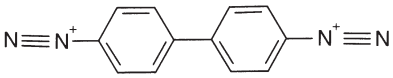


FIGURE 5.31 Reaction of *o*-tolidine with sodium nitrite in the presence of HCl yields a highly reactive diazo-derivative.

o-Tolidine is a benzidine derivative that should be considered a potential carcinogen. Handling should be done with proper safety precautions and with the use of a fume hood to avoid breathing in any dust particles. The reagent is sparingly soluble in water, but is more soluble under the dilute acidic conditions necessary for activation to a diazonium derivative.

9.2. *bis*-Diazotized Benzidine

Benzidine, or *p*-diaminodiphenyl, may be diazotized with sodium nitrite to form a homobifunctional diazonium crosslinking agent useful in conjugating active hydrogen-containing molecules (Figure 5.33). The coupling reaction proceeds *via* electrophilic attack on atoms containing extractable hydrogens. Particularly reactive are the phenolic side chains of tyrosine residues and the imidazole rings of histidine groups.

Bis-Diazotized Benzidine

Benzidine is a known carcinogen and should be handled with extreme caution (Fourth Annual Report on Carcinogens; NTP 85-002, 1985, p. 37). The solid and its vapors may be rapidly absorbed through skin. Protective clothing and the use of a fume hood are recommended. The compound is only sparingly soluble in water as the free base. The dihydrochloride form, however, is soluble in water and ethanol.

bis-Diazotized benzidine has been used to create active hydrogen-reactive spacer arms on chromatographic

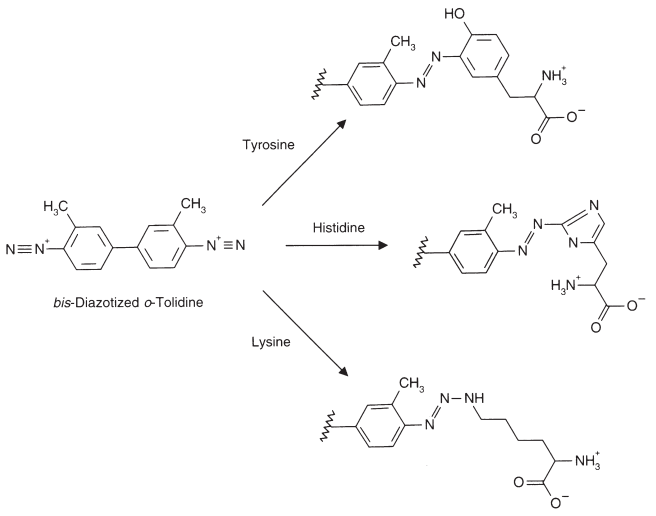

FIGURE 5.32 *bis*-Diazotized tolidine can form crosslinks with proteins through available tyrosine, histidine, or lysine residues.

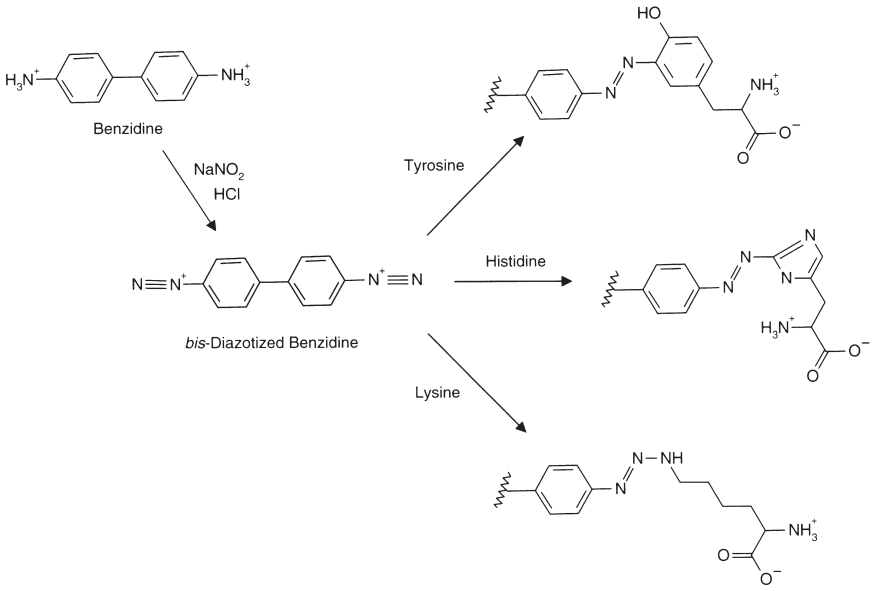

FIGURE 5.33 Benzidine can be diazotized with sodium nitrite and HCl for reaction with proteins through their tyrosine, histidine, or lysine side-chain groups.

matrices (Silman *et al.*, 1966; Lowe and Dean, 1971). The compound may be used similarly to *o*-tolidine for the conjugation of active hydrogen-containing molecules (see Section 9.1, and Chapter 3, Section 6.1).

10. *BIS*-ALKYLHALIDES

Homobifunctional reagents containing reactive halogen groups on both ends are capable of crosslinking sulfhydryl-, amino-, or histidine-containing molecules by nucleophilic substitution. Three forms of activated halogen functionalities can be used to create these reagents: haloacetyl derivatives (see Chapter 3, Section 2.1), benzyl halides that react through a resonance activation process with the neighboring benzene ring, and alkyl halides that possess the halogen β to a nitrogen or sulfur atom, as in *N*- and *S*-mustards. Haloacetyl compounds typically are iodo- or bromo-derivatives, the simplest of which are 1,3-dibromoacetone (Husain and Lowe, 1968) and various iodoacetyl derivatives of short diamine alkyl spacers (Ozawa, 1967) (Figure 5.34). Benzyl halides also are usually iodo or bromo derivatives, whereas the halo-mustards mainly employ chloro- and bromo-forms (Figure 5.35).

Reactive halogen crosslinkers are mainly specific for sulfhydryl groups at physiological pH, however at more alkaline pH values they can readily cross-react with amines and the imidazole nitrogens of histidine residues. Some reactivity with hydroxyl-containing compounds also may be realized, particularly with trichloro-*s*-triazine (TsT) derivatives under alkaline conditions (see Chapter 15, Section 2.3).

Most of the *bis*-alkyl halides referenced in the literature are unavailable commercially and therefore must be synthesized. Some key references to the preparation and use of these compounds for the crosslinking of sulfhydryl-containing proteins and other molecules include Goodlad (1957), Segal and Hurwitz (1976), Ewig and Kohn (1977), Wilchek and Givol (1977), Prestayko *et al*. (1981), Luduena *et al*. (1982), Hiratsuka (1988), and Aliosman *et al*. (1989).

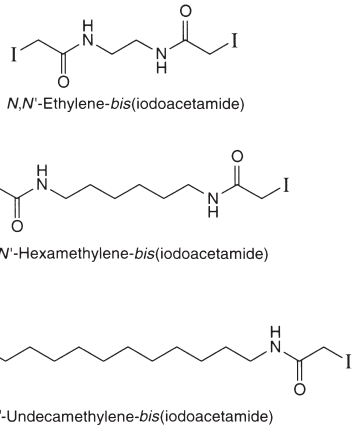

FIGURE 5.34 Several varieties of iodoacetylated diamine compounds have been investigated for crosslinking proteins through sulfhydryl groups.

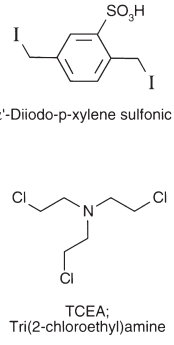

FIGURE 5.35 Benzylhalides and halo-mustards can be used as crosslinking agents reactive toward sulfhydryl groups.

CHAPTER

6

Heterobifunctional Crosslinkers

Heterobifunctional conjugation reagents contain two different reactive groups that can couple to two different functional targets on proteins and other macromolecules (Figure 6.1). For example, one part of a crosslinker may contain an amine-reactive group, while another portion may consist of a sulfhydryl-reactive group. The result is the ability to direct the crosslinking reaction to selected parts of target molecules, thus garnering better control over the conjugation process.

Heterobifunctional reagents can be used to crosslink proteins and other molecules in a two- or three-step process that limits the degree of polymerization often obtained using homobifunctional crosslinkers (Chapter 2, Section 1.2, and Chapter 5, Section 2.2). In a typical conjugation scheme, one protein is modified with a heterobifunctional compound using the crosslinker's most reactive or most labile end. The modified protein is then purified from excess reagent by gel filtration or rapid dialysis. Most heterobifunctionals contain at least one reactive group that displays extended stability in aqueous environments, therefore allowing purification of an activated intermediate before adding the second molecule to be conjugated. For instance, an *N*-hydroxysuccinimide (NHS ester–maleimide heterobifunctional (for example, see Section 1.3, this chapter) can be used to react with the amine groups of one protein through its NHS ester end (the most labile functionality), while preserving the activity of its maleimide functionality. Since the maleimide group has greater stability in aqueous solution than the NHS ester group, a maleimide-activated intermediate may be created. After a quick purification step, the maleimide end of the crosslinker can then be used to conjugate to a sulfhydryl-containing molecule.

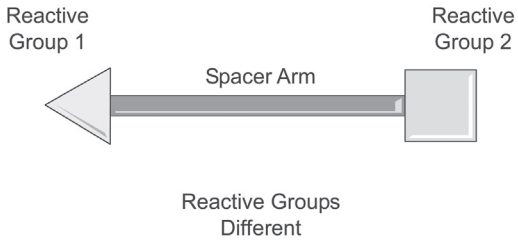

FIGURE 6.1 The general design of a heterobifunctional crosslinking agent includes two different reactive groups at either end and an organic cross-bridge of various length and composition. The cross-bridge may be constructed of chemically cleavable components for selective disruption of conjugates.

Such multi-step protocols offer greater control over the resultant size of the conjugate and the molar ratio of components within the crosslinked product. The configuration or structure of the conjugate can be regulated by the degree of initial modification of the first protein and by adjusting the amount of second protein added to the final conjugation reaction. Thus, low- or high-molecule-weight conjugates may be obtained to better fashion the product toward its intended use.

Heterobifunctional crosslinking reagents may also be used to site-direct a conjugation reaction toward particular parts of target molecules. Amines may be coupled on one molecule while sulfhydryls or carbohydrates are targeted on another molecule. Directed coupling is often important in preserving critical epitopes or active sites within macromolecules. For instance, antibodies may be coupled to other proteins while directing the crosslinking reaction away from the antigen binding sites, thus maximizing antibody activity in the conjugate.

Heterobifunctional reagents containing one photoreactive end may be used to insert nonselectively into target molecules by UV irradiation. Ligands having specific affinity toward a receptor may be labeled with a photoreactive crosslinker, allowed to interact with its target, and then photolyzed to permanently label the receptor at its binding site. The photoreactive group is stable until exposed to high-intensity light at UV

© 2013 Elsevier Inc. All rights reserved.

wavelengths. Photoaffinity labeling techniques are an important investigative tool for determining binding site characteristics.

The third component of all heterobifunctional reagents is the cross-bridge or spacer that ties the two reactive ends together. Crosslinkers may be selected based not only on their reactivities, but also on the length and type of cross-bridge they possess. Some heterobifunctional families differ solely in the length of their spacer. The nature of the cross-bridge may also govern the overall hydrophilicity of the reagent. For instance, polyethylene glycol (PEG)-based cross-bridges create hydrophilic reagents that provide water solubility to the entire heterobifunctional compound (see Chapter 18, Section 1). A number of heterobifunctionals contain cleavable groups within their cross-bridges, lending greater flexibility to the experimental design. A few crosslinkers contain peculiar cross-bridge constituents that actually affect the reactivity of their functional groups. For instance, it is known that a maleimide group that has an aromatic ring immediately next to it is less stable to ring opening and loss of activity than a maleimide that has an aliphatic ring adjacent to it. In addition, conjugates destined for use *in vivo* may have different properties depending on the type of spacer on the associated crosslinker. Some spacers may be immunogenic and cause specific antibody production to occur against them. In other instances, the half-life of a conjugate *in vivo* may be altered by the choice of cross-bridge, especially when using cleavable reagents.

The following heterobifunctional reagents are organized according to their reactivities. The majority are commercially available and well-documented in the literature as to their properties. Additional heterobifunctional compounds are described in Chapter 17 (Chemoselective Ligation; Bioorthogonal Reagents) and Chapter 18, Section 1 (Discrete PEG Reagents).

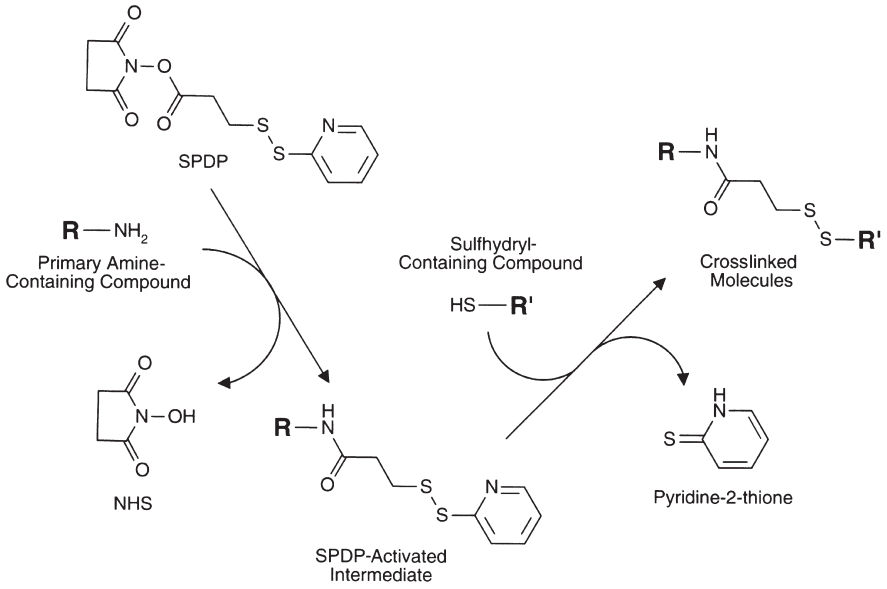
1. AMINE-REACTIVE AND SULFHYDRYL-REACTIVE CROSSLINKERS

Perhaps the most popular heterobifunctional reagents are those which contain amine-reactive and sulfhydryl-reactive ends. The amine-reactive group is usually an active ester, most often an NHS ester, while the sulfhydryl-reactive portion may be one of several different functional groups. The amine-reactive end of these crosslinkers is typically an acylating agent possessing a good leaving group that can undergo nucleophilic substitution to form an amide bond with primary amines. The sulfhydryl-reactive portion, by contrast, is usually an alkylating agent that is capable of creating either thioether or disulfide linkages with sulfhydryl-containing molecules. Depending on the chemistry chosen, linkages with a sulfhydryl-containing molecule may be either permanent covalent bonds or reversible disulfide bonds that can be cleaved by use of a suitable disulfide reductant.

The active ester chemistry of the amine-reactive end of these crosslinkers is characteristically the most labile functional group, being susceptible to rapid hydrolysis under the aqueous conditions of a conjugation reaction. The sulfhydryl-reactive group, however, is usually much more stable to breakdown in aqueous environments. Therefore, these reagents typically are used in multi-step conjugation protocols wherein one protein or molecule is first modified through its amines to yield a sulfhydryl-reactive intermediate. After removal of excess crosslinker by gel filtration, a second protein or molecule containing a sulfhydryl group is added to effect the final conjugation. The stability of the sulfhydryl-reactive end of these crosslinkers allows greater control over the crosslinking process than is possible with single-step procedures.

1.1. SPDP, LC-SPDP, and Sulfo-LC-SPDP

SPDP, *N*-succinimidyl 3-(2-pyridyldithio)propionate, is one of the most popular heterobifunctional crosslinking agents available. The activated NHS ester end of SPDP reacts with amine groups in proteins and other molecules to form an amide linkage. The 2-pyridyldithiol group at the other end reacts with sulfhydryl residues to form a disulfide linkage with thiol-containing molecules (Carlsson *et al.*, 1978) (Figure 6.2). The crosslinker is used extensively to form enzyme conjugates for use in immunoassays or in labeled DNA probe techniques. It is also frequently used for the preparation of immunotoxin conjugates for *in vivo* administration (Chapter 20, Section 3). In addition, the reagent is effective in creating sulfhydryls on proteins and other molecules (Chapter 2, Section 4.1). Once modified with SPDP, a protein can be treated with dithiothreitol (DTT) (or another disulfide-reducing agent) to release the pyridine-2-thione leaving group and form a free sulfhydryl. The terminal SH group can then be used to conjugate with any crosslinking agents containing sulfhydryl-reactive groups, such as maleimide or iodoacetyl (both for covalent conjugation) or 2-pyridyldithiol groups (for reversible conjugation).



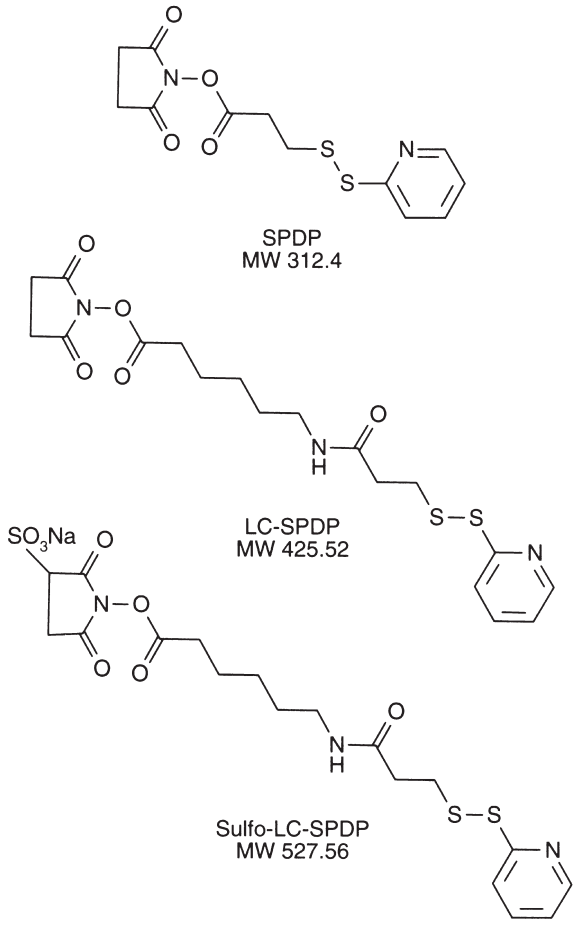


FIGURE 6.2 SPDP can react with amine-containing molecules through its NHS ester end to form amide bonds. The pyridyl disulfide group can then be coupled to a sulfhydryl-containing molecule to create a cleavable disulfide bond.

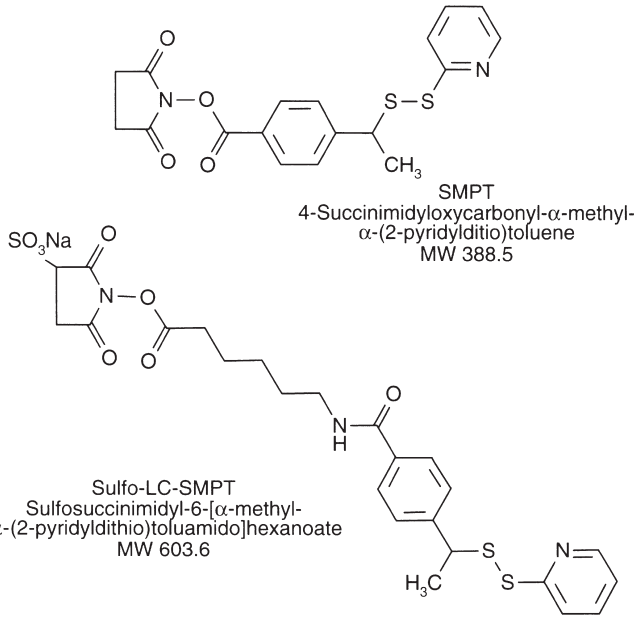
There are three forms of SPDP analogs currently available commercially (Thermo Fisher): the standard SPDP, a long-chain version designated LC-SPDP, and a water soluble, sulfo-NHS form also containing an extended chain, called sulfo-LC-SPDP. Both the standard SPDP and the LC-SPDP are insoluble in aqueous solutions and must first be solubilized in DMSO prior to addition to the reaction solution. The sulfo-LC-SPDP may be solubilized directly in water or buffer. The long-chain versions extend the length of the crosslinker for those applications that require greater accessibility to react with sterically hindered functional groups. Since many sulfhydryl residues are found below the surface of a protein structure in more hydrophobic domains, the longer spacer arm of the LC versions may be more effective in conjugations with these groups. The deficiency in having long aliphatic spacers, however, is that the reagent becomes much more hydrophobic. Care should be taken not to over modify proteins in order to avoid the potential for precipitation.

SPDP or its analogs have been used in many conjugation applications, including the preparation of peptide-based immunoconjugates for prostate cancer therapy (Rege *et al.*, 2007), the preparation of antibody conjugates for a time-resolved fluorescence assay system (Liang *et al.*, 2007), in the study of bone morphogenetic protein type 2 receptor in pulmonary hypertension (Reynolds *et al.*, 2007), and to form conjugates of cationic cell-permeable peptides with siRNA for delivery into targeted cells (Lee *et al.*, 2012).



The following procedure is a suggested multi-step protocol involving the activation of one protein by modification of its amines through the NHS ester end of SPDP, purification of this active intermediate, and subsequent addition of a sulfhydryl-containing molecule for conjugation via the remaining pyridyl disulfide group.

Protocol

1. Dissolve a protein or macromolecule containing primary amines at a concentration of 10 mg/ml in 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Other non-amine-containing buffers such as borate, HEPES, and bicarbonate may also be used in this reaction. Avoid sulfhydryl-containing components in the reaction mixture as these will react with the pyridyl disulfide end of SPDP. The effective pH for the NHS ester modification reaction is in the range of 7 to 9, but hydrolysis will increase at the higher end of this range.
2. Dissolve SPDP at a concentration of 6.2 mg/ml in DMSO (makes a 20-m*M* stock solution). Alternatively, LC-SPDP may be used and dissolved at a concentration of 8.5 mg/ml in DMSO (also makes a 20-m*M* solution). If the water soluble sulfo-LC-SPDP is used, a stock solution in water may be prepared just prior to adding an aliquot to the thiolation reaction. In this case, prepare a 10-m*M* solution of sulfo-LC-SPDP by dissolving 5.2 mg/ml in water. Since an aqueous solution of the crosslinker will degrade by hydrolysis of the sulfo-NHS ester, it should be used quickly to prevent significant loss of activity. If a sufficiently large amount of protein will be modified, the solid may be added directly to the reaction mixture without preparing a stock solution in water to allow accurate weighing of sulfo-LC-SPDP.
3. Add 25 µl of the stock solution of either SPDP or LC-SPDP in DMSO to each ml of the protein to be modified. If sulfo-LC-SPDP is used, add 50 µl of the stock solution in water to each ml of protein solution.
4. Mix and react for at least 30 min at room temperature. Longer reaction times, even overnight, will not adversely affect the modification.
5. Purify the modified protein from reaction byproducts by dialysis or gel filtration using 50-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2. Alternatively, centrifugal spin columns containing a desalting resin may be used for rapid purification (Thermo Fisher).
6. Add a sulfhydryl-containing protein or other molecule to the purified SPDP-modified protein to effect the conjugation reaction. Molecules lacking available sulfhydryl groups may be modified to contain them by a number of methods (Chapter 2, Section 4.1). The amount of this second protein added to the reaction should be governed by the desired molar ratio of the two proteins in the final conjugate. The conjugation reaction should be done in the presence of at least 10-m*M* EDTA to prevent metal-catalyzed sulfhydryl oxidation.

1.2. SMPT and Sulfo-LC-SMPT

SMPT, succinimidyloxycarbonyl-α-methyl-α-(2-pyridyldithio) toluene, is a heterobifunctional crosslinking agent that contains an amine-reactive NHS ester on one end and a sulfhydryl-reactive pyridyl disulfide group on the other end. SMPT is therefore an analog of SPDP that differs only in its cross-bridge, which contains an aromatic ring and a hindered disulfide group (Thorpe *et al.*, 1987; Ghetie *et al.*, 1990). The spacer arm of SMPT is slightly longer than SPDP (11.2 Å *versus* 6.8 Å), but the presence of the benzene ring and an α-methyl group adjacent to the disulfide sterically hinders the structure sufficiently to provide increased half-life of conjugates *in vivo*.

Conjugation reactions performed using SMPT often proceed by a multi-step protocol involving modification of one protein through its amine groups to create a pyridyl disulfide-activated intermediate. Since SMPT is not soluble in water, the reagent is first solubilized in DMF or DMSO and an aliquot of this stock solution added to the reaction. The NHS ester end of the reagent reacts with ε- and N-terminal amine groups to create stable amide linkages. After removal of excess crosslinker by gel filtration or dialysis, a second protein containing a

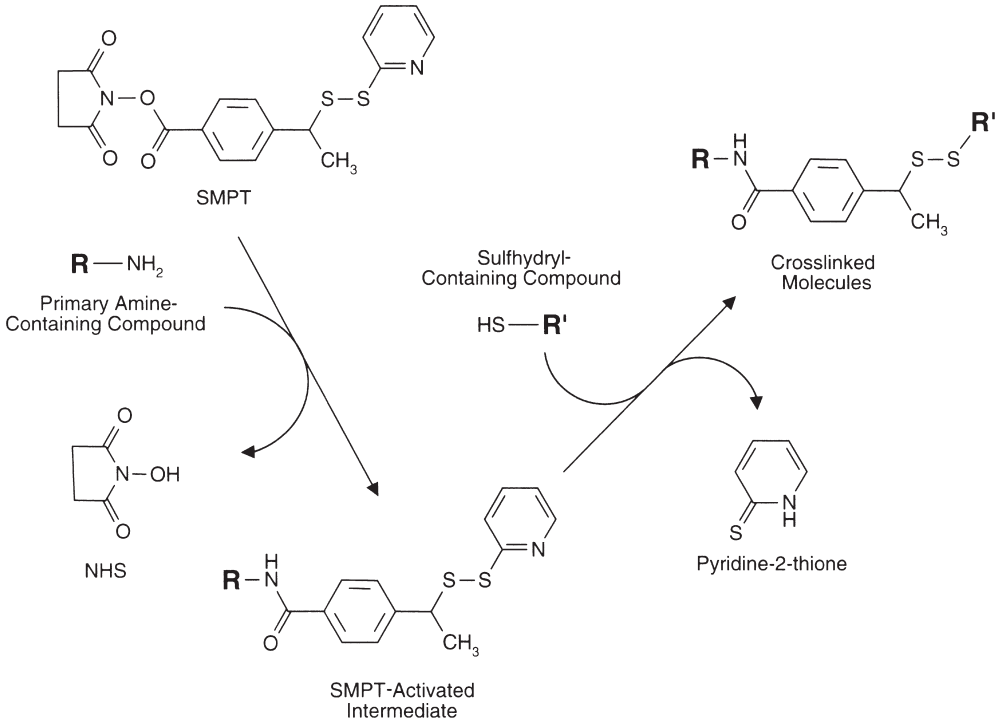


FIGURE 6.3 SMPT can form crosslinks between an amine-containing molecule and a sulfhydryl-containing compound through amide and disulfide linkages, respectively. The hindered nature of the disulfide group provides better stability toward reduction and cleavage.

sulfhydryl group is added to effect the final conjugation (Figure 6.3). The resultant protein–protein crosslink contains a disulfide bond that is susceptible to cleavage by reduction, although more slowly due to the hindered nature of the cross-bridge.

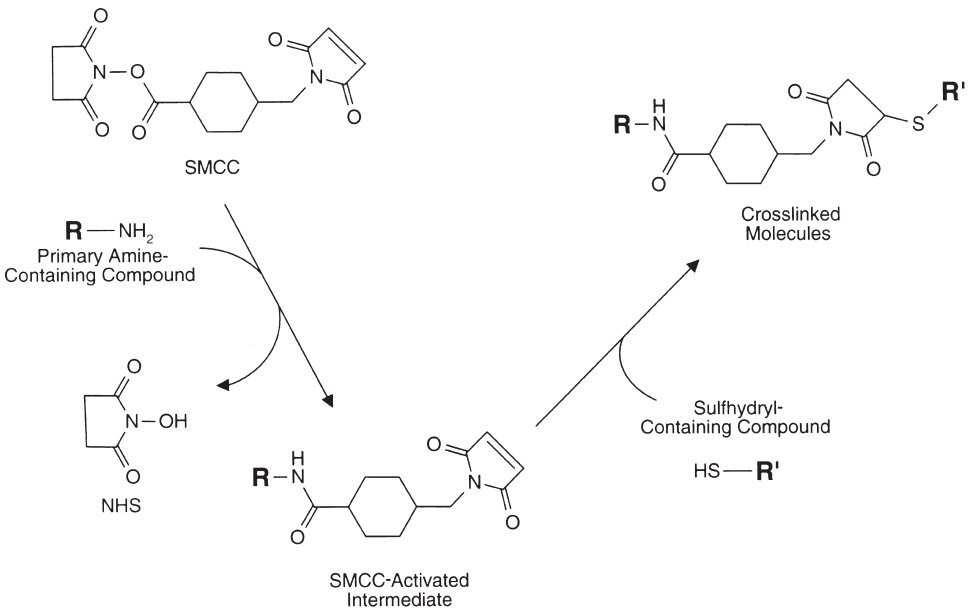
SMPT is often used for the preparation of immunotoxin conjugates that contain a monoclonal antibody directed against some cell-surface antigen (usually a tumor-associated antigen) crosslinked to a protein toxin molecule. It has been shown that a cleavable linkage between the antibody and toxin molecules helps to ensure a potent immunotoxin (Lambert *et al.*, 1985). Increased cytotoxicity is typically observed for immunotoxin conjugates containing cross-bridge disulfides as opposed to non-cleavable linkages. Cleavability presumably facilitates the release of the toxin from the antibody after the conjugate has bound to the cell surface. However, the disulfide bonds formed from some crosslinkers, such as SPDP, are readily reduced and cleaved *in vivo*—often before they reach their target. The hindered disulfide of SMPT has distinct advantages in this regard. Thorpe *et al.* (1987) showed that SMPT conjugates had approximately twice the half-life *in vivo* as SPDP conjugates.

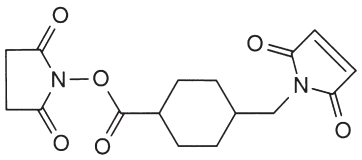
A water soluble analog of SMPT, called sulfo-LC-SMPT, or sulfosuccinimidyl-6-[α-methyl-α-(2-pyridyldithio) toluamido]hexanoate, is available from Thermo Fisher. The sulfo–NHS ester end of the reagent provides the water solubility due to the negative charge of the sulfonate group. While sulfo-LC-SMPT has the same chemical reactivity as SMPT, its cross-bridge contains an additional 6-aminocaproic acid spacer providing a 20-Å crosslink as opposed to the 11.2-Å length of SMPT. The reactivity and use of sulfo-LC-SMPT are essentially the same as that of SMPT, except that the reagent may be added directly to aqueous reaction media or pre-dissolved in water. A stock solution made in water should be used immediately to prevent extensive NHS ester hydrolysis.

SMPT or sulfo-LC-SMPT has been used to develop conjugates for *in vivo* delivery of siRNA to hepatocytes (Rozema *et al.*, 2007), in preparing an anti-CD25-immunotoxin conjugate (Mielke *et al.*, 2007), and in preparing conjugates for selective depletion of donor lymphocytes in stem cell transplantation (Solomon *et al.*, 2005). The crosslinkers have also been used to form "stealth" liposomes carrying chemotherapeutics through the conjugation of anti-tumor antibodies (Manjappa *et al.*, 2011).

1.3. SMCC and Sulfo-SMCC

SMCC, succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate, is a heterobifunctional reagent with significant utility in crosslinking proteins, particularly in the preparation of antibody–enzyme and hapten–carrier conjugates (Hashida and Ishikawa, 1985;





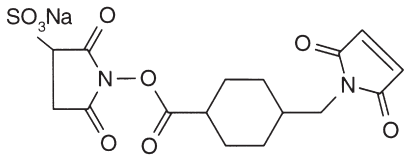


FIGURE 6.4 SMCC reacts with amine-containing molecules to form stable amide bonds. Its maleimide end may then be conjugated to a sulfhydryl-containing compound to create a thioether linkage.

Dewey *et al.*, 1987). In fact, it may be the most popular crosslinker ever designed for protein conjugation purposes. The NHS ester end of the reagent can react with primary amine groups on proteins to form stable amide bonds. The maleimide end of SMCC is specific for coupling to sulfhydryls when the reaction pH is in the range of 6.5 to 7.5 (Smyth *et al.*, 1964) (Figure 6.4).

11.6 Å

Sulfo-SMCC;
Sulfosuccinimidyl 4-(*N*-maleimidomethyl)-
cyclohexane-1-carboxylate
Water Soluble
MW 436.37
11.6 Å

At pH 7, the reaction of the maleimide group with sulfhydryls proceeds at a rate 1000-times greater than its reaction with amines. At more alkaline pH values, however, its reaction with amines becomes more evident. The maleimide end may also undergo hydrolysis to an open maleamic acid form that is unreactive toward sulfhydryls. Hydrolysis may occur after sulfhydryl coupling to the maleimide, as well. This ring-opening reaction typically happens faster at higher pH values. However, the maleimide group of SMCC displays unusual stability up to pH 7.5. The increased stability of SMCC's maleimide group may be due to it not being attached directly to an aromatic ring structure. By contrast, some maleimide-containing reagents, such as *N,N′-o*-phenylenedimaleimide and *N,N′*-oxydimethylenedimaleimide are far less stable under these conditions. Reportedly, only 4% of the maleimide groups of SMCC will decompose at neutral pH within 2 h at 30°C (Ishikawa *et al.*, 1983). For this reason, proteins may be modified with SMCC to form relatively long-lived, maleimide-activated intermediates. The SMCC derivative may then be freeze-dried to provide a stock preparation of sulfhydryl-reactive protein.

SMCC is frequently used to prepare hapten–carrier or antibody–enzyme conjugates. In both applications, one of the molecules is activated (usually the carrier or the enzyme) with the crosslinker, purified to remove excess reagents, and then mixed with the sulfhydryl-containing second molecule to make the final conjugate. Published applications using SMCC are numerous, but include conjugation of glucose oxidase to rabbit antibodies (Yoshitake *et al.*, 1979), crosslinking

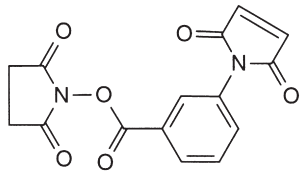
Fab′ fragments to horseradish peroxidase (Imagawa *et al.*, 1982; Yoshitake *et al.*, 1982a,b; Ishikawa *et al.*, 1983; Uto *et al.*, 1991), coupling anti-digoxin $F(ab')_2$ fragments to β-galactosidase (Freytag *et al.*, 1984), preparing conjugates of alkaline phosphatase and human IgG $F(ab')_2$ fragments (Mahan *et al.*, 1987), and preparing immunogens (Peeters *et al.*, 1989). SMCC has also been used to prepare antibody–drug conjugates targeted to CD79 for treatment of non-Hodgkin lymphoma (Polson *et al.*, 2007), to make antibody-conjugated, radiolabeled carbon nanotubes for tumor targeting (McDevitt *et al.*, 2007), and to prepare peptide–ovalbumin conjugates to study nucleus-to-cytoplasm shuttling of human acireductone dioxygenase (Gotoh *et al.*, 2007). In addition, Hoppmann *et al.* (2011) used sulfo-SMCC to prepare Affibody–albumin bioconjugates for HER2-positive cancer targeting *in vivo*.

Since SMCC is a water-insoluble crosslinker, it must first be dissolved in organic solvent (DMSO or DMF) before adding it to a protein to be modified. In some cases, addition of even a small amount of organic solvent to a protein solution may be detrimental to activity. To be safe, no more than 10 to 20% solvent should be present in the aqueous reaction medium.

Sulfo-SMCC, sulfosuccinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate, is a water soluble analog of SMCC that possesses a negatively-charged sulfonate group on it *N*-hydroxysuccinimide ring. The charge gives just enough polarity to the molecule to provide water solubility at a level of at least 10 mg/ml at room temperature. This allows direct addition of the reagent to reaction mixtures without prior dissolution in organic solvent. The crosslinker is known to be soluble at a concentration of at least 10-m*M* in the following buffers: (a) 50-m*M* sodium acetate, pH 5.0; (b) 50-m*M* sodium borate, pH 7.6; and (c) 0.1-*M* sodium phosphate, pH 6 to 7.5. Aqueous stock solutions may be prepared using sulfo-SMCC, but these should be dissolved rapidly and used immediately to prevent extensive loss of sulfo–NHS coupling ability due to hydrolysis. Concentrated aqueous stock solutions (up to about 50 mg/ml) may be made by heating for a few minutes under hot running water. Quickly cool to room temperature before using. However, to avoid the potential of activity loss by hydrolysis, even sulfo-SMCC may be dissolved in DMSO prior to adding a small aliquot to an aqueous reaction.

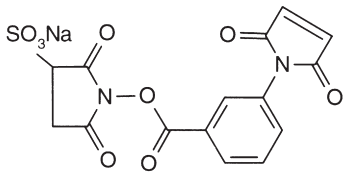
The following is a generalized protocol for the activation of a protein with sulfo-SMCC with subsequent conjugation to a sulfhydryl-containing second molecule or protein. Specific examples of the use of this crosslinker to make antibody–enzyme or hapten–carrier conjugates may be found in Chapter 20, Section 1.1, and Chapter 19, Section 5, respectively.

Protocol



1. Dissolve 10 mg of a protein or other macromolecule to be activated with sulfo-SMCC in 1 ml of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
2. Weigh out 2 mg of sulfo-SMCC and add it to the above solution. Mix gently to dissolve. To aid in measuring the exact quantity of crosslinker, a concentrated stock solution may be made in water (or DMSO) and an aliquot equal to 2 mg transferred to the reaction solution. If a stock solution is made, it should be dissolved rapidly and used immediately to prevent extensive hydrolysis of the active ester. As a general guideline of addition for a particular protein activation, the use of a 40- to 80-fold molar excess of crosslinker over the amount of protein present usually results in good activation levels.
3. React for 1 h at room temperature with periodic mixing.
4. Immediately purify the maleimide-activated protein by applying the reaction mixture to a desalting column packed with a desalting resin. The use of a centrifugal spin column may provide faster separations (Thermo Fisher). Do not use dialysis to purify the solution, since the maleimide activity will be lost over the time course required to complete the operation. To obtain good separation between the protein peak (eluting first) and the peak representing excess reagent and reaction byproducts (eluting second), the applied sample size should be no more than 8% of the column bed volume. If complete separation of the activated protein from excess crosslinker is not obtained, then the maleimide content contributed from contaminating crosslinker may prevent subsequent conjugate formation. Perform the chromatography using 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Collect 1 ml fractions and pool the peak containing the protein. At this point, the maleimide-activated protein may be used immediately in a conjugation reaction with a sulfhydryl-containing protein or other molecule or freeze-dried to preserve the maleimide activity.
5. To effect the conjugation reaction, mix the maleimide-activated protein at the desired molar ratio with a sulfhydryl-containing molecule dissolved in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. The purified protein from step 4 may be concentrated if necessary using centrifugal concentrators, but this should be done quickly to avoid extensive loss of activity. The molar ratio of addition depends on the desired conjugate to be obtained. For instance, if coupling a sulfhydryl-containing small molecule to a protein, the molecule might be added in excess to the amount of maleimide activity present on the protein if a conjugate linking all reactive sites is desired. In such a case, at least a 10- to 100-fold molar excess

may be appropriate (see Chapter 19, Section 5). However, if preparing protein–protein conjugates, as in the case of antibody–enzyme conjugates, the ratio of maleimide-activated protein to the sulfhydryl-containing protein is a matter of choice. Often, when coupling enzymes to antibodies, the enzyme is in molar excess over the antibody (see Chapter 20, Section 1.1). Typical molar ratios of enzyme-to-antibody can range from 2:1 to 7:1.



6. React for 2 to 24h at room temperature or 4–24h at 4°C.
7. The conjugate may be isolated by gel filtration if the molecular weight of the complex is sufficiently different from that of the unconjugated molecules.

1.4. MBS and Sulfo-MBS

MBS, *m*-maleimidobenzoyl-*N*-hydroxysuccinimide ester, is a heterobifunctional crosslinking agent containing an NHS ester on one end and a maleimide group on the other end. The NHS ester can react with primary amines in proteins and other molecules to form stable amide bonds, while the maleimide end nearly exclusively reacts with sulfhydryl groups to create stable thioether linkages (Figure 6.5). These characteristics allow highly controlled conjugation reactions to be performed with MBS using two or three step processes. In this sense, the NHS ester end of the reagent is typically reacted with the first protein to be crosslinked, forming a maleimide-activated intermediate. The maleimide group is more stable to breakdown by hydrolysis than the NHS ester, so the activated intermediate can be quickly purified from excess crosslinker and reaction byproducts before adding it to the sulfhydryl-containing second molecule. However, due to the aromatic ring adjacent to its maleimide functional group, MBS displays less stability toward maleimide ring opening than SMCC (Section 1.3, this chapter). Unlike SMCC, MBS is therefore not recommended for preparing freeze-dried, maleimide-activated proteins, since during the processing necessary to purify and stabilize the derivative much activity can be lost by hydrolysis.

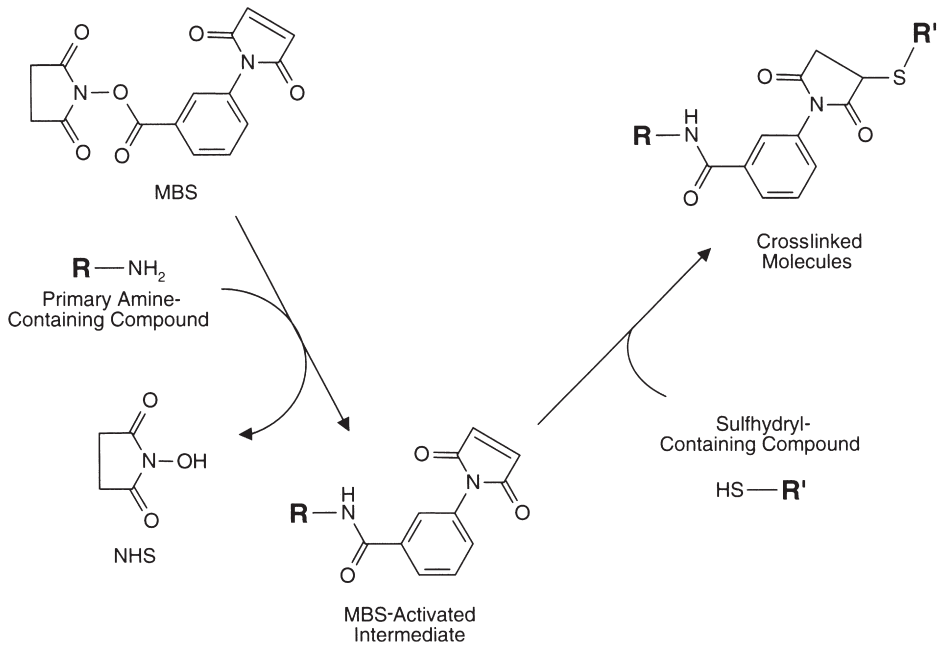

FIGURE 6.5 The two-step conjugation procedure for the MBS crosslinking of an amine-containing molecule with a sulfhydryl-containing molecule.

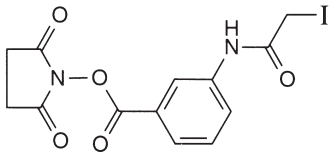
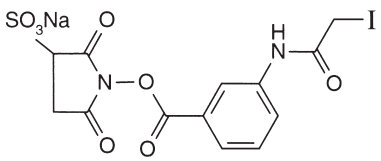
MBS contains a benzoic acid derivative as its cross-bridge, thus lending considerable hydrophobicity to the entire molecule. Since the reagent is water insoluble, it must first be dissolved in organic solvent before adding it to an aqueous reaction medium. Making a concentrated stock solution of MBS in DMF or DMSO allows transfer of a small amount to a conjugation reaction (total concentration of the organic solvent should not exceed 10% in the reaction buffer). When these solvents are used, a micro-emulsion typically is formed in the aqueous solution, which provides crosslinker efficiently to the conjugating species. The reagent is also readily permeable to membrane structures due to its hydrophobic nature.



Sulfo-MBS, *m*-maleimidobenzoyl-*N*-hydroxysulfosuccinimide ester, is a water soluble analog of MBS that contains a negatively charged sulfonate group on its NHS ring (Martin and Papahadjopoulos, 1982; Aithal *et al*., 1988). The negative charge lends enough hydrophilicity to the crosslinker to allow direct addition of the reagent to aqueous reaction media without prior dissolution in organic solvents. Sulfo-MBS has the identical reactivity of MBS.

MBS was one of the first and most popular of the family of NHS ester–maleimide heterobifunctionals (Kitagawa and Aikawa, 1976). It has been used extensively to produce antibody–enzyme and other enzyme conjugates (Kitagawa *et al*., 1978; Freytag *et al*., 1984; O'Sullivan *et al*., 1979), in the preparation of hapten–carrier immunogens (Liu *et al*., 1979; Lerner *et al*., 1981; Kitagawa *et al*., 1982; Niman *et al*., 1985; Chamberlain *et al*., 1989; Edwards *et al*., 1989; Miller *et al*., 1989; Swanson *et al*., 1991), and for making immunotoxin conjugates (Youle and Nevelle, 1980; Dell'Arciprete *et al*., 1988; Myers *et al*., 1989). Additional applications include investigations of carnitine palmitoyltransferase 1 (Faye *et al*., 2007), preparation of a targeting conjugate containing Cyt1Aa toxin directed at myeloma cells (Cohen *et al*., 2007), and development of an improved method for coupling synthetic peptide haptens to carrier proteins (Lateef *et al*., 2007). Ji *et al*., (2012) also used MBS to prepare an arginine–glycine–aspartic acid (RGD) peptide conjugated to albumin nanoparticles for targeted delivery to pancreatic cancer cells.



The generalized protocol for performing a multi-step conjugation reaction with MBS or sulfo-MBS is similar to that described for SMCC (Section 1.3, this chapter). Specific examples may be found in the cited references.

1.5. SIAB and Sulfo-SIAB

SIAB, *N*-succinimidyl(4-iodoacetyl)aminobenzoate, is a heterobifunctional crosslinker containing amine-reactive and sulfhydryl-reactive ends (Weltman, 1983). The NHS ester of SIAB can couple to primary amine-containing molecules, forming stable amide linkages (Chapter 3, Section 1.4). The other end contains an iodoacetyl group that is specific for coupling to sulfhydryl residues, creating stable thioether bonds (Chapter 3, Section 2.1). The aminobenzoate cross-bridge is a hydrophobic spacer that helps the reagent become fully permeable to membrane structures.

MW 402.15
10.6 Å

Sulfo-SIAB;
Sulfo-succinimidyl(4-iodoacetyl)-
aminobenzoate
MW 504.2
10.6 Å

Since SIAB is water insoluble, it must be dissolved first in organic solvent prior to addition to an aqueous reaction medium. The most commonly used solvents for this purpose include DMSO and DMF. Typically, a concentrated stock solution is prepared in one of these solvents and an aliquot added to the protein conjugation solution. Long-term storage of the reagent in these solvents is not recommended, however, due to slow uptake of water and breakdown of the NHS ester end.

Conjugations done with SIAB usually proceed by a multi-step process. Because the crosslinker's NHS ester end is its most labile functionality, an amine-containing protein or molecule is reacted first to create an iodoacetyl-activated intermediate (Figure 6.6). This iodoacetyl derivative is stable enough in aqueous solution to allow purification of the derivatized protein from excess reagent and other reaction byproducts without significant loss of activity. The only consideration is to protect the iodoacetyl derivative from light, which may generate iodine and reduce the activity of the intermediate. Finally, the modified protein is mixed with a sulfhydryl-containing molecule to effect the conjugation through a thioether bond. The result of such two-step procedures is to direct the coupling toward only sulfhydryls on the second molecule while avoiding the polymerization problems that can occur with single-step protocols. Conjugations done with SIAB should avoid buffer components containing amines (i.e., Tris, glycine, or imidazole) or sulfhydryls

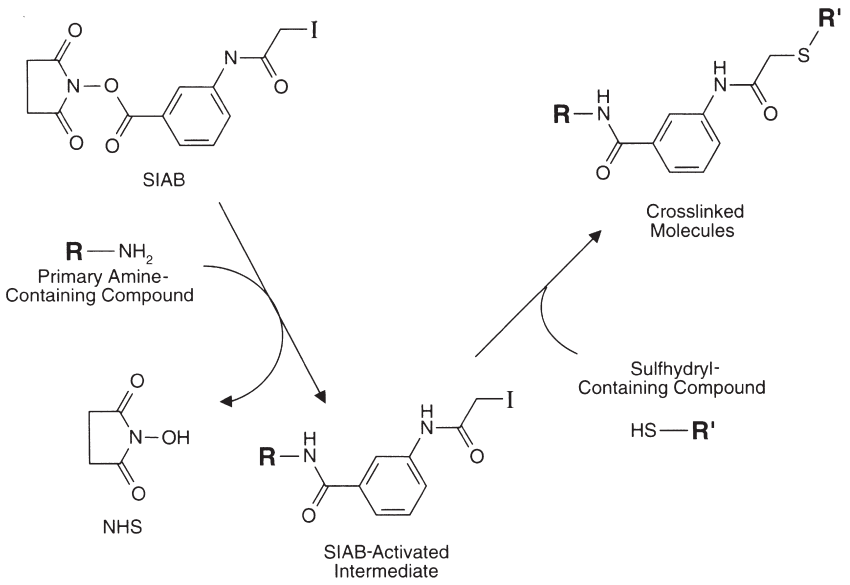

FIGURE 6.6 SIAB may be used to modify an amine-containing molecule for subsequent conjugation to a sulfhydryl-containing molecule.

(e.g., DTT, 2-mercaptoethanol, cysteine), since these will compete with the desired crosslinking reactions.

Sulfo-SIAB, sulfosuccinimidyl(4-iodoacetyl)aminobenzoate, is a water soluble analog of SIAB that contains a negatively charged sulfonate on its NHS ring. The negative charge lends enough hydrophilicity to the entire molecule to provide good solubility in aqueous solutions (up to about 10-m*M*). Sulfo-SIAB may be added directly to reaction mediums without prior dissolution in organic solvent, or solutions that are more concentrated may be made in water before transfer of an aliquot to the reaction to facilitate easy addition of small quantities. Aqueous stock solutions should be dissolved rapidly and used immediately to avoid excessive hydrolysis of the NHS ester.

SIAB and sulfo-SIAB have been used to make a high-capacity RNA affinity column for the purification of human IRP1 and IRP2 (Allerson *et al.*, 2003), to couple antibodies or Fab fragments to amine-modified microparticles (Härmä *et al.*, 2000), in the attachment of oligonucleotides to surfaces for detection arrays (Adessi *et al.*, 2000), and in the preparation of polymer bioconjugates for targeted drug delivery (Viadya *et al.*, 2011).

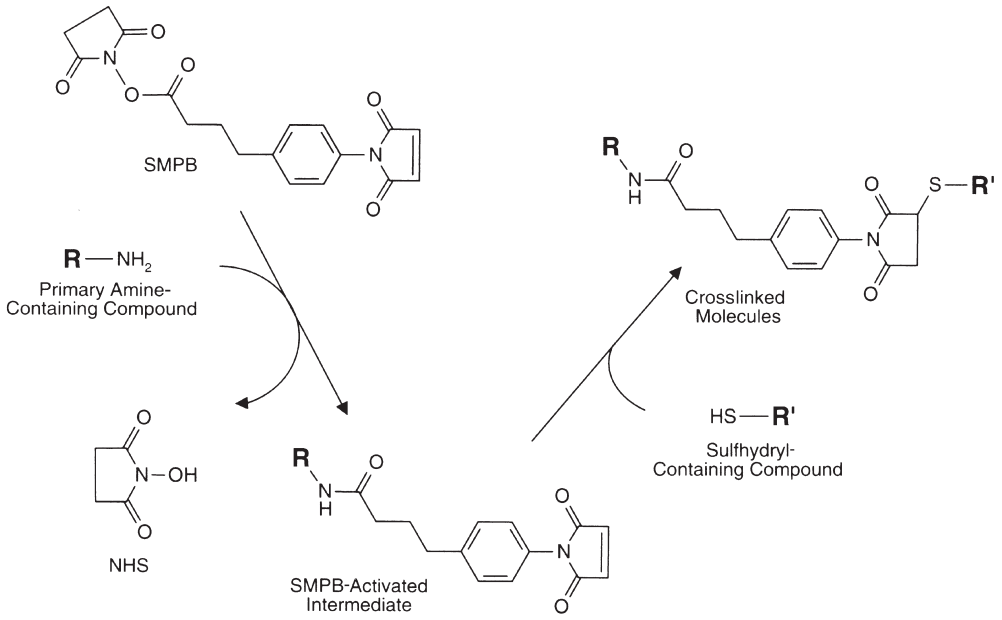
The following protocol illustrates the use of SIAB in preparing antibody–enzyme conjugates using β-galactosidase.

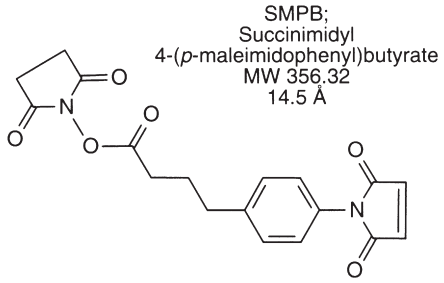
Protocol

1. Dissolve a specific antibody to be conjugated at a concentration of 10 mg/ml in 50-m*M* sodium borate, 5-m*M* EDTA, pH 8.3 (reaction buffer).
2. Dissolve SIAB (Thermo Fisher) in DMSO at a concentration of 1.4 mg/ml. Alternatively, dissolve sulfo-SIAB in deionized water at a concentration of 1.7 mg/ml. Prepare fresh and use immediately. Protect from light.
3. Add 100 µl of the SIAB stock solution to each ml of the antibody solution. Mix gently to dissolve.
4. React for 1 h at room temperature in the dark.
5. Purify the modified antibody by gel filtration on a desalting resin. Spin columns may be used to speed the separation process (Thermo Fisher). Perform the chromatography using the reaction buffer. To obtain good separation, apply sample at a ratio of no more than 8% of the total column gel volume. Monitor the eluting peak by using a small aliquot of each fraction and reacting it with a protein detection reagent such as Coomassie Protein Assay Reagent (Thermo Fisher) in a microplate. This avoids exposure of the entire modified protein fractions to UV light from a spectrophotometer, which could inactivate the iodoacetyl group. Collect the first peak eluting from the column, which contains the protein.
6. Add β-galactosidase to the activated antibody solution at a ratio of 4 mg of enzyme per mg of antibody.
7. React for 1 h at room temperature in the dark.
8. To block any remaining iodoacetyl sites, add cysteine to a final concentration of 5-m*M* and react for an additional 15 min at room temperature.
9. Purify the conjugate by gel filtration using a buffer of choice (e.g., PBS, pH 7.4).

1.6. SMPB and Sulfo-SMPB

SMPB, succinimidyl-4-(*p*-maleimidophenyl)butyrate, is a heterobifunctional analog of MBS (Section 1.4, this





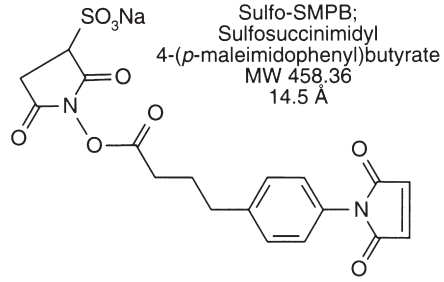


FIGURE 6.7 SMPB may be used in a two-step procedure to conjugate an amine-containing molecule to a sulfhydryl-containing compound, forming amide and thioether bonds, respectively.

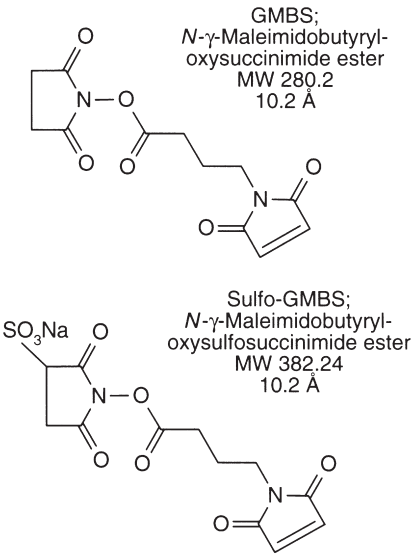
chapter) containing an extended cross-bridge (Thermo Fisher). The reagent has an amine-reactive NHS ester on one end and a sulfhydryl-reactive maleimide group on the other end (Figure 6.7). Conjugates formed using SMPB thus are linked by stable amide and thioether bonds. A comparison with SPDP-produced conjugates concluded that SMPB formed more stable complexes that survive *in vivo* for longer periods (Martin and Papahadjopoulos, 1982).

Conjugation reactions performed with SMPB are typically multi-step procedures, wherein a protein is modified through its amine groups, purified to remove excess reagent, and then mixed with a sulfhydryl-containing molecule to effect the final conjugation. The maleimide group of SMPB is highly specific for coupling to sulfhydryl-containing proteins and other molecules, thus directing the conjugation to discrete points on the second molecule. This maleimide is, however, more labile to ring opening in aqueous solution than the maleimide group of SMCC due to its proximity to an aromatic ring. Therefore, the first protein modified with SMPB (to obtain a maleimide-activated intermediate) should be purified quickly to prevent extensive activity loss from hydrolysis and maleimide ring opening.



SMPB contains a hydrophobic cross-bridge and relatively nonpolar ends, which allows the reagent to permeate membrane structures. Due to its water-insolubility, it must be dissolved in an organic solvent prior to adding an aliquot to a reaction mixture. The solvents DMF and DMSO work well for this purpose. A concentrated stock solution prepared in these solvents allows for easy addition of a small amount to a conjugation reaction. Long-term storage in these solvents is not recommended due to slow water pickup and possible hydrolysis of the NHS ester end.

A water soluble analog to SMPB, called sulfo-SMPB [sulfosuccinimidyl-4-(*p*-maleimidophenyl)butyrate] contains a negatively charged sulfonate group which lends considerable hydrophilicity to the molecule (Thermo Fisher). Sulfo-SMPB may be added directly to aqueous reaction mixtures without prior dissolution in organic solvent. Concentrated stock solutions made in water should be dissolved quickly and used immediately to prevent hydrolysis of the NHS ester.

SMPB or sulfo-SMPB have been used to conjugate preformed vesicles and Fab′ fragments in a liposome carrier study (Martin and Papahadjopoulos, 1982), to attach insulin molecules to reconstituted Sendai virus envelopes (Gitman *et al.*, 1985), to target loaded virus envelopes by covalently attaching insulin molecules to receptor-depleted cells (Gitman *et al.*, 1985b), to form alkaline phosphatase–Fab′ fragment conjugates for an ELISA (Teale and Kearney, 1986), to prepare peptide–protein immunogen conjugates (Iwai *et al.*, 1988), to study the transport of the variant surface glycoprotein of *Trypanosome brucia* (Bangs *et al.*, 1986), and to prepare immunotoxin conjugates (Myers *et al.*, 1989). SMPB or sulfo-SMPB have also been used to modify glass slides for coupling thiol-modified oligonucleotides (Zhang *et al.*, 2006), to investigate the protein decorin (Zhu *et al.*, 2005), to create conjugates with β-galactosidase that can cross the blood–brain barrier (Zhang and Pardridge (2005), and to develop a microRNA delivery system using virus-like particles (Pan *et al.*, 2012).

1.7. GMBS and Sulfo-GMBS

GMBS, *N*-(γ-maleimidobutyryloxy)succinimide ester, is a heterobifunctional crosslinking agent that contains an NHS ester on one end and a maleimide group on the other (Fujiwara *et al.*, 1988) (Thermo Fisher). Its internal cross-bridge contains a linear four-carbon spacer, resulting in 10.2-Å crosslinks between conjugated molecules (Figure 6.8). GMBS is water insoluble and therefore must be dissolved in organic solvent. Typically, a concentrated stock solution is prepared in DMF or DMSO just before use, and then an aliquot of the solution is transferred to the aqueous reaction medium. The result is the formation of a micro-emulsion that effectively supplies crosslinker to the aqueous phase.

GMBS can be used in multi-step conjugation protocols wherein an amine-containing molecule or protein is first modified via the NHS ester end (its most labile reactive group) to create a stable amide bond. The derivative at this point contains reactive maleimide groups able to couple with the available sulfhydryl groups on a second protein or molecule. This active intermediate is then purified to remove excess reagent

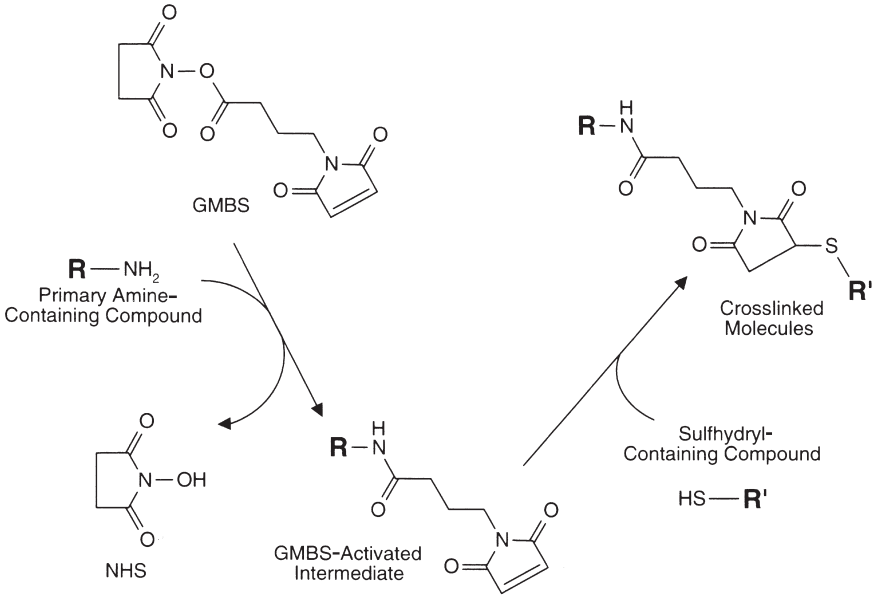


FIGURE 6.8 The reaction of GMBS with an amine-containing molecule yields a maleimide-activated intermediate that can then be used to crosslink with a sulfhydryl-containing compound.

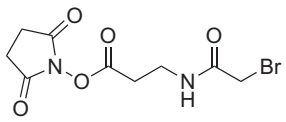
and reaction byproducts, and immediately added to the sulfhydryl-containing molecule to effect the final conjugation.

The maleimide group of GMBS is adjacent to an aliphatic spacer, so its stability toward ring opening should be better than crosslinkers like MBS which contain adjacent aromatic groups. Hydrolysis of the maleimide group results in loss of sulfhydryl coupling capability. However, GMBS is not as stable as the hindered maleimide group of SMCC, since the cyclohexane ring of that reagent inhibits hydrolysis and ring opening.

Sulfo-GMBS, *N*-(γ-maleimidobutyryloxy)sulfosuccinimide ester, is a water soluble analog of GMBS containing a negatively charged sulfonate group on its NHS ring (Thermo Fisher). The charge provides enough hydrophilicity to allow at least 10-m*M* concentrations of the crosslinker to be made in aqueous reaction mediums. Its reactivity is identical to that of GMBS.



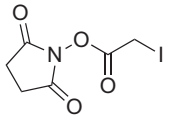
GMBS or sulfo-GMBS have been used for studying carnitine palmitoyltransferase 1 in its formation of a complex within the outer mitochondrial membrane (Faye *et al.*, 2007), for investigating protein organization of the postsynaptic density (Liu *et al.*, 2006), for studying the structure and dynamics of rhodopsin (Jacobsen *et al.*, 2006), and to produce conjugates of cell-penetrating peptides for delivery of antisense oligomers (Moulton, 2012).

The protocol for using GMBS or sulfo-GMBS in protein–protein crosslinking applications is similar to that of SMCC or sulfo-SMCC (see Section 1.3).

1.8. SBAP

SPAB is succinimidyl-3-(bromoacetamide)propionate, a short amine- and thiol-reactive reagent built from a central beta-alanine core. Inman *et al.* (1991) used this compound to modify BOC-protected lysine at its epsilon amine group in order to incorporate bromoacetyl reactive groups into synthesized peptides. SPAB may be used similar to SIAB in procedures for crosslinking proteins or other molecules containing amines or thiols.

The NHS ester end of the molecule can be used to modify proteins by reaction at pH 7 to 9 in phosphate, HEPES, or borate buffers. Use a buffer concentration of 50- to 100-m*M* to prevent pH drift to acidic values as the reaction takes place. SPAB can be dissolved in DMSO as a concentrated stock solution before adding an aliquot to the aqueous reaction medium. After purification of the modified protein by gel filtration or dialysis, the bromoacetyl group on the first protein may be coupled to a thiol-containing protein by reaction at pH 8.5 in borate buffer. The bromoacetyl group on the crosslinker and the intermediate activated protein should be protected from light to prevent degradation. In addition, reducing agents should be avoided (especially those containing thiols) to prevent inactivation and coupling to the reactive group prior to coupling with the desired thiol-containing protein.



SBAP;
Succinimidyl-3-(bromoacetomido)propionate
MW: 307.10

1.9. SIA

The shortest amine-reactive and thiol-reactive crosslinker available is SIA, which is simply the NHS ester of iodoacetate, also called succinimidyl iodoacetate or NHS-iodoacetate. After conjugation, the crosslinked molecules or proteins are held together by only a 1.5-Å spacer represented by the two-carbon length of the acetate core. When conjugating proteins using this reagent, it is unlikely that there will be any cross-bridge-related artifacts introduced into the conjugate, such as extreme hydrophobicity or immunogenicity. The reactivity and use of SIA are similar to those of SIAB, which has identical reactive groups but is built on a longer cross-bridge.

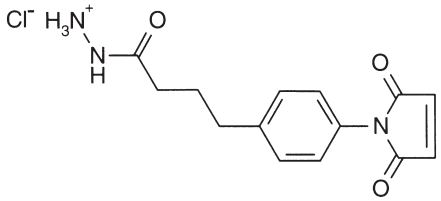
The NHS ester end of SIA is typically reacted with an amine-containing protein or molecule first, because it is the most labile end of the reagent. During handling and use, SIA should be protected from light to prevent degradation of the iodoacetyl group. In addition, avoid the presence of reducing agents (particularly thiol-containing compounds), which will react with the iodoacetyl end and inactivate it. The compound can be dissolved before use in dry DMSO as a concentrated stock solution and then an aliquot of this solution is added to an aqueous reaction mixture to initiate the amine modification reaction using the NHS ester end. After the first protein is modified, the excess crosslinker is removed by size exclusion chromatography or dialysis before the addition of a thiol-containing protein to link the two molecules together.

SIA;
Succinimidyl iodoacetate
(NHS-iodoacetate)
MW: 283.02

Thorpe *et al.* (1984) used SIA to conjugate intact ricin to an antibody and by virtue of the short linkage arm was able to effectively block the galactose binding site

on the B chain. In addition, Rector *et al.* (1978) used this reagent to activate IgG for conjugation with thiolated proteins in a highly controlled reaction, which produced conjugates of defined composition. More recently, Choi *et al.* (2011) used SIA to prepare a RGD labeled metalloproteinase 2 probe as an antitumor agent, and McCarthy *et al.* (2012) used it to prepare a thrombus targeting nanoparticle conjugated with recombinant tissue plasminogen activator (tPA).

2. CARBONYL REACTIVE AND SULFHYDRYL REACTIVE CROSSLINKERS



A relatively new set of heterobifunctional crosslinking agents now are available which contain a carbonyl-reactive group on one end and a sulfhydryl-reactive functionality on the other end. The main utility of these reagents is in conjugating carbohydrate-containing molecules, such as glycoproteins, to sulfhydryl-containing molecules. Both polysaccharide residues and sulfhydryl groups are usually present on proteins in limiting quantities and at discrete sites. In certain cases, conjugation through these groups can direct the coupling reaction away from critical active centers or binding sites, thus preserving activity of the proteins after crosslinking. A prime example of the advantages of this type of directed coupling can be seen when conjugating antibody molecules to other proteins, such as enzymes. The carbohydrate residues of immunoglobulin molecules often occur on the Fc portion, away from the antigen binding sites. Coupling procedures which direct the crosslinking reaction to parts on the antibody removed from the antigen binding sites have the best chance of retaining activity after conjugate formation. However, some antibodies do contain glycosylation sites in the Fab region of the molecule, thus making conjugation strategies through carbohydrates less certain as to their affect on antigen binding activity (Endo *et al.*, 1995; Mattu *et al.*, 1998).

The carbonyl-reactive group on these crosslinkers is a hydrazide that can form hydrazone bonds with aldehyde residues. To utilize this functional group with carbohydrate-containing molecules, the sugars must first be mildly oxidized to contain aldehyde groups by treatment with sodium periodate. Oxidation with this compound will cleave adjacent carbon–carbon bonds which possess hydroxyl groups, as are abundant in polysaccharide molecules (Chapter 2, Sections 2 and 4.4).

Two types of sulfhydryl-reactive functions are available on these reagents: pyridyl disulfide groups and maleimide groups. The pyridyl disulfide group will react with a sulfhydryl residue to create a disulfide bond. This linkage is reversible by treatment with a disulfide reducing agent. Reaction of a maleimide group with a sulfhydryl, however, forms a permanent thioether bond of good stability. Thus, either reversible or permanent conjugates may be designed using these heterobifunctionals.

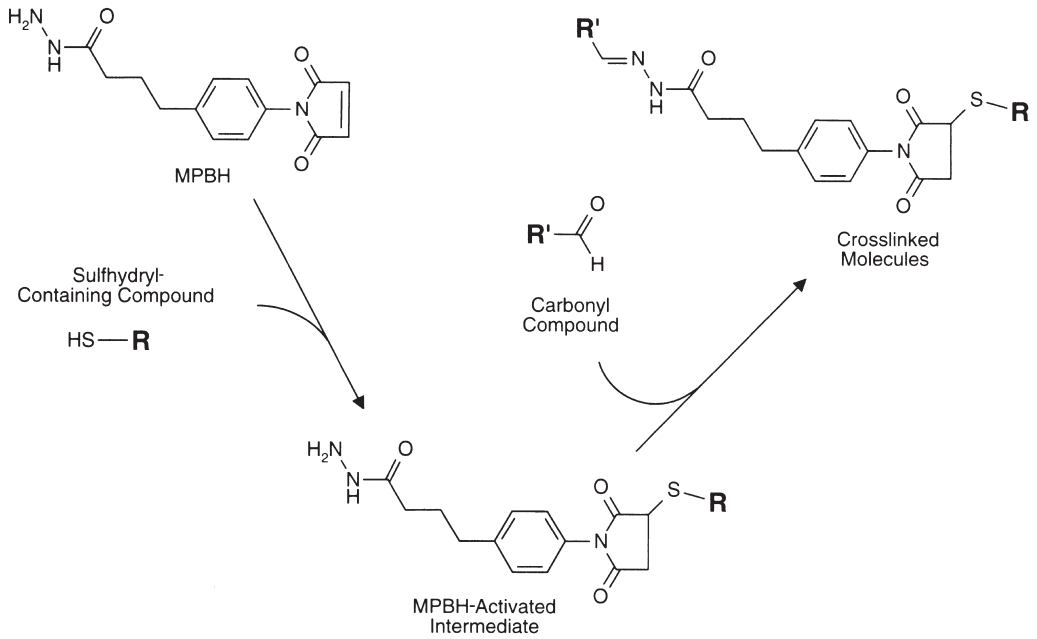
2.1. MPBH

MPBH, or 4-(4-*N*-maleimidophenyl)butyric acid hydrazide, is a heterobifunctional crosslinking agent that contains a carbonyl-reactive hydrazide group on one end and a sulfhydryl-reactive maleimide on the other end (Thermo Fisher). The cross-bridge between the two functional ends provides a 17.9-Å spacer. The hydrazide group is produced as the hydrochloride salt. The reagent as a whole has good water solubility. It can be dissolved in 0.1-*M* sodium acetate, pH 5.5, up to a concentration of 327 mg/ml. It is also freely soluble in DMSO and may be stored as a concentrated stock solution in this solvent without degradation.

MPBH
4-(4-*N*_Maleimidophenyl)butyric acid hydrazide hydrochloride
MW 309.75
17.9 Å

The maleimide group of MPBH is adjacent to an aromatic ring and thus may exhibit instability to hydrolysis in aqueous solutions, especially at alkaline pH. Hydrolysis opens the maleimide ring and destroys its coupling ability with sulfhydryls. However, both reactive ends of the crosslinker are stable enough to survive a multistep coupling protocol without extensive loss of activity. Thus, a sulfhydryl-containing protein or molecule may be modified via the maleimide end of MPBH, the derivative purified by gel filtration to remove excess reactants, and then mixed with a glycoprotein (that has previously been oxidized to provide aldehyde residues) to effect the final conjugation (Figure 6.9). The opposite approach is also possible: modification of the glycoprotein first, purification, and subsequent mixing with a sulfhydryl-containing molecule. With this second option, however, the purification step should be carried out quickly to prevent extensive hydrolysis of the maleimide group.

MPBH has been used to conjugate CD4 without loss of biological activity (Chamow *et. al.*, 1992), to prepare a polyethyleneimine–lipid conjugate as a pH-sensitive carrier for gene delivery (Sawant *et al.*, 2012), and in the development of a multiplexed bead-based assay for profiling glycosylation patterns (Li *et al.*, 2011).



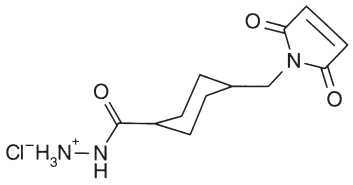


FIGURE 6.9 MPBH reacts with sulfhydryl-containing molecules through its maleimide end to produce thioether linkages. Its hydrazide group can then be used to conjugate with carbonyl-containing molecules (such as periodate oxidized carbohydrates that contain aldehydes) to give hydrazone bonds.

2.2. M_2C_2H

M_2C_2H, 4-(*N*-maleimidomethyl)cyclohexane-1-carboxyl-hydrazide, is a heterobifunctional crosslinking agent that contains a carbonyl-reactive hydrazide group on one end and a sulfhydryl-reactive maleimide group on the other end (Thermo Fisher). The reagent is similar to MPBH (described previously), but the maleimide group on M_2C_2H is expected to be more stable in aqueous solutions, since it is adjacent to an aliphatic cyclohexane ring instead of an aromatic phenyl group. In this sense, the cross-bridge of M_2C_2H is nearly identical to that of SMCC, which contains one of the most stable maleimide groups known. The hydrophobic, hindered environment of the cyclohexane ring should provide similar stability advantages to this reagent. Reaction of the maleimide group with a sulfhydryl residue results in the formation of a stable thioether bond.

M_2C_2H
4-(*N*-Maleimidomethyl)cyclohexane-
1-carboxyl-hydrazide hydrochloride
MW 287.75
15.1 Å

On the other end of the crosslinker, the hydrazide functional group can react with periodate-oxidized carbohydrate molecules or with the reducing end of carbohydrates to form hydrazone linkages (Chapter 2, Sections 2 and 4.5). Thus, glycoproteins can be targeted specifically at their polysaccharide chains, avoiding crosslinking at active sites, which can lead to activity losses (Figure 6.10). The crosslinker has been used to produce polymer bioconjugates for drug delivery (Vaidya *et al.*, 2011).

M_2C_2H is slightly soluble in aqueous solutions, reportedly having a maximal solubility of 3.2 mg/ml in 0.1-*M* sodium acetate at pH 5.5. It is also soluble in organic solvents, which allows for the preparation of concentrated stock solutions to be made prior to addition of a small aliquot to an aqueous reaction mixture. The crosslinker is particularly stable in acetonitrile.

2.3. PDPH

PDPH, 3-(2-pyridyldithio)propionyl hydrazide, is a heterobifunctional reagent that possesses a carbonyl-reactive hydrazide group on one end and a sulfhydryl-reactive pyridyl disulfide group on the other end (Thermo Fisher). Thus, sulfhydryl-containing proteins or other thiol molecules may be conjugated to carbohydrate-containing molecules (after treatment of the polysaccharide portion with sodium periodate to create aldehyde residues) (Figure 6.11). Using this crosslinker,

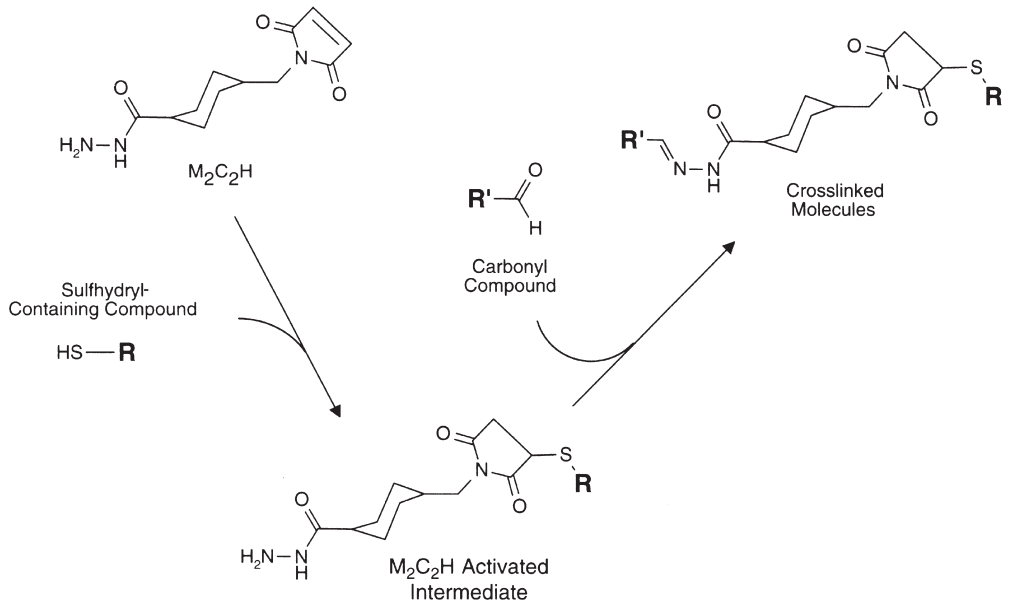

FIGURE 6.10 M_2C_2H can be used to crosslink a sulfhydryl-containing molecule with an aldehyde-containing compound. Glycoproteins may be conjugated using this reagent after treatment with sodium periodate to form reactive aldehyde groups.

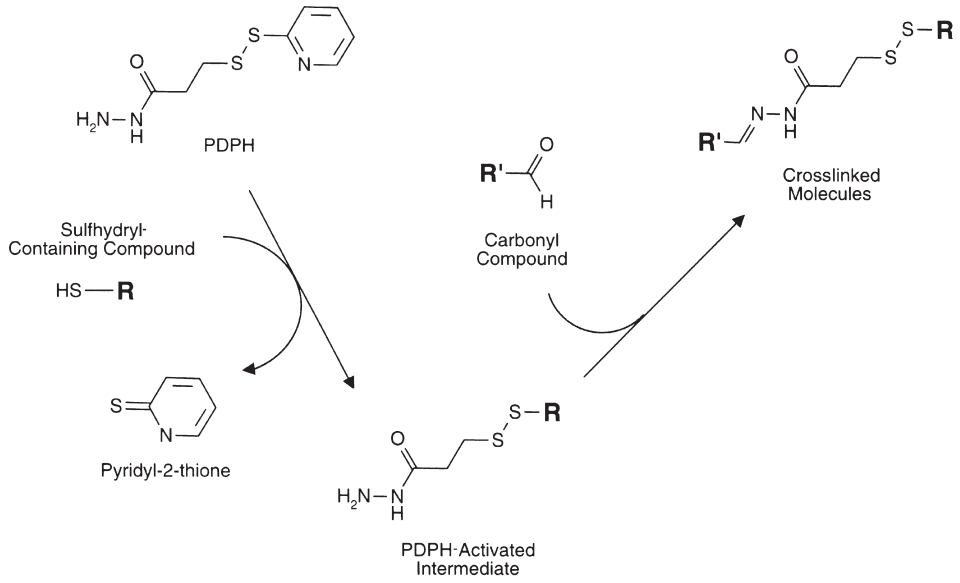

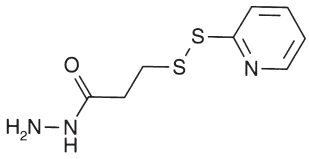

FIGURE 6.11 PDPH reacts with thiol-containing compounds through its pyridyl disulfide end to form reversible disulfide linkages. Its hydrazide end may then be subsequently conjugated with an aldehyde-containing molecule to form hydrazone bonds. Glycoproteins may be crosslinked using this approach after periodate activation to generate aldehyde groups.

glycoproteins can be coupled specifically through their carbohydrate chains, in many cases better avoiding active centers or binding sites than when coupling through abundant polypeptide groups like amines. Since the pyridyl disulfide group reacts with sulfhydryls to create disulfide bonds, the crosslinked proteins can be cleaved by reduction with DTT (Chapter 2, Section 4.1).

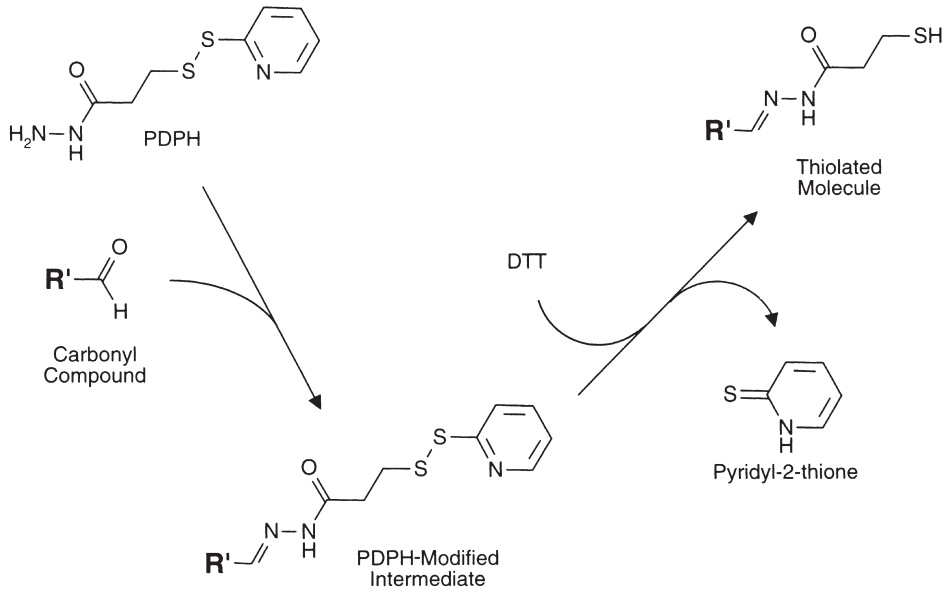

FIGURE 6.12 PDPH may be used to add a sulfhydryl group to an aldehyde-containing molecule. After reacting its hydrazide end with the aldehyde to form a hydrazone bond, the pyridyl disulfide may be reduced with DTT to create a free thiol.

PDPH may also be used as a thiolation reagent to add sulfhydryl functional groups to carbohydrate molecules. The reagent can be used in this sense similar to the protocol described for AMBH (Chapter 2, Section 4.1). After modification of an oxidized polysaccharide with the hydrazide end of PDPH, the pyridyl group is removed by treatment with DTT, leaving the exposed sulfhydryl (Figure 6.12).

PDPH is soluble in 0.1-*M* sodium acetate, pH 5.5, at a maximal concentration of 14.2 mg/ml. The reagent is particularly stable in acetonitrile for preparation of concentrated stock solutions.

PDPH has been used in the preparation of immunotoxin conjugates (Zara *et al.*, 1991). It has also been used to create a unique conjugate of nerve growth factor (NGF with an antibody directed against the transferrin receptor OX-26, which could traverse the blood–brain barrier (Friden, 1993). Labeling of antibody molecules with PDPH at oxidized polysaccharide sites followed by reduction to free the sulfhydryl has been used to form a technetium-99 m complex for radiopharmaceutical use (Ranadive *et al.*, 1993) (Chapter 12, Section 1.5). PDPH has also been used to study the uptake of rsCD4 across the blood–brain barrier (Walus *et al.*, 1996), to prepare an NGF conjugate (Bäckman *et al.*, 1996), to study novel engineered cell surface receptors (Lee *et al.*, 1999), and to prepare siRNA conjugates with poly (D,L-lactic-co-glycolic acid) (PLGA) via a cleavable disulfide bond (Lee *et al.*, 2011).

3. AMINE-REACTIVE AND PHOTOREACTIVE CROSSLINKERS

An important class of heterobifunctional reagents is the photoreactive crosslinkers that have one end that can be photolyzed to initiate coupling. Photoreactive crosslinkers may be designed to utilize any one of a number of photosensitive groups, including aryl azides, fluorinated aryl azides, benzophenones, anthraquinones, certain diazo compounds, and diazirine derivatives (Chapter 3, Section 7.5). The best photoreactive groups are stable in aqueous solution in the dark, and may be activated at the desired time by a pulse of light at the appropriate wavelength. The other end of these heterobifunctionals usually contains a spontaneously reactive functionality that will couple rapidly with certain groups present on target molecules. This secondary functionality is sometimes called *thermoreactive* to differentiate it from the photoreactive end and to emphasize its ready reactivity or sometimes its labile nature in aqueous environments. The thermoreactive end is typically amine reactive, sulfhydryl reactive, carbonyl reactive, carboxylate reactive, or arginine reactive. Still another class of photoreactive heterobifunctionals may use a biotin handle at one end to crosslink specifically, but noncovalently, with avidin or streptavidin molecules (Chapter 11, Section 6.5).

Photoreactive groups can be categorized by the reactive species that is generated upon photolysis. The most popular type of photosensitive group, an

aryl azide derivative, forms a short-lived nitrene that reacts extremely rapidly with the surrounding chemical environment (Gilchrist and Rees, 1969). Subsequent evidence, however, indicates that the photolyzed intermediates of aryl azides can undergo ring expansion to create nucleophile-reactive dehydroazepines. Instead of inserting nonselectively at active carbon–hydrogen bonds, dehydroazepines have a tendency to react preferentially with nucleophiles, especially amines (Figure 6.13). However, some investigators have shown that aryl azides that possess a perfluorinated ring structure or are substituted completely with halogen atoms are quite efficient at forming the desired nitrene intermediate (Keana and Cai, 1990; Cai *et al*., 1993; Schnapp and Platz, 1993; Schnapp *et al*., 1993; Soundararajan *et al*., 1993; Yan *et al*., 1994). A few crosslinking reagents now use halogen-substituted phenyl azides to provide greater efficiency of photoreactive insertion into target molecules (Chapter 24, Sections 2.2 and 3.2).

One advantage of aryl azide photoreactive crosslinkers is that they have a relatively low energy of activation, which is optimal in the long UV region. In addition, many aryl azides possess nitro groups on their associated aromatic ring structures. These electron-withdrawing groups tend to increase the optimal wavelength for photolysis upwards close to the 350-nm range. The benefit of this approach is that relatively low light exposure at the higher energy UV wavelengths avoids potential bond breakage that may occur with some sensitive compounds upon photolysis. In addition, some biological molecules can undergo crosslinking reactions upon irradiation with UV light of less than 300 nm (e.g., DNA).

Other phenyl azide-containing reagents possess hydroxyl groups on their aromatic rings. These electron-donating groups activate the ring system to allow electrophilic substitution reactions to occur on the crosslinker prior to its use. A major application of this

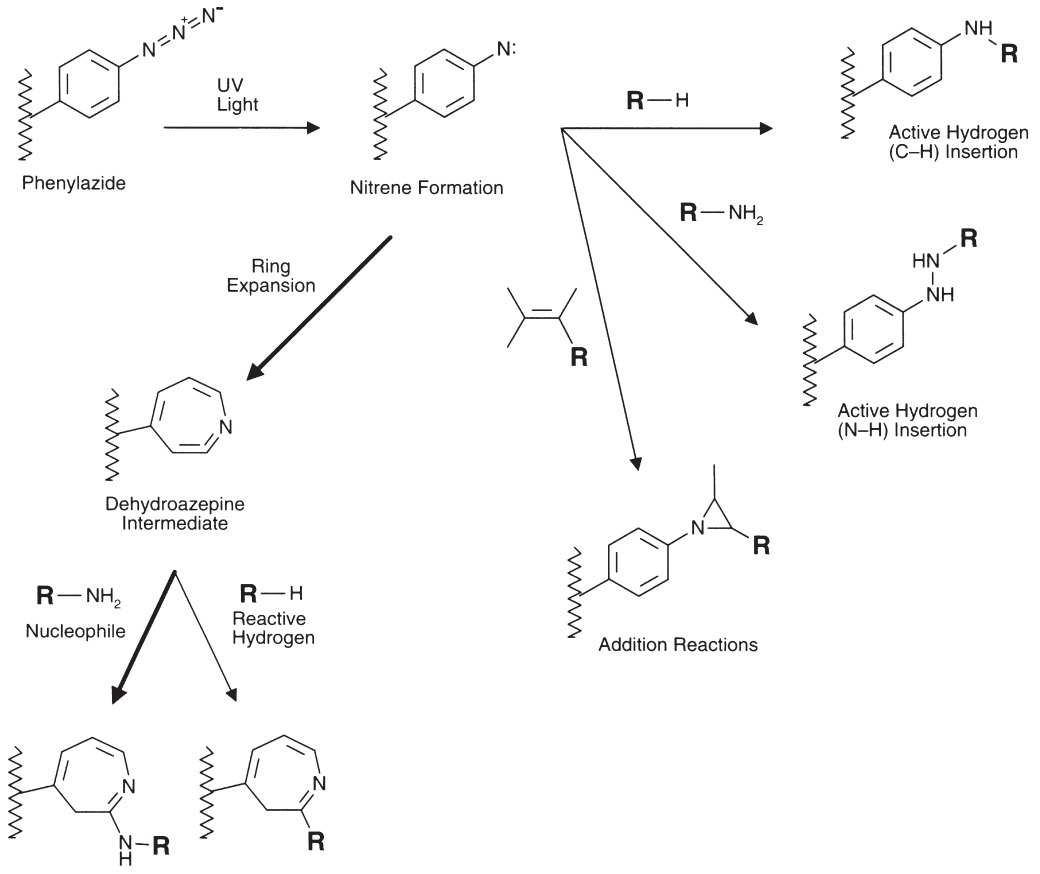

FIGURE 6.13 Photoactivation of a phenyl azide group with UV light results in the formation of a short-lived nitrene. Nitrenes may undergo a number of reactions, including insertion into active carbon–hydrogen or nitrogen–hydrogen bonds and addition to points of unsaturation in carbon chains. The most likely route of reaction, however, is to ring-expand to a dehydroazepine intermediate. This group is highly reactive toward nucleophiles, especially amines.

ability is to radioiodinate the photoreactive end, thus permitting crosslinking and detection of proteins within samples.

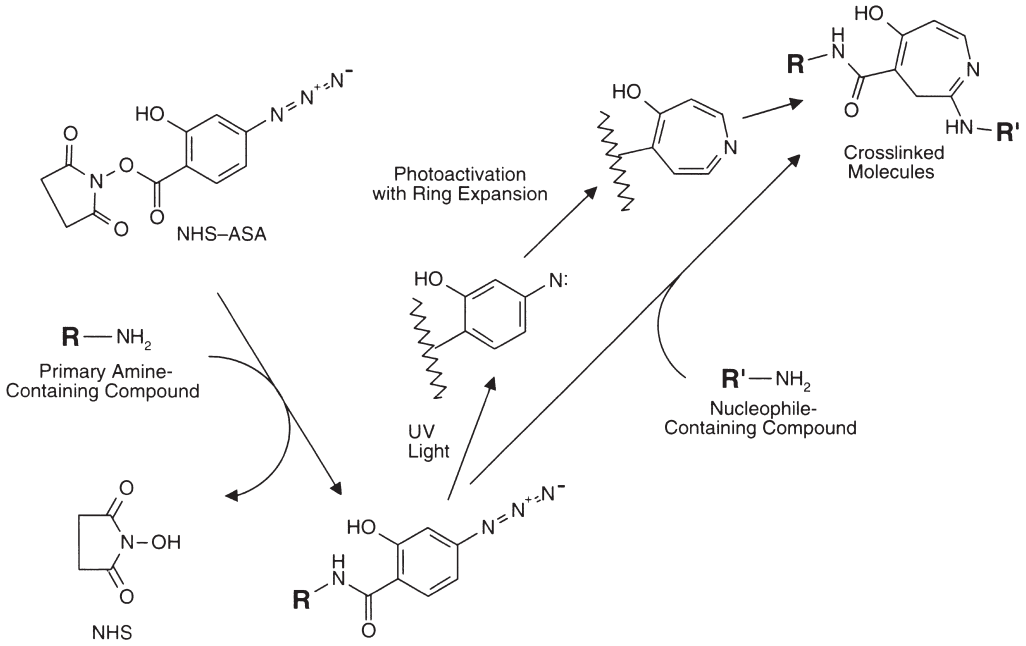
Suitable light sources for photolyzing include sunlamps manufactured by a number of companies, such as Philips Ultrapnil MLU 300 W, General Electric sunlamp RSM 275 W, or National Self-Ballasted BHRF 240–250 V 250 W W-P lamp. Irradiation for 15 min with such lamps while the sample is cooled in an ice bath will result in good photolysis of photoreactive crosslinkers and modification reagents. In addition, many long-wavelength UV light sources with irradiation capability at about 366 nm work well.

Although photoreactive aryl azides are relatively inert to thermochemical reactions prior to photolysis, they are not stable in the presence of sulfhydryl compounds which can reduce the azide functionality to an amine with concomitant release of N_2. Avoid, therefore, the use of reductants such as DTT or 2-mercaptoethanol before the photoreaction step, as these can react with the aryl azide within minutes (Staros *et al.*, 1978). Also, avoid amine-containing buffer components such as Tris or glycine, because of the potential for nucleophilic reactivity with the photolyzed dehydroazepine intermediate formed from photolysis of unsubstituted phenyl azides.

Of the following amine-reactive and photoreactive crosslinkers, the overwhelming majority use an aryl azide group as the photosensitive functional group. Only a few use alternative photoreactive chemistries, particularly perfluorinated aryl azide, benzophenone, or diazo compounds. For general background information on photoreactive crosslinkers, see Das and Fox (1979), Kiehm and Ji (1977), Vanim and Ji (1981), and Brunner (1993).

3.1. NHS–ASA, Sulfo-NHS–ASA, and Sulfo-NHS–LC–ASA

NHS–ASA (*N*-hydroxysuccinimidyl-4-azidosalicylic acid) is a heterobifunctional reagent containing an NHS ester on one end and a photoreactive aryl azide group on the other (Thermo Fisher). The amine-reactive NHS ester can be reacted with proteins or other primary amine-containing molecules to yield a photosensitive derivative suitable for probing biological interaction sites. Upon photolysis with a long UV light source, the aryl azide end is activated to covalently complex with closely associated target molecules (Figure 6.14). The small cross-bridge of NHS–ASA is built from a salicylate derivative that contains a hydroxyl group on the aromatic ring. The ring-activating nature of this group provides an iodination site on the crosslinker to allow tracking of modified molecules (Ji and Ji, 1982) (Chapter 12, Section 2.5).



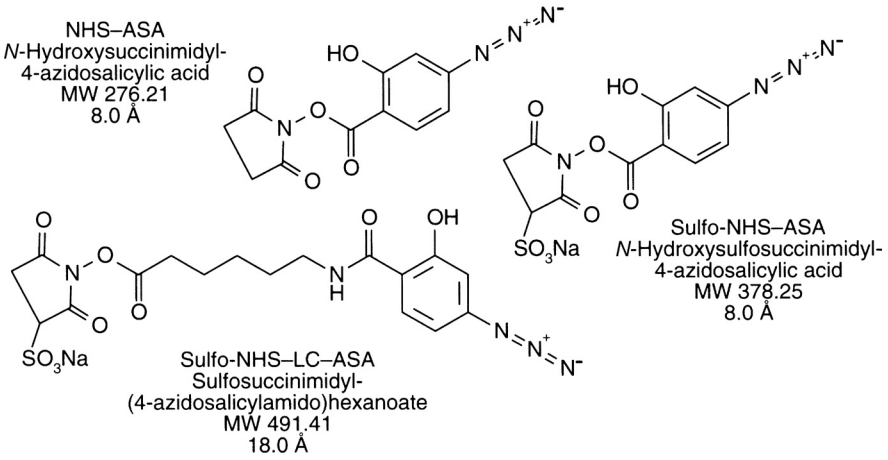


FIGURE 6.14 NHS–ASA reacts with amine-containing compounds to form stable amide linkages. Photoactivation with UV light results in ring expansion to a dehydroazepine intermediate, which can react with amines to form covalent bonds.

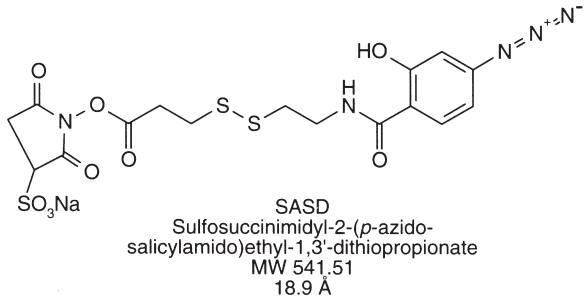

Reported applications of NHS–ASA include photoaffinity labeling of ^{125}I–ASA–Con A to erythrocyte ghosts (Ji and Ji, 1982), derivatization of human choriogonadotropin with ^{125}I–NHS–ASA with photo-initiated crosslinking of the α-β dimer (Ji *et al.*, 1985), radiolabeling of D-glucose and conjugation of the sugar to the human erythrocyte monosaccharide transporter protein (Shanahan *et al.*, 1985), photoaffinity labeling of a bacterial sialidase (van der Horst *et al.*, 1990), identification of the peptide binding site of DnaK (Zhang and Walker, 1996), and characterization of the vitamin B-12 receptor (Nguyen, 1999).

Two analogs of NHS–ASA that provide alternative physical characteristics are available. Sulfo-NHS–ASA is a water soluble version of the crosslinker that contains a negatively charged sulfonate group on its NHS ring. Sulfo-NHS–LC–ASA also has the water-solubility advantage provided by a sulfonate, but it possesses a longer cross-bridge made from a 6-aminocaproic acid chain in its internal structure. The longer spacer increases the potential distance between conjugated molecules, thus allowing more flexibility in the experimental design. Both analogs are still iodinatable to provide radiolabeling capability.

3.2. SASD

SASD (sulfosuccinimidyl-2-(*p*-azidosalicylamido) ethyl-1,3′-dithiopropionate) is a heterobifunctional crosslinker containing a photoreactive group and an amine-reactive NHS ester (Thermo Fisher). The NHS ring possesses a negatively-charged sulfonate group which lends water solubility to the reagent. The cross-bridge of SASD contains a central disulfide group that provides cleavability after conjugation. Reaction with a disulfide reducing agent such as DTT breaks the disulfide bond and releases the crosslinked molecules. The photosensitive end of SASD is built from a salicylic acid derivative which contains a ring-activating hydroxyl group. Due to the presence of this group, the crosslinker can be radiolabeled with ^{125}I prior to a conjugation reaction. Iodination occurs *ortho* or *para* to the hydroxyl group on the phenyl ring, next to the aryl azide function (Figure 6.15) (Chapter 12, Section 2.5).

The combination of radiolabeling and cleavability provides the ability to detect the fate of the protein that retains the radiolabel after disulfide reduction. Thus, for investigations involving biomolecular interactions, a purified protein can be labeled with SASD through its amine groups via the NHS ester end of the crosslinker, allowed to interact *in vivo* with unknown target proteins, and photolyzed to effect a crosslink with these unknown substances. Subsequently the complex can be localized in the cell or effectively isolated by following the radiolabel. Alternatively, the conjugate can be cleaved by reduction, which results in the label being transferred to the unknown interacting protein, and its fate determined or the identity of the unknown protein revealed through the radiolabel (Figure 6.16). Such label transfer reagents are described in more detail in Chapter 24, Section 3.

Reported applications of SASD involve modification of lipopolysaccharide (LPS) molecules and studying their interaction with albumin and an antibody directed against LPS (Wollenweber and Morrison, 1985), identification of the murine interleukin-3 receptor and an *N*-formyl peptide receptor (Sorenson *et al.*, 1986), crosslinking of factor V and Va to iodinated peptides (Chattopadhyay *et al.*, 1992), and a comparison of radiolabeling techniques for the crosslinker (Shephard *et al.*,

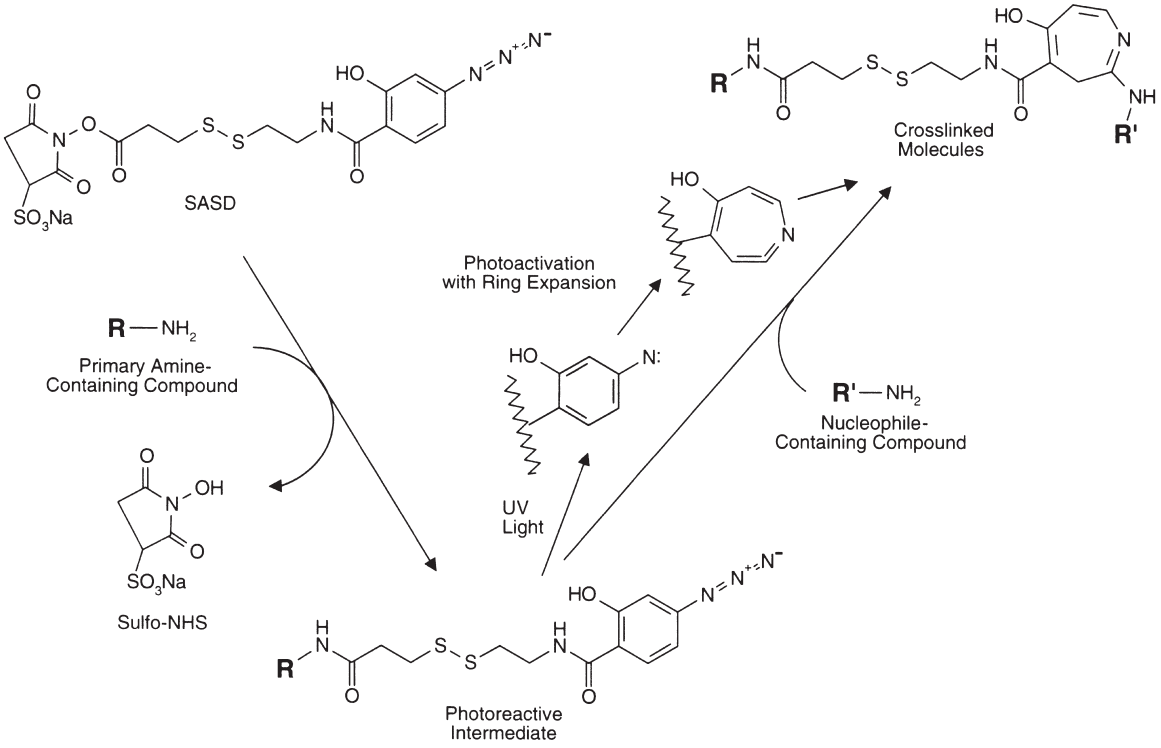

FIGURE 6.15 SASD is a photoreactive crosslinker that can be used to modify amine-containing compounds through its NHS ester end and subsequently photoactivated to initiate coupling with nucleophiles (after ring expansion to an intermediate dehydroazepine derivative). The crosslinks may be selectively cleaved at the internal disulfide group using DTT.

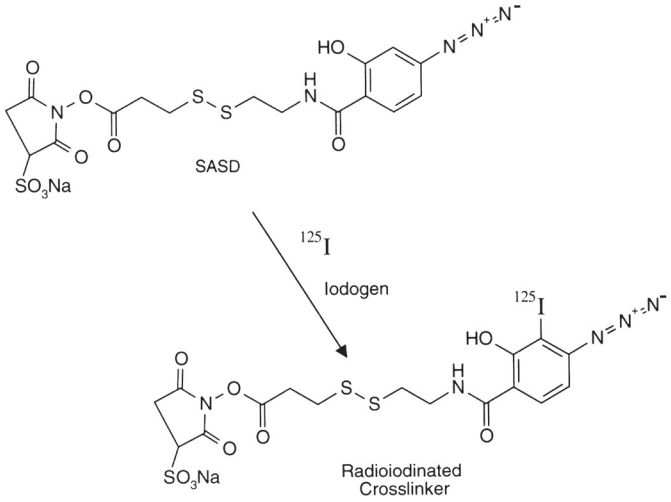

FIGURE 6.16 The hydroxyl group on the phenyl azide ring of SASD may be iodinated with ^{125}I to allow radiolabeling studies to be done on photolyzed conjugates.

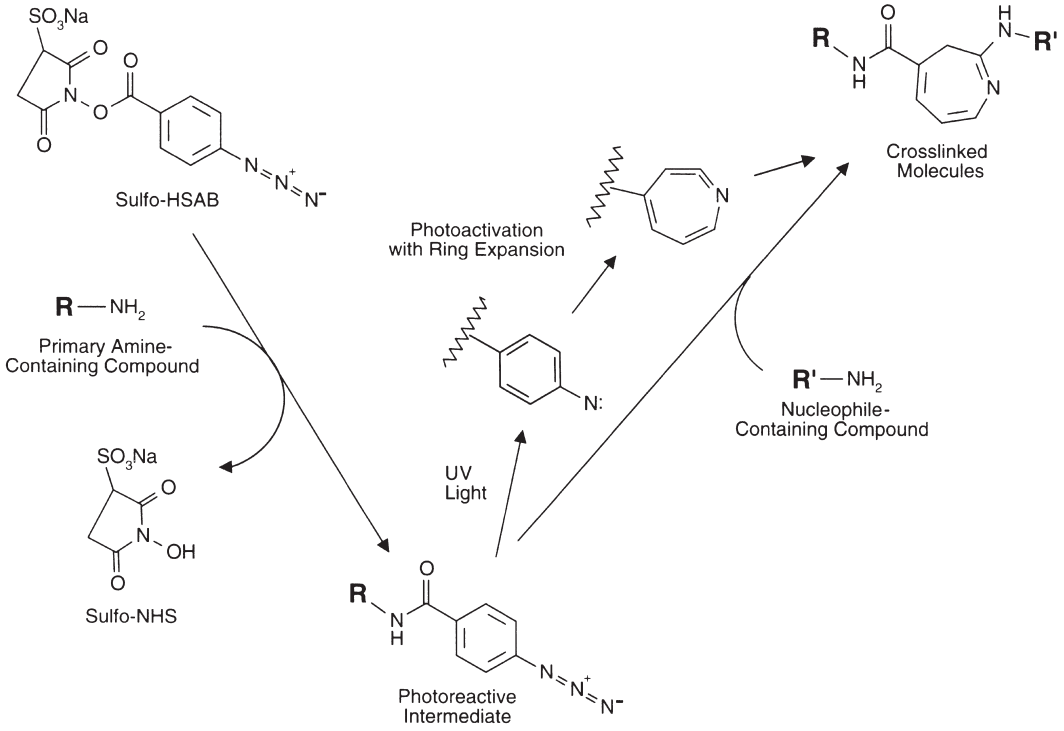
1988). Other studies have involved the investigation of protein interactions using the label transfer nature of radioiodinated SASD (Gupta *et al.*, 2005; Lindersson *et al.*, 2005; LeFebvre *et al.*, 2006) and the development of photoaffinity probes for studying carbohydrate biology (Yu *et al.*, 2012).

The best radiolabeling technique for SASD is to use the Iodogen method (Shephard *et al.*, 1988) described in Chapter 12, Section 2.3. The following suggested protocol for using SASD was based on the method described in the Thermo Fisher Catalog.

Protocol

The following operations should be performed using standard safety procedures for working with radioactive compounds. All steps involving SASD prior to initiation of the photoreaction should be carried out protected from light to avoid loss of phenyl azide activity. The radiolabeling procedure should be performed quickly to prevent excessive loss of NHS ester activity due to hydrolysis.

1. Radiolabel 55 nmol of SASD using Iodogen (Thermo Fisher) and 40 µCi $Na^{125}I$ for 30 s. Do not use Chloramine-T, since termination of the iodination reaction with this reagent involves addition of a reducing agent which may cleave the disulfide bonds of the crosslinker.
2. Terminate the iodination by removing the SASD solution from the Iodogen reagent using a transfer pipette. Be careful not to carry any solid Iodogen reagent with the transfer. Since free radioactive iodine may still be present in the solution, it may be necessary to add an iodine scavenger to prevent



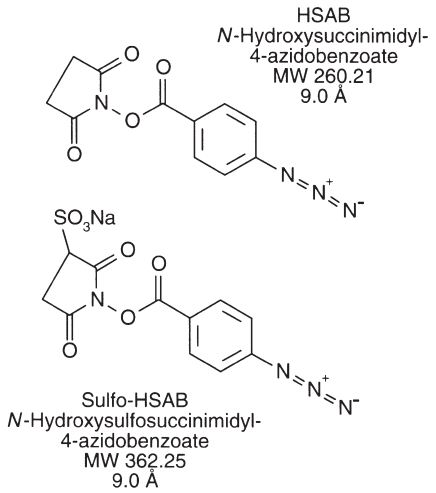


FIGURE 6.17 Sulfo-HSAB is a short photoreactive crosslinker that can be used to modify amine-containing molecules through its NHS ester end to form amide linkages. After photoactivation, the phenyl azide group can react with amines to create a covalent bond.

the possibility of radiolabels being incorporated into the proteins being crosslinked. Suitable scavengers include tyrosine or *p*-hydroxyphenylacetic acid. Adding these compounds in molar excess to the amount of iodine present will prevent any secondary modifications from occurring. Immediately add the radiolabeled SASD solution to the equivalent of 16 nmol of a protein to be modified. The protein should be dissolved previously in a minimum quantity of 0.1-*M* sodium borate, pH 8.4 (conjugation buffer). The more concentrated the protein, the more efficient will be the modification reaction.

3. React for 30 min to create the SASD derivative, coupled through the NHS ester reactive group of the crosslinker onto available amine groups of the protein (forming amide bonds).
4. Purify the modified protein by desalting using a desalting resin and performing the chromatography using a buffer of choice. Pool fractions containing protein. The protein should be radiolabeled at this point and also contain photoreactive phenyl azide groups from the SASD modification.
5. Add the SASD-modified protein to a second protein or other molecule to be conjugated. After mixing, expose the solution to long-wave UV light for 10 to 15 min at room temperature to effect the conjugation. The solution may be kept on ice to prevent over heating of sensitive proteins.

3.3. HSAB and Sulfo-HSAB

HSAB (*N*-hydroxysuccinimidyl-4-azidobenzoate) is a heterobifunctional reagent containing an amine-reactive NHS ester on one end and a photoreactive phenyl azide group on the other end (Thermo Fisher). The small cross-bridge, built from a benzoic acid group, provides crosslinking ability at short intermolecular distances. Reaction of one protein *via* the NHS ester end of the crosslinker provides a stable derivative that can be incubated with a target molecule and then photolyzed to effect the final conjugation (Figure 6.17).

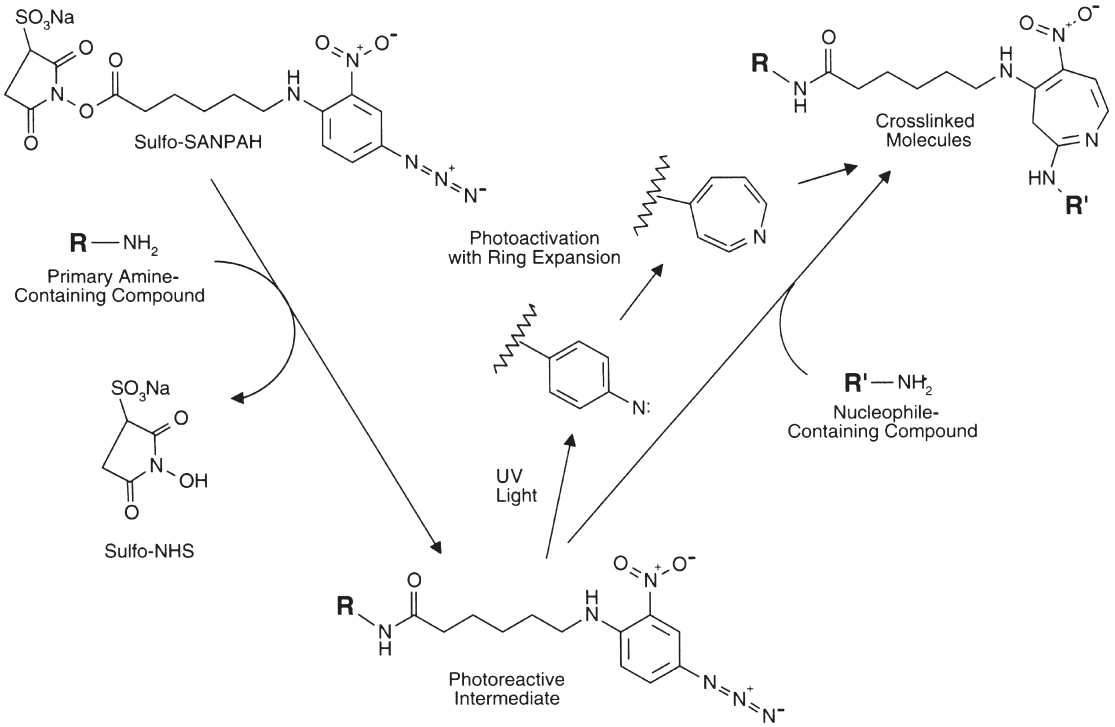

FIGURE 6.18 The reaction sequence of crosslinking with sulfo-SANPAH first involves derivatizing an amine-containing molecule using its NHS ester end to create an amide bond. Exposure to UV light then causes ring expansion to the dehydroazepine derivative, which can couple with amines to form the final conjugate.

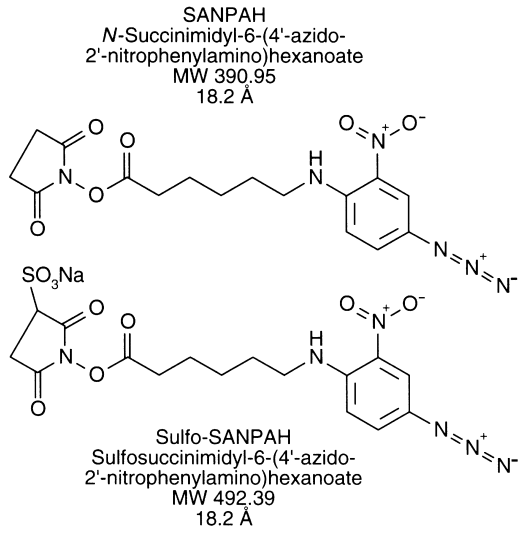
Reactions performed with HSAB should involve dissolution of the crosslinker in organic solvent prior to addition to an aqueous reaction medium. DMSO or DMF are suitable solvents to prepare concentrated stock solutions. Protect all solutions from light to avoid loss of photoreactive phenyl azide groups prior to the desired point of photolysis.

Reported applications of HSAB include photoaffinity labeling of peptide hormone binding sites (Galardy *et al.*, 1974), photoaffinity labeling of the insulin receptor with derivatized insulin analog (Yeung *et al.*, 1980), identifying nerve growth factor receptor proteins in sympathetic ganglia membranes (Massague *et al.*, 1981), labeling of the hormone receptor of both α and β subunits of human choriogonadotropin (Ji and Ji, 1981), isolation of *in situ* crosslinked ligand–receptor complexes (Ballmer-Hofer *et al.*, 1982), crosslinking vasoactive intestinal polypeptide to its receptors on intact human lymphocytes (Wood and O'Dorisio, 1985), conjugation of monoclonal antibodies to nanoparticle polymers (Le *et al.*, 2012), and conjugation of proteins to poly(butyl cyanoacrylate) nanoparticles (Reukov *et al.*, 2011).



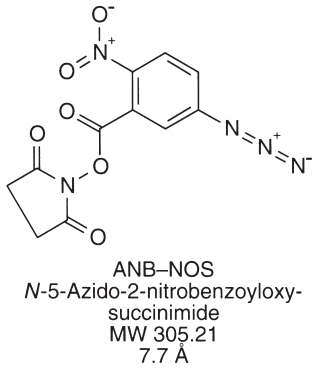
Sulfo-HSAB, *N*-hydroxysulfosuccinimidyl-4-azidobenzoate, is a water soluble analog of HSAB possessing a negatively charged sulfonate group on its NHS ring. This crosslinker may be added directly to aqueous reaction media without prior dissolution in organic solvent. To aid in the addition of small quantities of the reagent, a concentrated solution of sulfo-HSAB may be made in water and then an aliquot added to the reaction. Aqueous stock solutions should be dissolved quickly and used immediately to prevent extensive hydrolysis of the NHS ester.

HSAB and sulfo-HSAB have also been used to investigate serum amyloid A (Cai *et al.*, 2007), the functional role of C-terminal sequence elements in the transporter associated with antigen processing (Ehses *et al.*, 2005), and the kinetics of intermolecular interactions during cytochrome *c* protein folding (Nishida *et al.*, 2004).

3.4. SANPAH and Sulfo-SANPAH

SANPAH (*N*-succinimidyl-6-(4′-azido-2′-nitrophenylamino)hexanoate) is a heterobifunctional crosslinking agent containing an NHS ester and a photoreactive phenyl azide group (Thermo Fisher). The NHS ester end can react with amine groups in proteins and other molecules, forming stable amide linkages. The photoreactive end is sensitive to long UV light, being selectively activated to a highly reactive nitrene or dehydroazepine intermediate. Either of these photolyzed species can couple to molecules within van der Walls contact, rapidly forming covalent bonds (Figure 6.18). The cross-bridge of SANPAH is a non-cleavable 6-aminohexanoic acid derivative, which provides a long spacer between conjugated molecules.

The phenyl azide group also contains a nitro group on the ring that has the effect of increasing the wavelength of optimal photolysis. Exposure to light at a wavelength in the range of 320 to 350 nm promotes the photoreaction process. SANPAH is a water-insoluble crosslinker that will permeate membrane structures efficiently. The reagent should be dissolved in DMSO or DMF prior to addition of an aliquot to an aqueous reaction medium.



Reported applications of SANPAH include the crosslinking of ligand–receptor complexes *in situ* (Ballmer-Hofer *et al.*, 1982), preparing photoactivatable glycopeptide derivatives for site-specific labeling of lectins (Baenziger and Fiete, 1982), photoaffinity labeling of the *N*-formyl peptide receptor binding site of intact human polymorphonuclear leukocytes (Schmitt *et al.*, 1983), and the crosslinking of vasoactive intestinal peptide to receptors on intact human lymphoblasts (Wood and O'Dorisio, 1985).

A water soluble version of this crosslinker also exists. Sulfo-SANPAH (sulfosuccinimidyl-6-(4′-azido-2′-nitrophenylamino)hexanoate) contains the negatively charged sulfonate group on its NHS ring, lending greater hydrophilicity to the compound. SANPAH and sulfo-SANPAH have also been used for investigations into endothelial cell spreading and adhesion (Wallace *et al.*, 2007), to study the behavior of preosteoblastic cells (Khatiwala *et al.*, 2006), to develop a real-time microscopic method for studying biomolecular interactions (Sasuga *et al.*, 2006), and to prepare ligand-modified agarose gels to study fibronectin- and collagen-mimetic ligands (Connelly *et al.*, 2011).

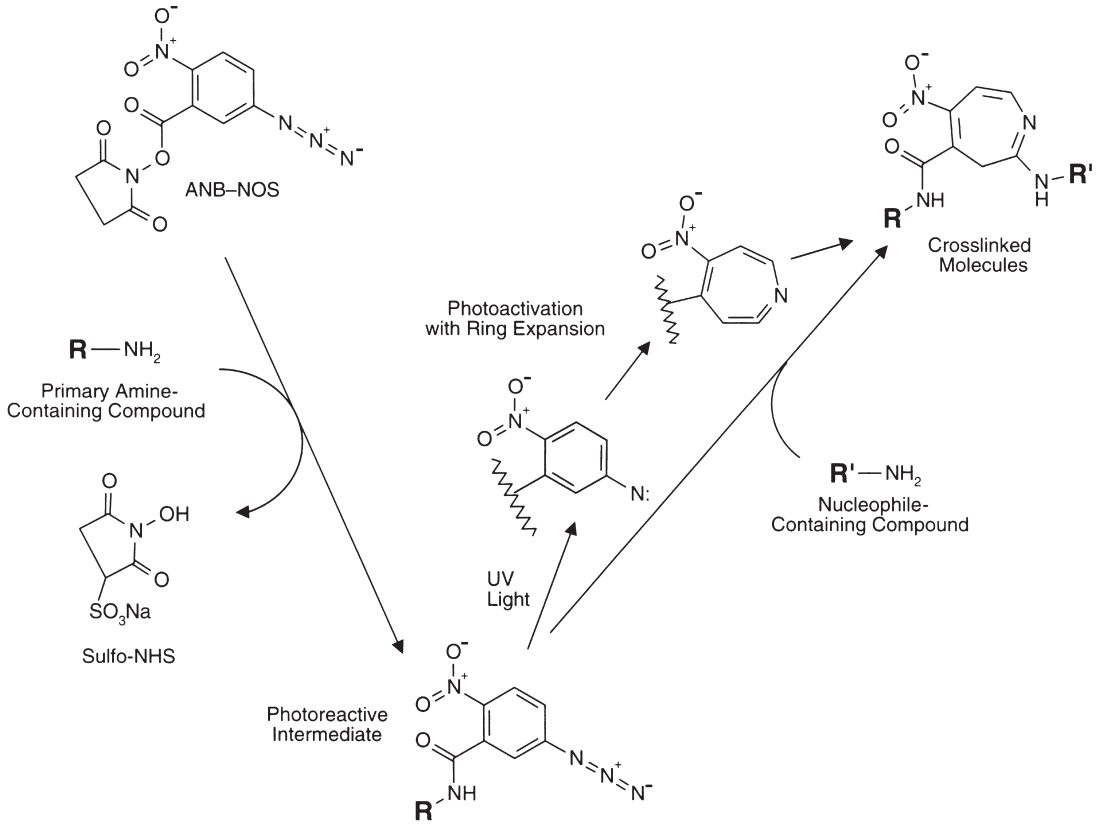
3.5. ANB-NOS

N-5-Azido-2-nitrobenzoyloxysuccinimide (ANB-NOS) is a photoreactive, heterobifunctional crosslinker containing an amine-reactive NHS ester group (Thermo Fisher). Its cross-bridge consists of a benzoic acid derivative, allowing molecules to be conjugated at relatively short 7.7-Å distances apart. The phenyl ring of ANB-NOS contains a nitro group that has the effect of shifting the optimal wavelength of activation to longer UV regions. The photoreaction is initiated by exposure to light in the range of 320 to 350 nm. Without the presence of the nitro group, activation would occur at much lower wavelengths, around 265 to 275 nm—wavelengths that potentially can damage biological molecules when exposed under high-photon irradiation. ANB-NOS typically is used to label an amine-containing protein or molecule by its NHS ester end. The resultant derivative is allowed to interact with other molecules that potentially can bind specifically to it and is photolyzed to effect the final conjugation, capturing any interacting partners (Figure 6.19).

Reported applications using this reagent include crosslinking of the aggregation state of cobra venom phospholipase A_2 (Lewis *et al.*, 1977) and conjugation of the signal sequence of nascent preprolactin to a polypeptide of the signal recognition particle (Krieg *et al.*, 1986). In addition, ANB-NOS has been used to capture interacting proteins in a two-step process (Nadeau and Carlson, 2007), to study the self-association of the yeast TATA-binding domain (Adams *et al.*, 2004), and to investigate the peptide-binding cleft of major histocompatibility complex (MHC) class I molecules (Park *et al.*, 2003).

3.6. SAND

Sulfosuccinimidyl-2-(*m*-azido-*o*-nitrobenzamido)-ethyl-1,3′-dithiopropionate (SAND) is a heterobifunctional reagent containing an amine-reactive sulfo-NHS ester at one end and a photoreactive phenyl azide group on the other end (Thermo Fisher). The presence of the sulfonate group on the NHS ring lends water solubility to the reagent due to its negative charge in aqueous solutions. In addition, the phenyl azide group contains a nitro constituent which shifts the



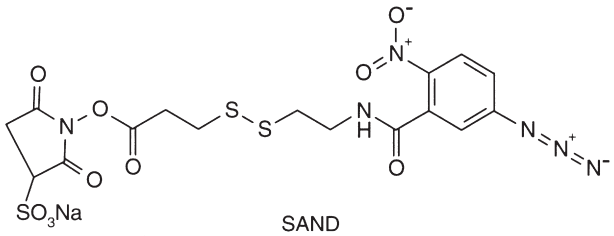


FIGURE 6.19 The NHS ester of ANB-NOS reacts with amines to form amide bonds. Subsequent photoactivation of the complex with UV light causes phenyl azide ring expansion and reaction with neighboring amines.

optimal range of photoactivation toward higher wavelengths—into the 320- to 350-nm region, thus decreasing the potential of photolytic damage to other sensitive groups that may be present during crosslinking. The extended cross-bridge of SAND (18.5 Å) provides a long spacer arm to accommodate even relatively distant sites between interacting molecules. The presence of a disulfide bond within the cross-bridge infers that the reagent is also cleavable by the use of a disulfide reductant, allowing the potential for disruption of the crosslinks after purification of the conjugate.

In use, SAND is first reacted with an amine-containing protein or other molecule—being careful to protect the photoreactive group from inadvertent degradation by exposure to excessive room light or sun. The modified intermediate is then allowed to interact with a target molecule. Finally, the photolyzing process is performed to effect a nonselective crosslink between the modified molecule and any target molecules within van der Waals distance to the crosslinker (Figure 6.20). Its use may be similar to that reported for sulfo-SANPAH, and its cleavability similar to that reported for SADP. For a more detailed discussion on the use of photoreactive crosslinkers to capture protein–protein interactions, see Chapter 24, Sections 2 and 3.

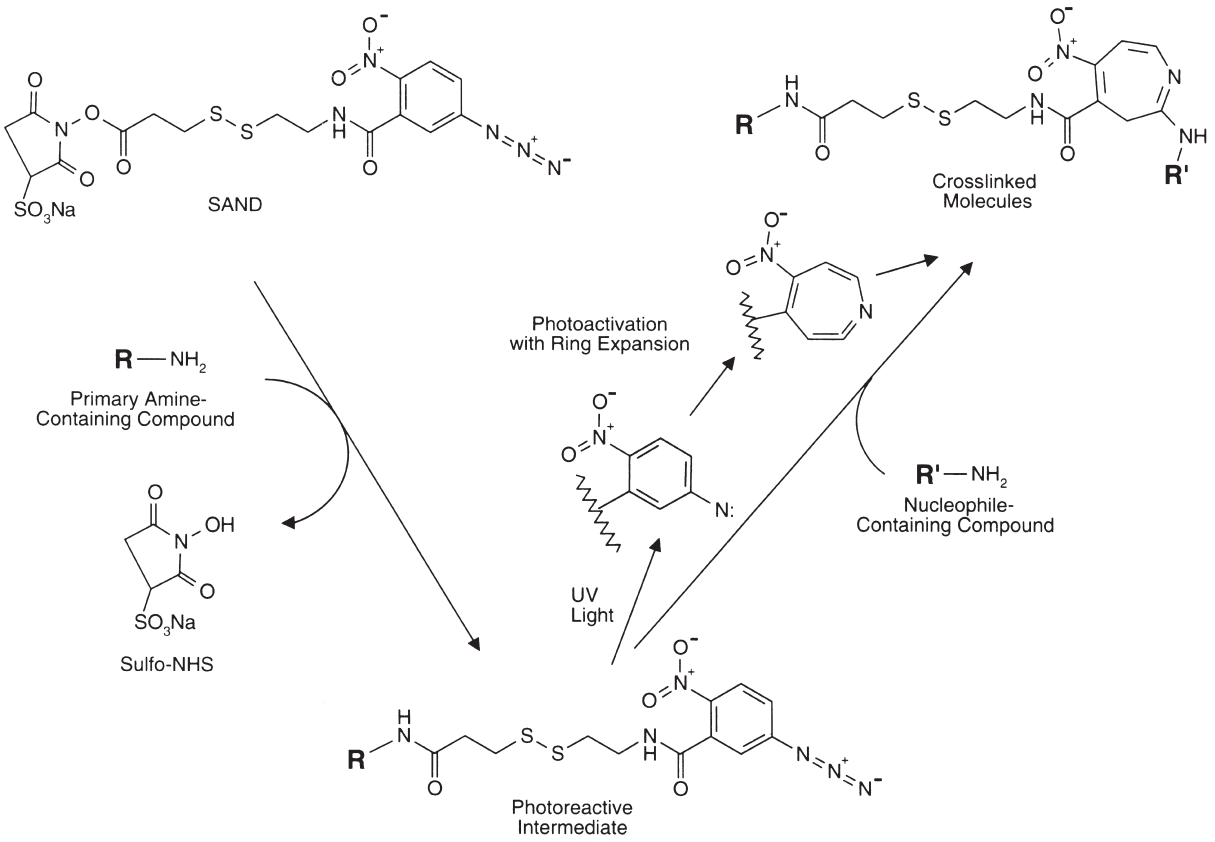
18.5 Å

3.7. SADP and Sulfo-SADP

SADP, N-succinimidyl-(4-azidophenyl)1,3′-dithiopropionate, is a photoreactive heterobifunctional crosslinker that is cleavable by treatment with a disulfide reducing agent (Thermo Fisher). The crosslinker contains an amine-reactive NHS ester and a photoactivatable phenyl azide group, providing specific, directed coupling at one end and nonselective insertion capability at the other end.

SADP is first used to modify a protein via its amine groups through the reactive NHS ester end of the crosslinker. After allowing for interaction of the modified



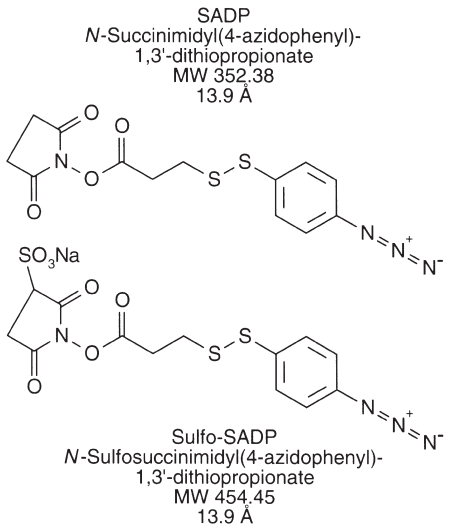


FIGURE 6.20 SAND can be used to modify amine-containing molecules and then photo-initiate crosslinking to another amine-containing molecule via a ring-expansion process. The conjugates may be disrupted by reduction of the cross-bridge disulfide with DTT.

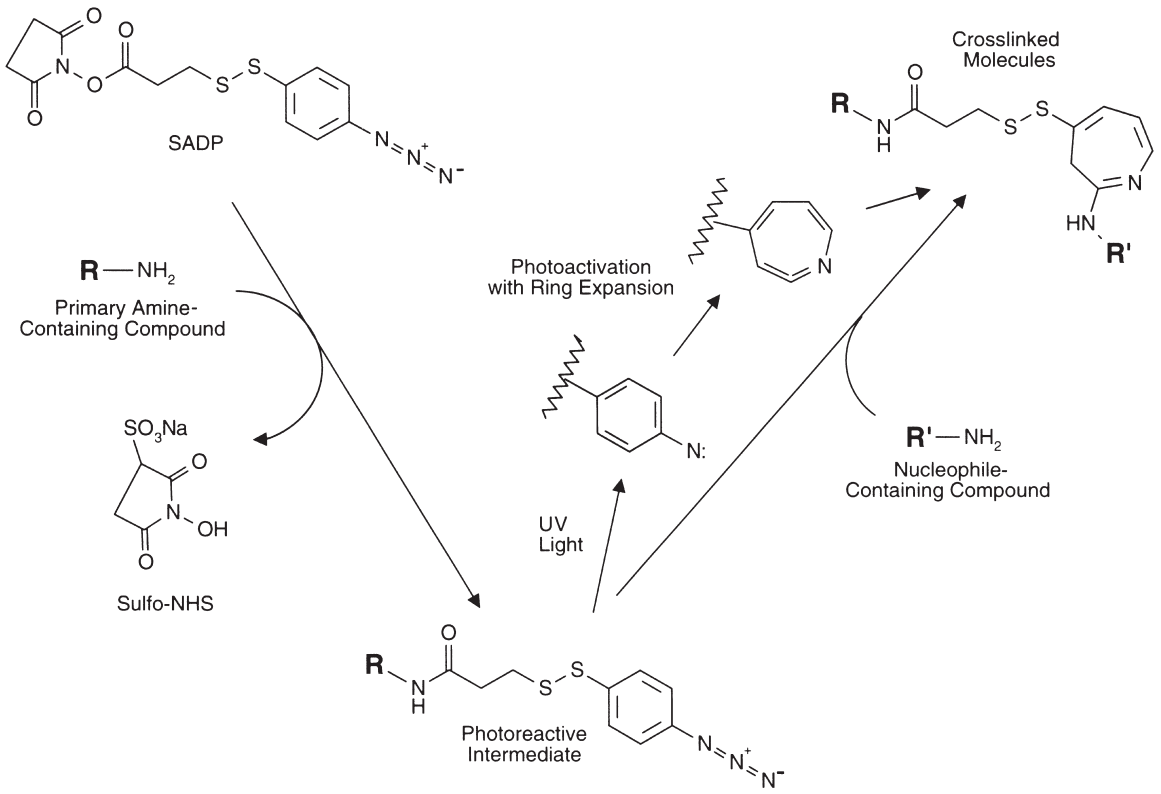
protein with target molecules, the photoreactive group is used to couple with any molecules within van der Waals distance. The photolysis reaction requires UV exposure in the range of 265 to 275 nm to form the final linkage. The presence of the disulfide group in SADP's cross-bridge allows disruption of crosslinks with 50-m*M* DTT after the conjugation reaction is complete (Figure 6.21).

SADP is hydrophobic and should be dissolved in organic solvent prior to addition of a small aliquot to an aqueous reaction. Concentrated stock solutions can be prepared in dry DMSO or DMF. Final concentration of the organic solvent in a crosslinking reaction should not exceed about 10% to prevent protein precipitation or denaturation.

Reported applications of SADP include the crosslinking of Con A to receptors on human erythrocyte membranes (Vanin and Ji, 1981), site-specific labeling of lectins using modified glycopeptides (Baenziger and Fiete, 1982), conjugation of a mouse cell-surface polypeptide with a Sendai virion envelope on newly infected cells (Zarling *et al.*, 1982), and crosslinking of platelet glycoprotein Ib (Jung and Moroi, 1983).

Sulfo-SADP is a water soluble analog of SADP which contains a negatively charged sulfonate group on its NHS ring. The reagent may be added directly to aqueous reaction mixtures without prior dissolution in an organic solvent. Concentrated stock solutions prepared in water should be used immediately to prevent extensive hydrolysis of the sulfo–NHS ester group.

SADP or sulfo-SADP have also been used to study the phenylalanine–methionine–arginine–phenylalanine–



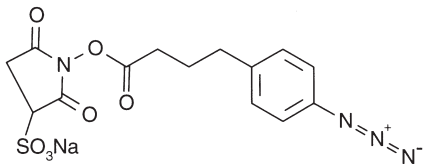


FIGURE 6.21 SADP reacts with amines via its NHS ester end to produce amide bonds. The modified molecule may then be photoactivated to create a nucleophile-reactive dehydroazepine intermediate able to covalently couple with amine-containing compounds.

amide-activated sodium channel (Coscoy *et al.*, 1998), various apolipoprotein E isoforms (Mann *et al.*, 1995), the high-affinity phenylalkylamine Ca^{2+} antagonist binding protein from guinea pig (Moebius *et al.*, 1994), the interaction of non-histone proteins with nucleosome core particles (Reeves and Nissen, 1993), and the interactions among cytochromes P-450 in the endoplasmic reticulum (Alston *et al.*, 1991). See Chapter 24 for methods of using photoreactive heterobifunctional crosslinkers to study protein interactions.

3.8. Sulfo-SAPB

Sulfo-SAPB, sulfosuccinimidyl 4-(*p*-azidophenyl) butyrate, is a photoreactive heterobifunctional reagent containing an amine-reactive sulfo-NHS ester at one end (Thermo Fisher). The crosslinker is similar in design to sulfo-HSAB (Section 3.3, this chapter), but it contains a three-carbon-longer cross-bridge. The sulfo–NHS ester provides water solubility to the reagent due to the negative charge of the sulfonate group. The phenyl-azide end can be photolyzed by exposure to UV light in the wavelength range of 265 to 275 nm (Figure 6.22). Sulfo-SAPB has been used in the bioconjugation of polymer scaffolds to create biotherapeutic agents for targeted drug delivery (Vaidya *et al.*, 2011). The commercial availability of the reagent provides additional options for spacer length to study the interactions between two proteins or other molecules.

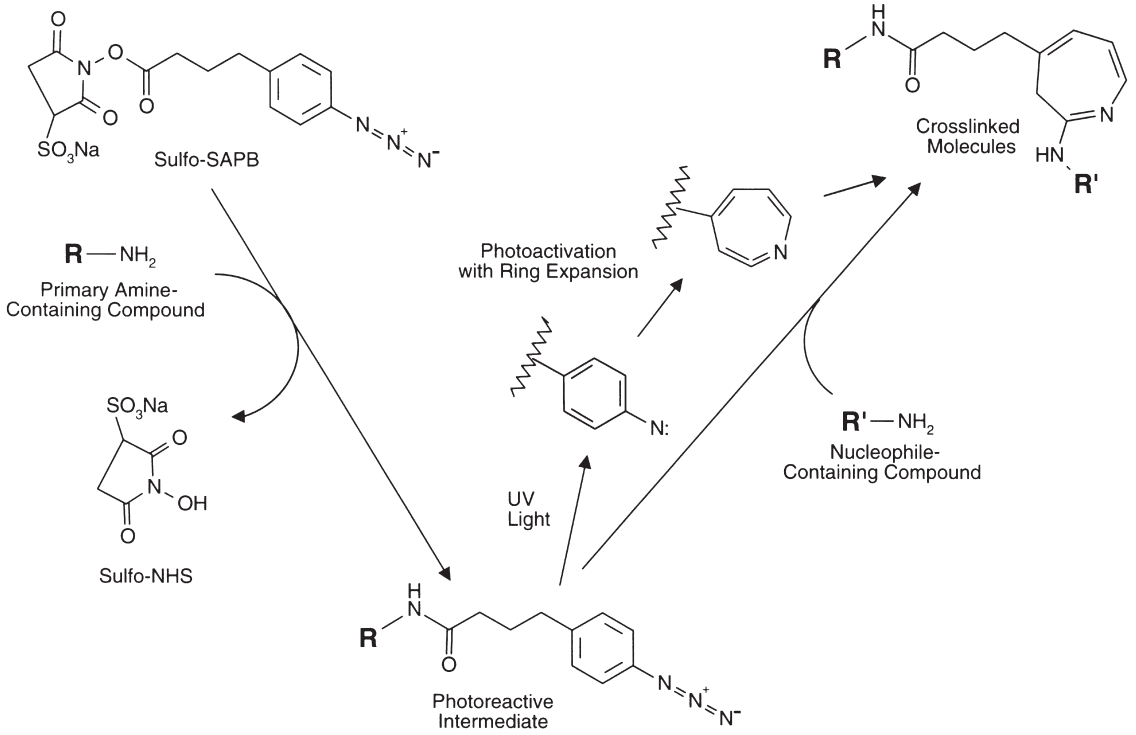
3.9. SAED

Sulfosuccinimidyl 2-(7-azido-4-methylcoumarin-3-acetamide)ethyl-1,3′-dithiopropionate (SAED) is a photoreactive heterobifunctional crosslinking agent that also contains a fluorescent group (Thermo Fisher). The sulfo-NHS ester end of the reagent reacts with primary amines in proteins and other molecules to form stable amide linkages. The photoreactive end is an AMCA derivative (Chapter 10, Section 3) containing a light-sensitive azide group on the aromatic ring. Photolyzing with light in the long UV range will result



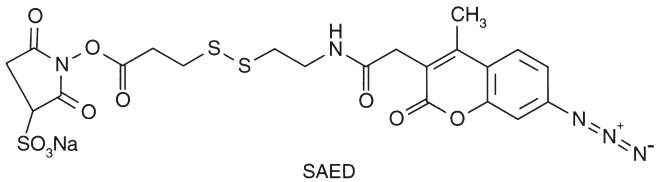


FIGURE 6.22 The reaction of sulfo-SAPB with an amine group is performed first to form an amide bond derivative through its NHS ester end. Subsequent exposure to UV light causes the phenyl azide group to ring expand to a highly reactive dehydroazepine, which can couple to nucleophiles, such as amines.

in nonselective bond formation with nucleophiles and active carbon–hydrogen bonds within van der Waals distance (Figure 6.23).

SAED
Sulfosuccinimidyl-2-(7-azido-4-methyl coumarin-3-acetamide)ethyl-1,3'-dithiopropionate
MW 621.6
23.6 Å

SAED is a relatively large crosslinker containing a long (22.5-Å) cross-bridge. The central portion of its cross-bridge contains a disulfide bond, making the reagent susceptible to cleavage with disulfide reducing agents. The aromatic character of the coumarin derivative creates a maximal UV absorptivity at 327 nm with an extinction coefficient of 18,200 $M^{-1}cm^{-1}$ for a 1-mg/ml solution in acetonitrile:water (15:2 v/v). The extinction coefficient at 298 nm for the same concentration of SAED in the identical solvent is 13,625 $M^{-1}cm^{-1}$.

SAED contains a sulfo-NHS ester with a negatively charged sulfonate group on its ring. The presence of this negative charge does lend some expected water solubility to the reagent (3 mg/ml at room temperature), but because of the reagent's large size, it does not provide the same water solubility benefits as with other smaller crosslinkers. It is also sparingly soluble in acetonitrile (2.5 mg/ml), but only if a small amount of water is present (15:2 acetonitrile:water, v/v). However, SAED is very soluble in DMSO and DMF (about 50 mg/ml). Stock solutions may be prepared in dry DMSO or DMF while maintaining fairly good stability of the reagent's functional groups. The addition of a small quantity of these stock solutions to an aqueous reaction medium facilitates the amine-modification process via the sulfo-NHS ester end of the crosslinker. The final concentration of organic solvent in the aqueous reaction should not exceed 10% to avoid protein denaturation and precipitation. Protect all solutions of the crosslinker from light to prevent premature activation of the photoreactive group.

The coumarin derivative of SAED is not fluorescent until the photolysis reaction is initiated. A protein modified with SAED will fluoresce after activation with UV light whether or not the photoreactive end actually couples to the intended target, since breakdown of the azide group on the ring is all that is required to initiate fluorescence. Thus, the level of SAED incorporation into a macromolecule may be assessed by the resultant coumarin fluorescence after separation of the derivative from excess reagent. Native AMCA has an excitation

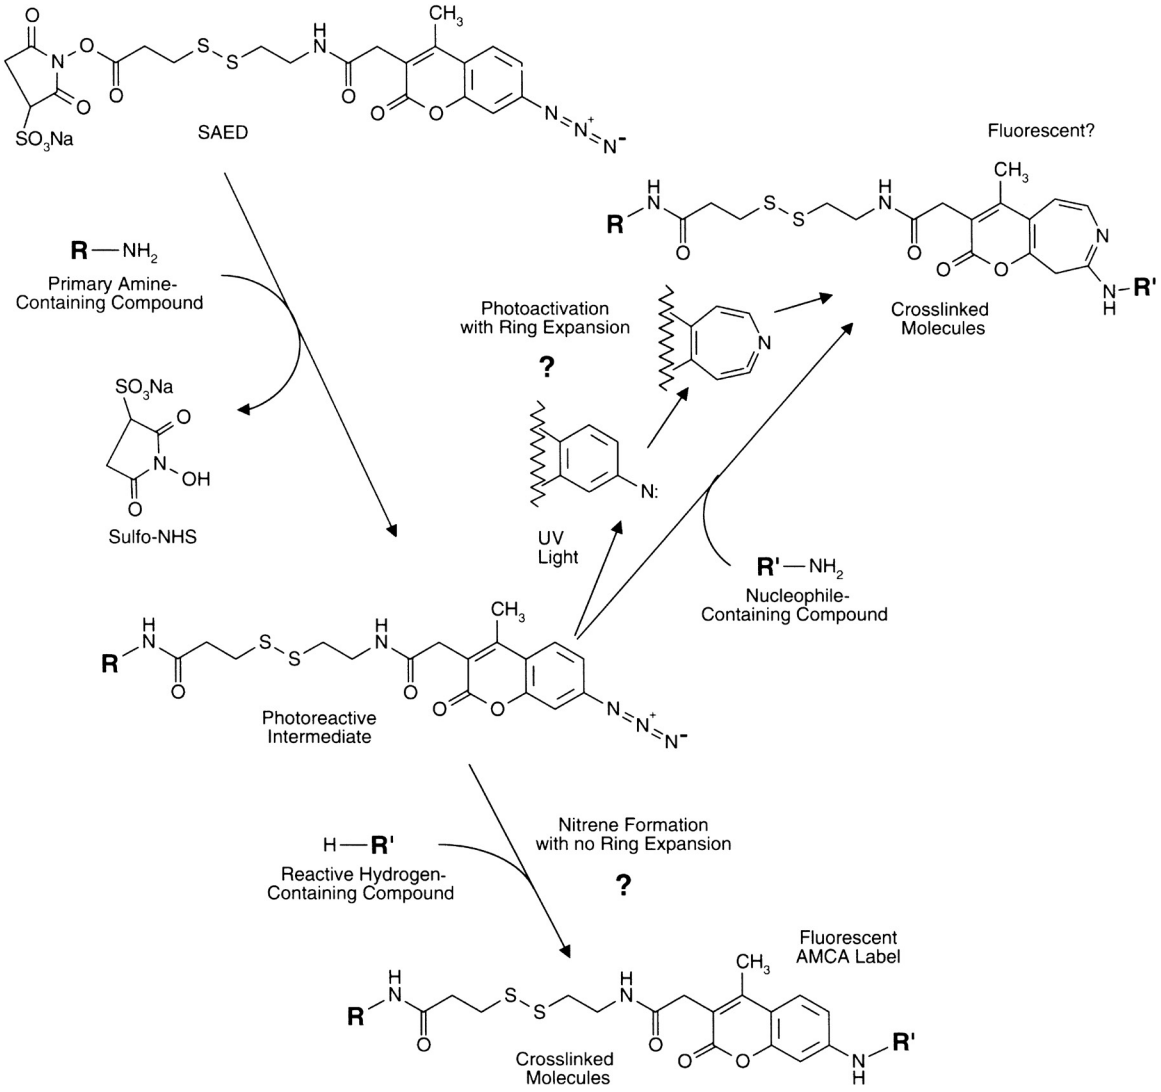

FIGURE 6.23 SAED can be used to modify amine-containing molecules through its NHS ester end. Subsequent exposure to UV light causes bond formation with nearby nucleophilic groups, such as amines. The photosensitive phenyl azide group is created on the aromatic ring of an AMCA fluorophore. Before photoactivation, the azide group makes the crosslinker nonfluorescent. After photoactivation, however, the azide group is either lost by N_2 generation or couples to a target molecule. Either way, the AMCA portion becomes fluorescent to allow tracking of the conjugate. The photoreaction may occur through ring expansion to an intermediate dehydroazepine or might happen through nitrene formation.

optimum at 345 to 350 nm and an emission wavelength range of 440 to 460 nm. The quantum yield of SAED may change somewhat upon its attachment to macromolecules due to fluorescent quenching; however, the coumarin tag will still remain fluorescently active even after crosslinking.

Since the crosslinker is cleavable, SAED provides a means of fluorescent transfer of the coumarin tag to a second molecule which interacts with the initially modified protein (Figure 6.24). For example, soybean trypsin inhibitor (STI) was labeled with SAED and then allowed to interact with trypsin. After photoreactive crosslinking of the two interacting molecules, the complex was reduced with DTT, breaking the conjugate and transferring the fluorescent tag to trypsin near the STI binding site (Thevenin *et al.*, 1991). This type of fluorescent label transfer reagent is important for studying unknown interacting proteins, because the unknown protein can be detected and isolated by the tag after cleavage of the complex.

In another study, SAED was used to investigate the role of the foot protein moiety of the triad and its relationship to Ca^{2+} release from sarcoplasmic reticulum (Kang *et al.*, 1991). Modification of poly-L-lysine (a Ca^{2+} release inducer) and neomycin with the crosslinker was carried out, followed by subsequent incubation with the

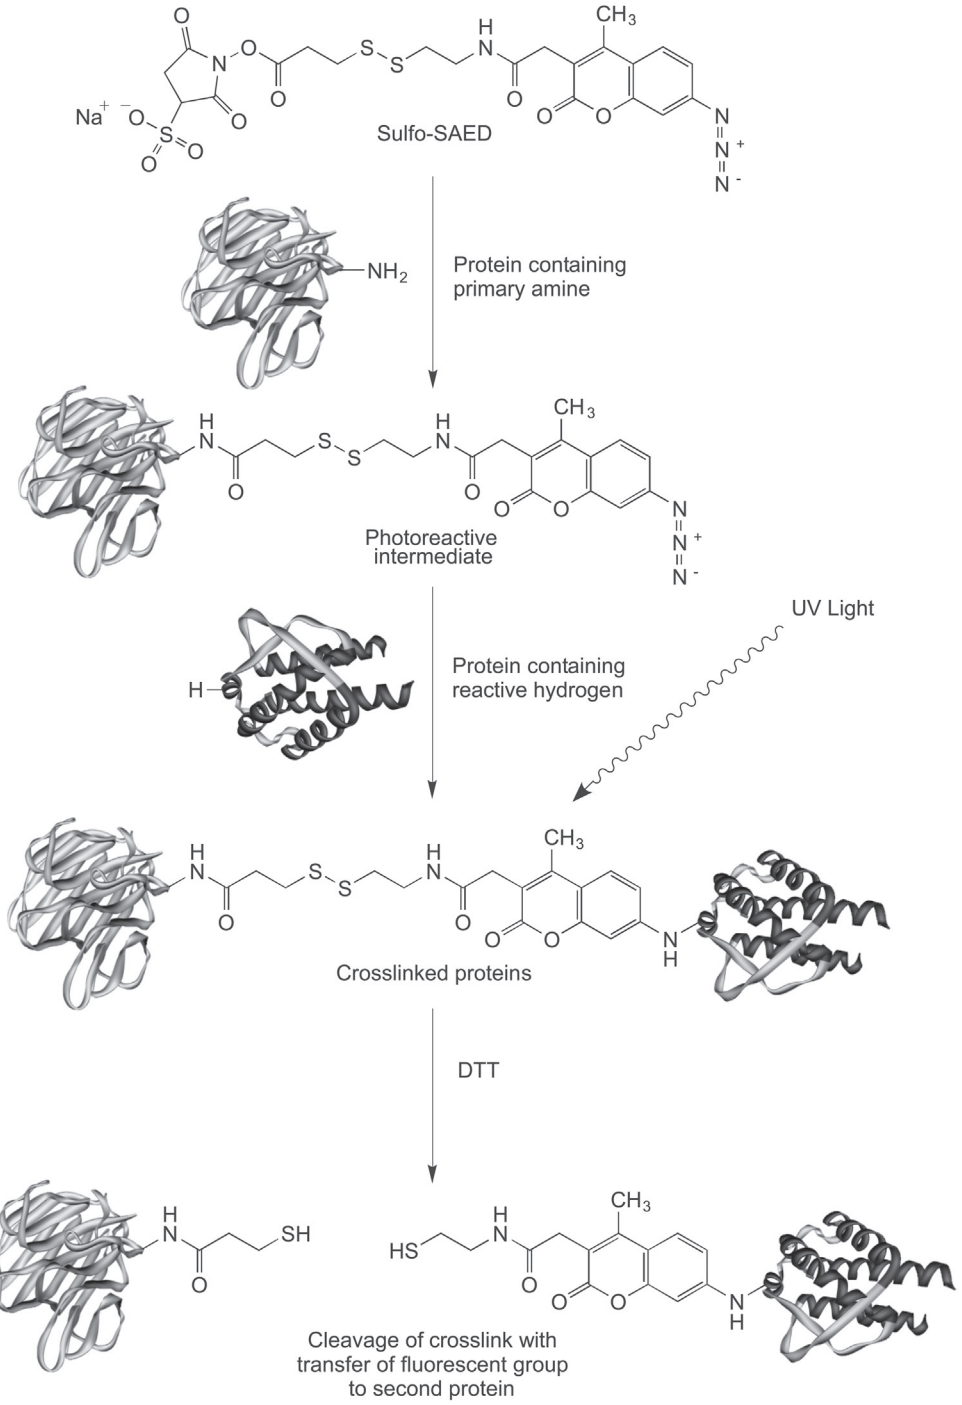

FIGURE 6.24 SAED may be used to transfer the fluorescent AMCA label from the first molecule modified with the crosslinker to the second molecule crosslinked with it by reduction of its internal disulfide bond. Thus, unknown target molecules may be fluorescently tagged to follow them *in vivo*.

foot protein and photoreactive conjugation. Cleavage of the crosslinks with a disulfide reductant allowed transfer of the fluorescent tag to the foot protein in areas near the binding sites. Fluorescent monitoring of conformational changes within the protein upon varying the Ca^{2+} concentration was then possible.

Since the photoreactive crosslinking step with SAED occurs rapidly upon exposure to even bright light within the visible spectrum, UV lamps are not required. However, special care should be taken to protect the reagent from exposure to light before the photolysis reaction is initiated. The solid should be stored in amber

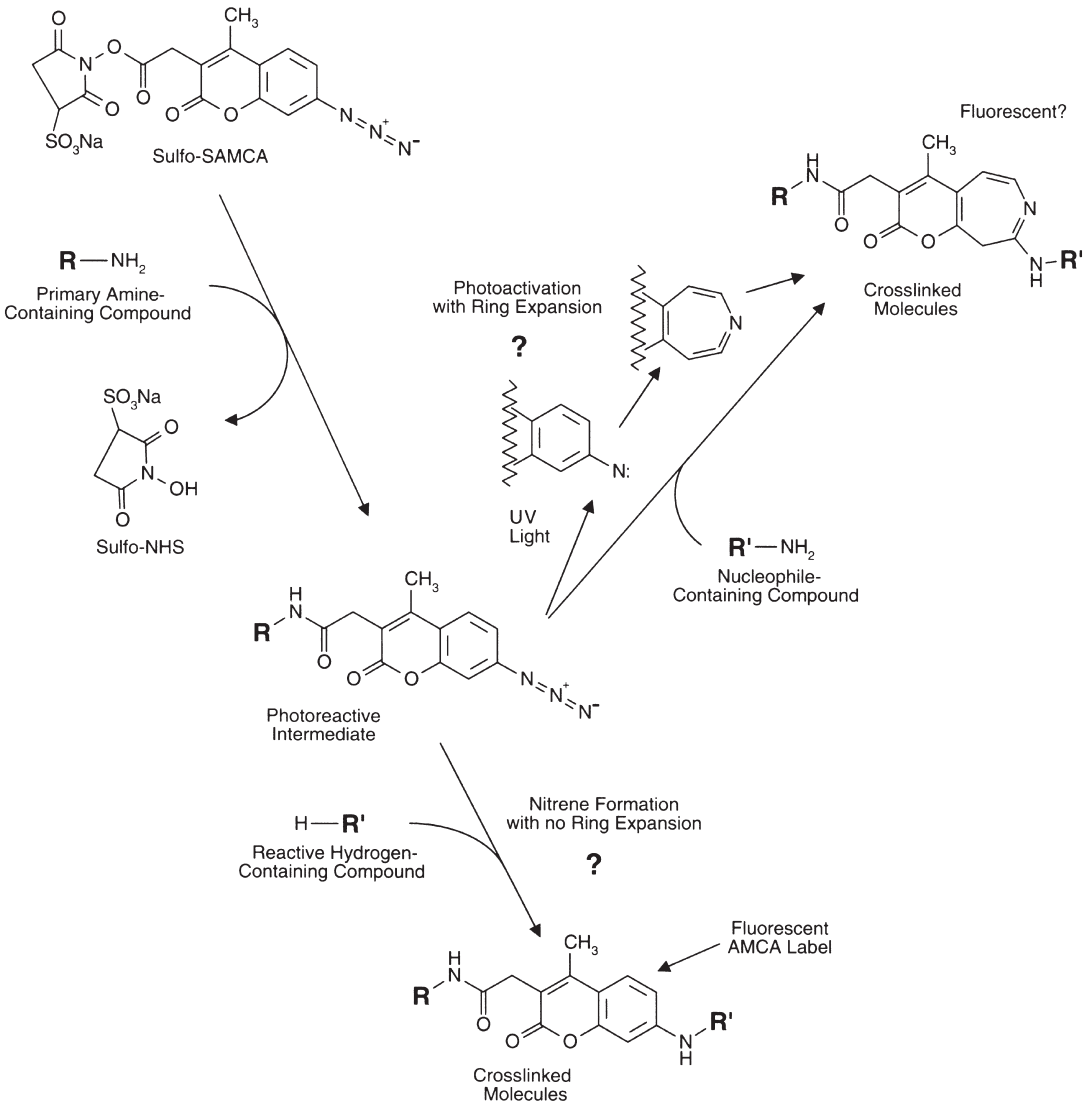

FIGURE 6.25 Sulfo-SAMCA can be used to modify amine-containing molecules through its NHS ester end. Subsequent exposure to UV light causes bond formation with nearby nucleophilic groups, such as amines. The photosensitive phenyl azide group is created on the aromatic ring of an AMCA fluorophore. Before photoactivation, the azide group makes the crosslinker nonfluorescent. After photoactivation, however, the azide group either is lost by N_2 generation or couples to a target molecule. Either way, the AMCA portion becomes fluorescent to allow tracking of the conjugate. The photoreaction may occur through ring expansion to an intermediate dehydroazepine or might happen through nitrene formation.

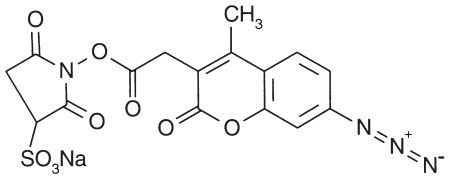
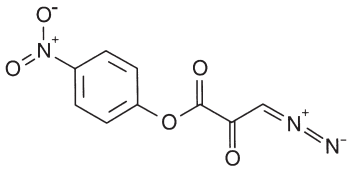


bottles and any stock solutions prepared in organic solvent should be wrapped to exclude light. In addition, the initial derivatization of an amine-containing molecule should be done in the dark in wrapped containers.

Additional applications of SAED include study of the ryanodine receptor (Yano *et al.*, 2005; Mochizuki *et al.*, 2007) and investigating the protein organization of the postsynaptic density (Liu *et al.*, 2006).

3.10. Sulfo-SAMCA

Sulfo-SAMCA, sulfosuccinimidyl 7-azido-4-methylcoumain-3-acetate, is a heterobifunctional reagent similar in design to SAED (Section 3.9, this chapter) (Thermo Fisher). One end of the crosslinker contains an amine-reactive sulfo-NHS ester, while the other end is an AMCA derivative (Chapter 10, Section 3) that contains a photosensitive phenyl azide group. Unlike SAED, however, sulfo-SAMCA contains a short noncleavable cross-bridge (12.8 Å) where the active ester functionality is constructed directly off the carboxylate group of AMCA without any other intervening spacer groups. Conjugated molecules will retain the fluorescent label, thus providing detectability to the complexes formed (Figure 6.25). However, since crosslinks formed with this reagent are not cleavable, sulfo-SAMCA



cannot function as a fluorescent label transfer agent in the fashion of SAED.

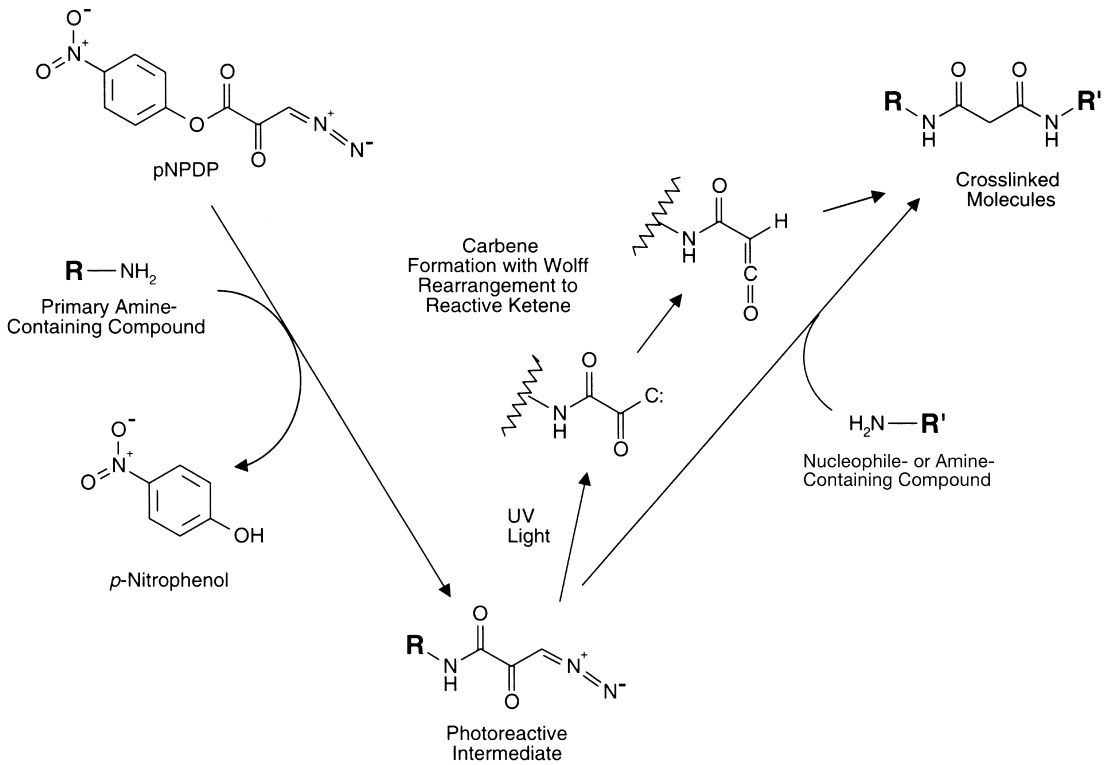
3.11. *p*-Nitrophenyl Diazopyruvate

Diazopyruvates represent a unique class of photoreactive reagents that are not often used in heterobifunctional crosslinker design. The *p*-nitrophenyl ester derivative of diazopyruvate provides amine-reactive, acylating potential, while the photosensitive group can be activated with UV light to generate reactive aldehydes. More specifically, the diazo functionality can by photolyzed by exposure to irradiation at 300 nm, forming a highly reactive carbene which can undergo a Wolff rearrangement that produces a ketene amide intermediate. In the presence of a nucleophilic species on a target molecule, the ketene can undergo an acylation reaction to form a stable malonic acid derivative. The photolyzed product thus can couple to hydrazide- or amine-containing targets to form covalent linkages (Figure 6.26).

pNPDP
p-Nitrophenyl diazopyruvate
MW 235

p-Nitrophenyl diazopyruvate (Invitrogen) is relatively insoluble in water or aqueous buffers, but may be pre-dissolved in DMF before adding an aliquot of the stock solution to an aqueous reaction mixture. All solutions of the reagent should be carefully protected from light to prevent premature photolysis. *p*-Nitrophenyl diazopyruvate has an absorbance maximum at 390 nm with a molar extinction coefficient of about 19,000 $M^{-1}cm^{-1}$ in methanol.



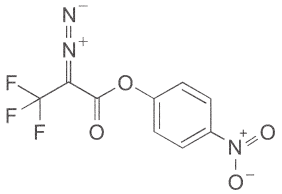


FIGURE 6.26 pNPDP reacts with amine-containing compounds by its *p*-nitrophenyl ester group to form amide bonds. After photoactivation of the diazo derivative with UV light, a Wolff rearrangement to a highly reactive ketene intermediate occurs. This group can couple to nucleophiles such as amines.

p-Nitrophenyl diazopyruvate has been used in the photoreactive crosslinking of calmodulin with adenylate cyclase from bovine brain (Harrison *et al.*, 1989), to crosslink aldolase (Goodfellow *et al.*, 1989), as a bonding agent for tissue containing type-I collagen (Givens *et al.*, 2003) or to bond to corneal tissue (Timberlake *et al.*, 2005), and in the photoreactive coupling of DNA to paramagnetic beads (Penchovsky *et al.*, 2000).

3.12. PNP–DTP

PNP–DTP, *p*-nitrophenyl-2-diazo-3,3,3-trifluoropropionate, is a photoreactive heterobifunctional crosslinker that contains an amine-reactive group on one end and a photosensitive diazo group on the other (Chowdhry *et al.*, 1976) (Thermo Fisher). *p*-Nitrophenyl esters react similarly to NHS esters (Chapter 5, Section 1, and Chapter 3, Section 1.4) but in this case with *p*-nitrophenol as the leaving group upon reaction with a nucleophile (Figure 6.27). Amine-containing target molecules such as proteins can be modified with this reagent to form amide bond derivatives possessing photoactivatable functionalities. The reagent is small enough to probe deep within the active centers of receptor molecules and other sites of biomolecular interactions.

PNP-DTP;
p-Nitrophenyl-2-diazo-
3,3,3-trifluoropropionate
Mol. Wt.: 275.14

PNP–DTP has been used to photoaffinity label the thyroid hormone nuclear receptors in intact cells by preparing a derivative of 3,5,3′-triiodo-L-thyronine with the crosslinker (Pascual *et al.*, 1982; Casanova *et al.*, 1984). Effective photoreactive conjugation was found to occur after irradiation with UV light at 254 nm or 310 nm.

4. SULFHYDRYL-REACTIVE AND PHOTOREACTIVE CROSSLINKERS

The benefits of nonselective photoreactive crosslinking can be merged with the directed coupling ability of sulfhydryl-reactive functionalities to create heterobifunctional reagents possessing greater utility than the standard amine- and photoreactive agents discussed previously. Having a sulfhydryl-reactive group on one end of the crosslinker allows the initial conjugation to take place at more discrete sites on proteins and other molecules before irradiation to effect the final photosensitive reaction.

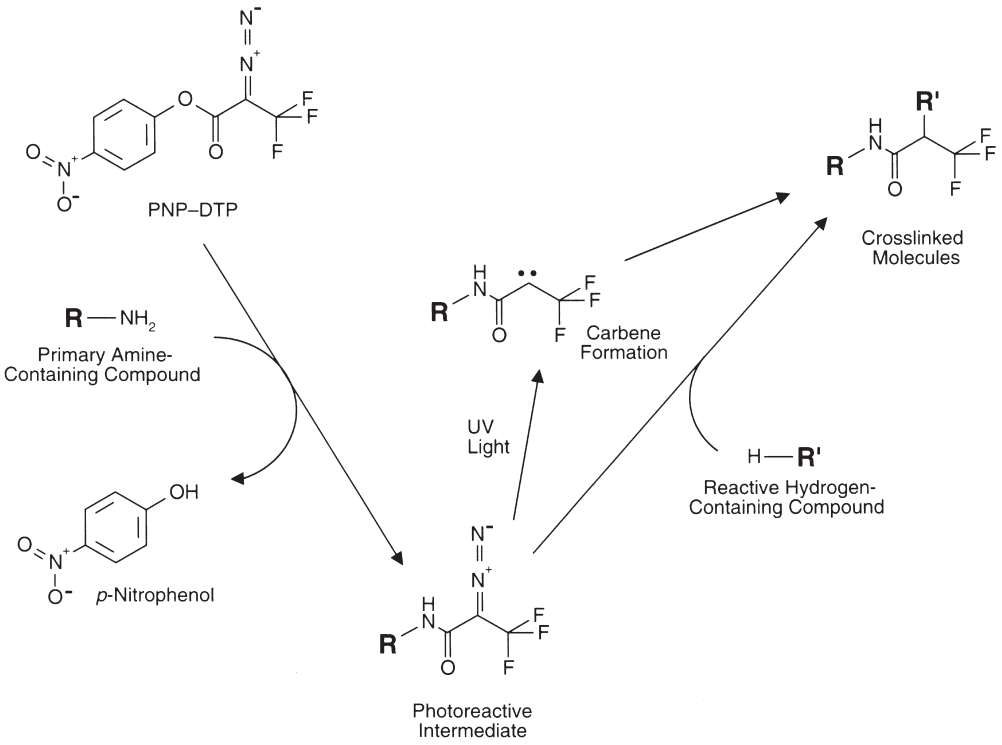
The following reagents contain a variety of sulfhydryl-reactive groups, including iodoacetyl derivatives, maleimide compounds, and pyridyl disulfide chemistries. The iodoacetyl and maleimide functions form permanent thioether bonds with target molecules containing free sulfhydryls. The pyridyl disulfide derivative reacts with SH groups to form reversible disulfide linkages, which can be cleaved with disulfide reducing agents, like DTT.

The photoreactive end of the following crosslinkers also varies from the traditional aryl azide group to the newer benzophenone and fluorinated aryl azide derivatives. The fluorinated phenyl azide functional groups will photolyze to true nitrenes without the ring expansion side reaction characteristic of aryl azides. The result is that fluorinated aryl azides more effectively insert into active carbon–hydrogen bonds, rather than potentially undergoing nucleophilic reactions like phenyl azides. In addition, benzophenone groups generally have higher degrees of bond formation with the intended target molecule compared to the yields obtained using traditional phenyl azides, due to their ability to be repeatedly photolyzed without breakdown of the precursor to an inactive form.

The number of commercially available crosslinkers for sulfhydryl- and photoreactive conjugations provide enough variety to design successful experiments in photolabeling, such as studying active centers and macromolecular interactions.

4.1. ASIB

ASIB, 1-(*p*-azidosalicylamido)-4-(iodoacetamido)butane, is a heterobifunctional crosslinker containing a sulfhydryl-reactive iodoacetyl group on one end and a photosensitive phenyl azide group on the other end (Thermo Fisher). The phenyl azide ring is substituted with a ring-activating hydroxyl group which provides the ability to radioiodinate the compound before the conjugation reaction is performed. Since both the iodoacetyl and phenyl azide functionalities are relatively stable in aqueous solutions, the steps involved in iodination and crosslinking do not detrimentally affect the subsequent reactivity of the reagent. All operations should be protected from light, however, to prevent premature photolysis before the desired crosslinking reaction is initiated. The cross-bridge of the reagent provides an 18.8-Å spacer between crosslinked molecules.



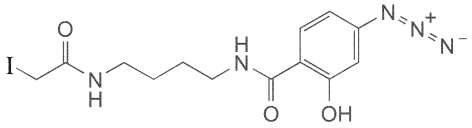


FIGURE 6.27 PNP–DTP can modify amine-containing molecules through its *p*-nitrophenyl ester group to form amide bonds. Exposure of its photosensitive diazo group with UV light generates a highly reactive carbene that can insert into active C—H or N—H bonds.

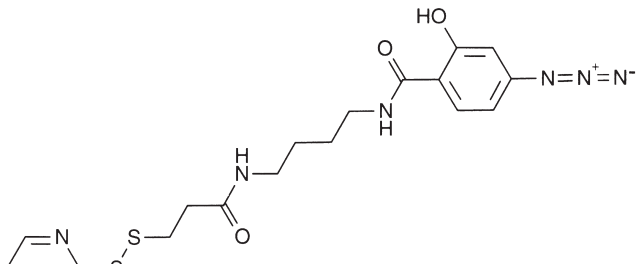

ASIB;
1-(*p*-Azidosalicylamido)-
4-(iodoacetamido)butane
Mol. Wt.: 417.20
18.8 Å

The reaction of ASIB with sulfhydryl-containing molecules can be performed at mildly alkaline pH with excellent specificity. Higher pH conditions may cause cross-reactivity with amines. Photolyzing with UV light may result in immediate reaction of the nitrene intermediate with a target molecule within van der Waals distance, or may result in ring expansion to the nucleophile-reactive dehydroazepine. The ring-expanded product is reactive primarily with amine groups (Figure 6.28).

4.2. APDP

APDP, N-[4-(*p*-azidosalicylamido)butyl]-3′-(2′-pyridyldithio) propionamide, is a radioiodinatable, heterobifunctional crosslinking agent that contains a sulfhydryl-reactive pyridyl disulfide group on one end and a photosensitive phenyl azide on the other end (Thermo Fisher). Radioiodinatable crosslinkers eliminate the need to radiolabel one of the reacting proteins, thus avoiding potential activity losses due to modification of important residues (Chapter 12, Section 2.5). They also allow radiolabeling of unknown target molecules which interact with the initially modified protein. APDP reacts with sulfhydryl-containing proteins and other molecules to form a reversible disulfide bond. If the crosslinker is radiolabeled prior to conjugation, cleavage of the disulfide group with DTT after crosslinking effectively transfers the iodinated portion to the secondary, photocoupled protein. This radiolabel transfer process allows tracking of a specific receptor or other interacting species after conjugation with its complementary ligand (Figure 6.29). APDP thus falls into the general category of label transfer reagents that can be used to study protein interactions (Chapter 24, Section 3).

APDP
N-[4-*p*-Azidosalicylamido)butyl]-3'-
(2'-pyridyldithio)propionamide
MW 446.55

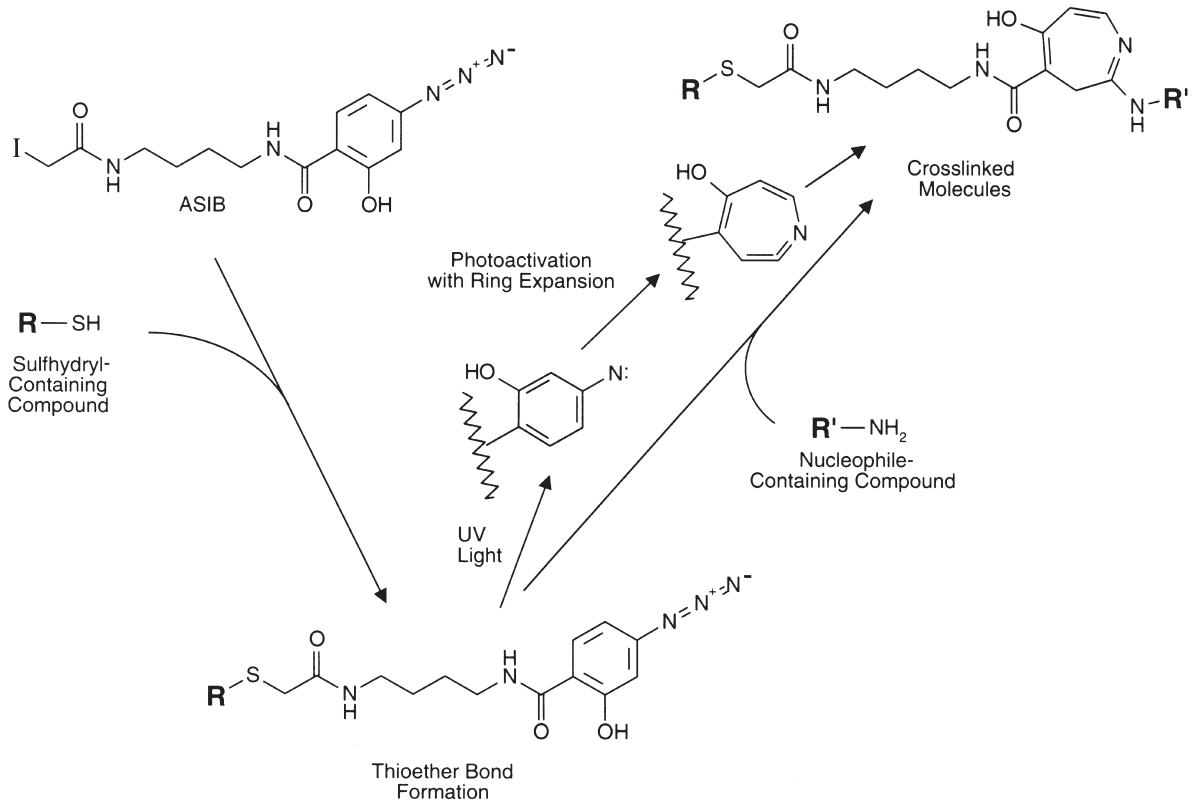

FIGURE 6.28 ASIB can react with sulfhydryl-containing molecules through its iodoacetate group to form thioether linkages. Subsequent exposure to UV light causes a ring-expansion process to occur, creating a highly reactive dehydroazepine intermediate that can couple to amine-containing molecules.

The reactions of APDP are similar to that of the reported compound *N*-(4-azidophenyl)thiophthalimide, a non-radioiodinatable crosslinker (Moreland *et al.*, 1988). Both the phenyl azide group and the pyridyl disulfide portion are stable in aqueous environments prior to the crosslinking reaction. The initial modification with a sulfhydryl-containing protein should be performed protected from light to preserve the activity of the photosensitive group. Avoid, also, in the reaction medium disulfide reducing agents that can react with the pyridyl disulfide group as well as inactivate the phenyl azide portion.

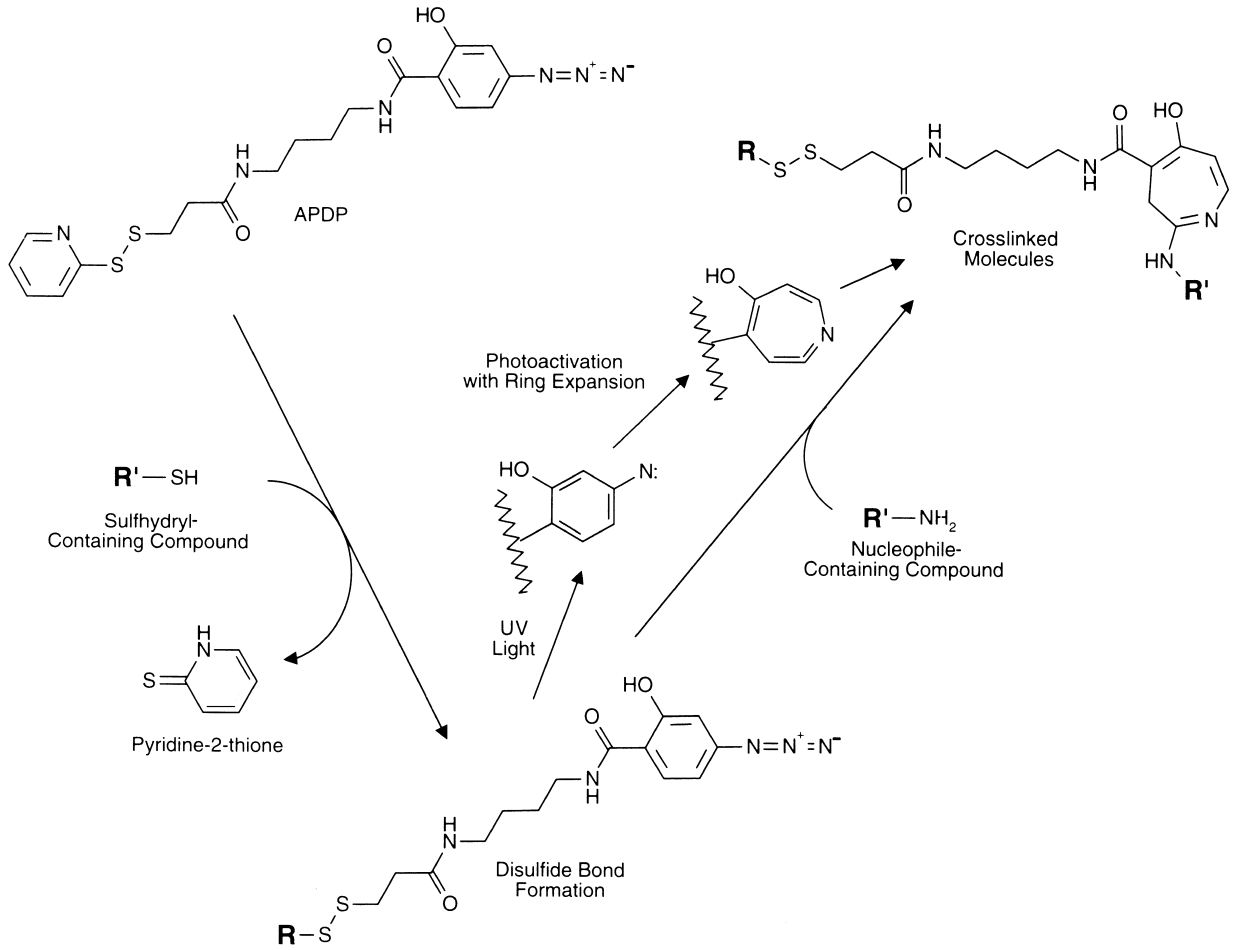
The cross-bridge of APDP provides a long, 21.02-Å spacer that is able to reach distant points between two interacting molecules. Cleavage of the crosslink with a disulfide reducing agent regenerates the original sulfhydryl-modified protein without leaving any other chemical groups behind. The remainder of the crosslinker stays attached to the second, interacting protein.

APDP is soluble in DMSO and DMF, but almost insoluble in acetone or water. Stock solutions may be prepared in DMSO or DMF and a small aliquot added to an aqueous reaction mixture. Do not exceed 10% organic solvent in the buffered reaction. Both functionalities of APDP will react in a variety of salt conditions and pH values. For reaction with a sulfhydryl-containing protein, a buffer at physiological pH containing a chelating agent to protect the free sulfhydryl groups from metal-catalyzed oxidation is recommended (i.e., 0.01- to 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA).

Iodination of the crosslinker may be performed according to the procedures discussed in Chapter 12, Section 2.5, or performed similar to that described for SASD (Section 3.2, this chapter).

4.3. Benzophenone-4-Iodoacetamide

A photoreactive group consisting of a benzophenone residue photolyzes upon exposure to UV light to give a highly reactive triplet-state ketone intermediate (Walling and Gibian, 1965). Similar to the reactive nitrene of photolyzed phenyl azides, the energized electron of an activated benzophenone can insert in active hydrogen–carbon bonds and other reactive groups to give covalent linkages with target molecules. Unlike phenyl azides, however, the decomposition or decay of the photoactivated species does not yield an inactive compound. Instead, benzophenones that have become deactivated without forming a covalent bond can once



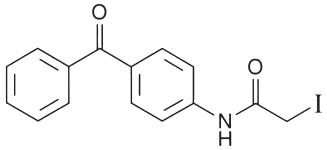


FIGURE 6.29 APDP can modify sulfhydryl-containing compounds through its pyridyl disulfide group to form disulfide bonds. Its phenyl azide end can then be photolyzed with UV light to couple with nucleophiles via a ring expansion process. The disulfide group of the crosslink can be selectively cleaved using DTT.

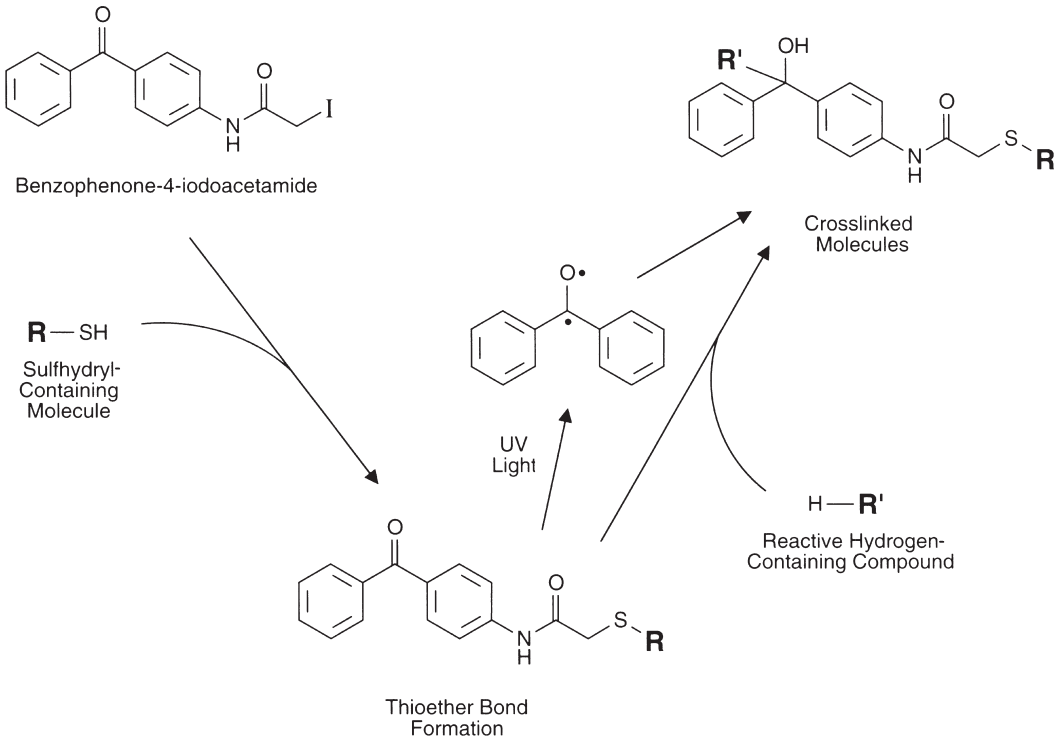
again be photolyzed to an active state. The results of this multiple-activation characteristic are more than one chance to form a crosslink with the intended target and much higher yields of photo-crosslinking.

The heterobifunctional crosslinker benzophenone-4-iodoacetamide is a photoreactive reagent containing a sulfhydryl-reactive iodoacetyl derivative at one end and a benzophenone group on the other end (Invitrogen) (Hall and Yalpani, 1980; Tao *et al.*, 1984; Lu and Wong, 1989). The iodoacetyl group has similar reactivity to the same group on the heterobifunctional reagent SIAB (Section 1.5, this chapter). Under alkaline conditions (pH 8–9), the iodoacetyl reaction is highly specific for sulfhydryl residues in proteins and other molecules, forming stable thioether linkages. The initial modification reaction of sulfhydryl-containing compounds should be performed protected from light to avoid premature photolysis of the benzophenone functionality. Also, avoid thiol-containing reducing agents in the sample, as these will react with the iodoacetyl group. After purification of the benzophenone-modified protein from excess reagent (by dialysis or gel filtration), it is mixed with a sample containing a second target molecule (e.g., a cell lysate) to allow an interaction to take place and then photolyzed with UV light to effect the final crosslink (Figure 6.30). Since repeated photolysis of the benzophenone species is possible, the yield of such conjugation reactions can be significantly higher than using other photoreactive groups. One report indicated that crosslinking with chymotrypsin approached 100% efficiency (Campbell and Gioannini, 1979).

Benzophenone-4-iodoacetamide
MW 365



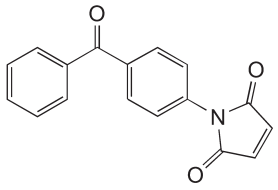


FIGURE 6.30 Benzophenone-4-iodoacetamide reacts with sulfhydryl-containing compounds to give thioether linkages. Subsequent photoactivation of the benzophenone residue gives a highly reactive triplet-state ketone intermediate. The energized electron can insert in active C—H or N—H bonds to give covalent crosslinks.

Benzophenone-4-iodoacetamide is water insoluble and should be pre-dissolved in DMF or another organic solvent prior to adding an aliquot to an aqueous reaction mixture. Stock solutions may be prepared and stored successfully if protected from light.

Benzophenone-4-iodoacetamide has been used to study the 100-kDa U5 snRNP protein (hPrp28p) and its interactions (Ismaili *et al.*, 2001).

4.4. Benzophenone-4-maleimide

Benzophenone-4-maleimide is a heterobifunctional photoreactive crosslinker that has sulfhydryl reactivity similar to benzophenone-4-iodoacetamide discussed in the previous section (Invitrogen). In this case, the sulfhydryl-reactive portion is provided by the presence of a maleimide group that couples to thiols by addition to the double bond (Chapter 3, Section 2.2). The maleimide group is specific for sulfhydryls under physiological conditions, and the reaction results in a thioether linkage that is quite stable. Sulfhydryl-containing proteins or other molecules modified with this reagent may be used in photoaffinity labeling studies to investigate the specific interactions between two molecules. After mixing a modified protein with a sample, the solution may be photolyzed to create a covalent crosslink between any interacting species. UV photolysis of the benzophenone group results in a highly reactive triplet-state intermediate which can rapidly insert or add to organic components within van der Waals distance (Figure 6.31). Decay of the active-state intermediate returns the photosensitive group to its original chemical form, thus allowing repeated photoactivations without losing the potential for coupling to its intended target.

Benzophenone-4-maleimide is water insoluble and should be pre-dissolved in DMF or another organic solvent prior to adding an aliquot to an aqueous reaction mixture. Stock solutions may be prepared and stored successfully if protected from light. The hydrophobicity

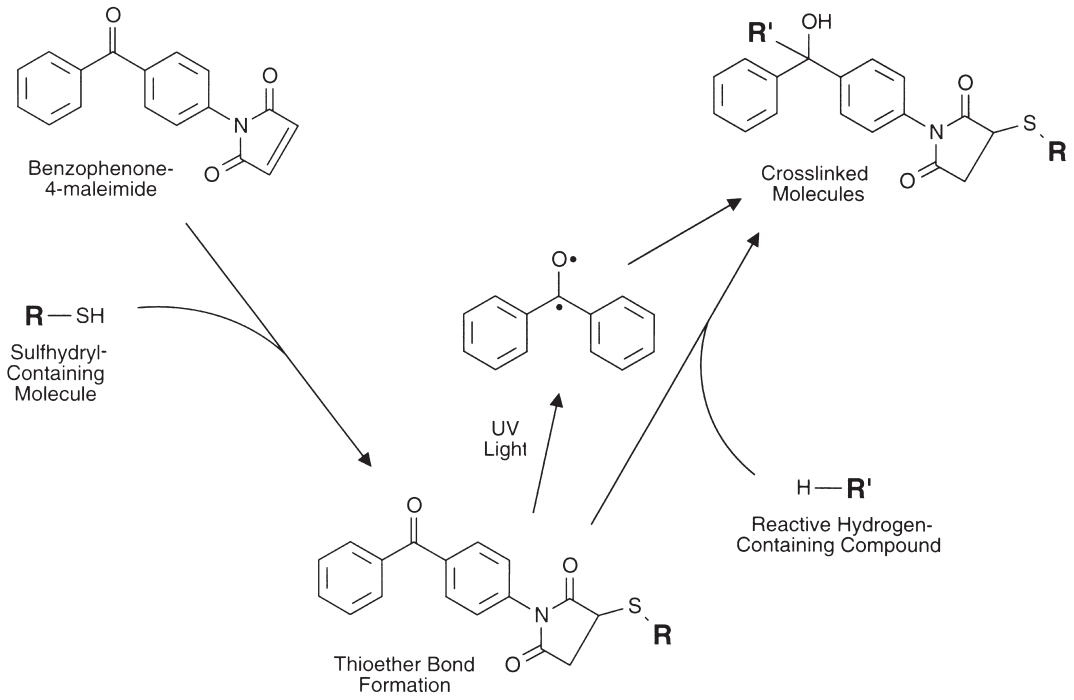

FIGURE 6.31 Benzophenone-4-maleimide can couple to thiol-containing molecules to form stable thioether bonds. Exposure of the benzophenone group to UV light causes transition to a triplet-state ketone of high reactivity for insertion into C—H or N—H bonds.

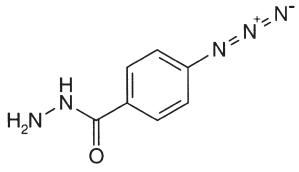

and bulkiness of the benzophenone group may cause insolubility problems in the initial protein that is modified if the derivatization is carried out at too high a level. Fortunately, the use of a sulfhydryl-reactive reagent can limit the degree of derivatization, since thiol groups usually are present in lower quantities and in more discrete locations than amines.

5. CARBONYL-REACTIVE AND PHOTOREACTIVE CROSSLINKERS

Crosslinking reagents containing a photoreactive group on one end and a carbonyl-reactive group on the other end are rare. The use of an amine group on one end of a photosensitive heterobifunctional reagent has been described (Drafler and Marinetti, 1977; Das and Fox, 1979; Gorman and Folk, 1980), but the presence of a hydrazide is required for spontaneous reactivity toward carbonyls. The following compound is the only commercially available reagent containing a phenyl azide photoreactive group and a hydrazide functional group.

5.1. ABH

ABH, *p*-azidobenzoyl hydrazide, is a small, heterobifunctional crosslinker containing a photoreactive phenyl azide group on one end and a hydrazide functionality on the other end (Thermo Fisher). The hydrazide can react with carbohydrate-containing molecules after oxidation with sodium periodate (Chapter 2, Section 4.4) to create aldehyde residues. The reaction forms a hydrazone linkage. Thus, glycoproteins may be specifically labeled on their polysaccharide chains for subsequent investigation of their interaction with receptor molecules (Figure 6.32). In this sense, lectin–carbohydrate interactions may be studied through direct modification of the sugar groups at or adjacent to the binding site. Other amine- or sulfhydryl-reactive probes may not be suitable for such studies due to the lack of amine or sulfhydryl groups near enough to a polysaccharide structure.

ABH
p-Azidobenzoyl hydrazide
MW 177.17
11.9 Å

The cross-bridge of ABH consists of a benzoic acid derivative and thus provides a short spacer between conjugated molecules. After ABH modification of a glycoprotein and incubation with a potential target

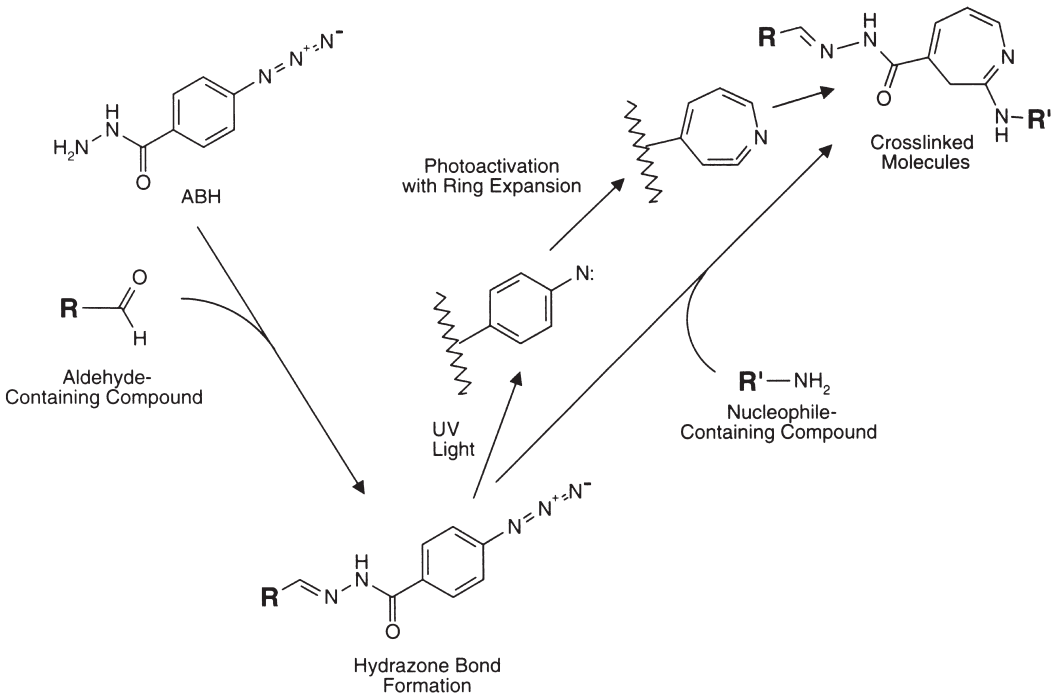

FIGURE 6.32 ABH reacts with aldehyde-containing compounds through its hydrazide end to form hydrazone linkages. Glycoconjugates may be labeled by this reaction after oxidation with sodium periodate to form aldehyde groups. Subsequent photoactivation with UV light causes transformation of the phenyl azide to a nitrene. The nitrene undergoes rapid ring expansion to a dehydroazepine that can couple to nucleophiles, such as amines.

molecule, the solution may be photolyzed with UV light to initiate the final crosslink. Prior to photolysis, the reagent and all modified species should be protected from light to prevent degradation of the phenyl azide group.

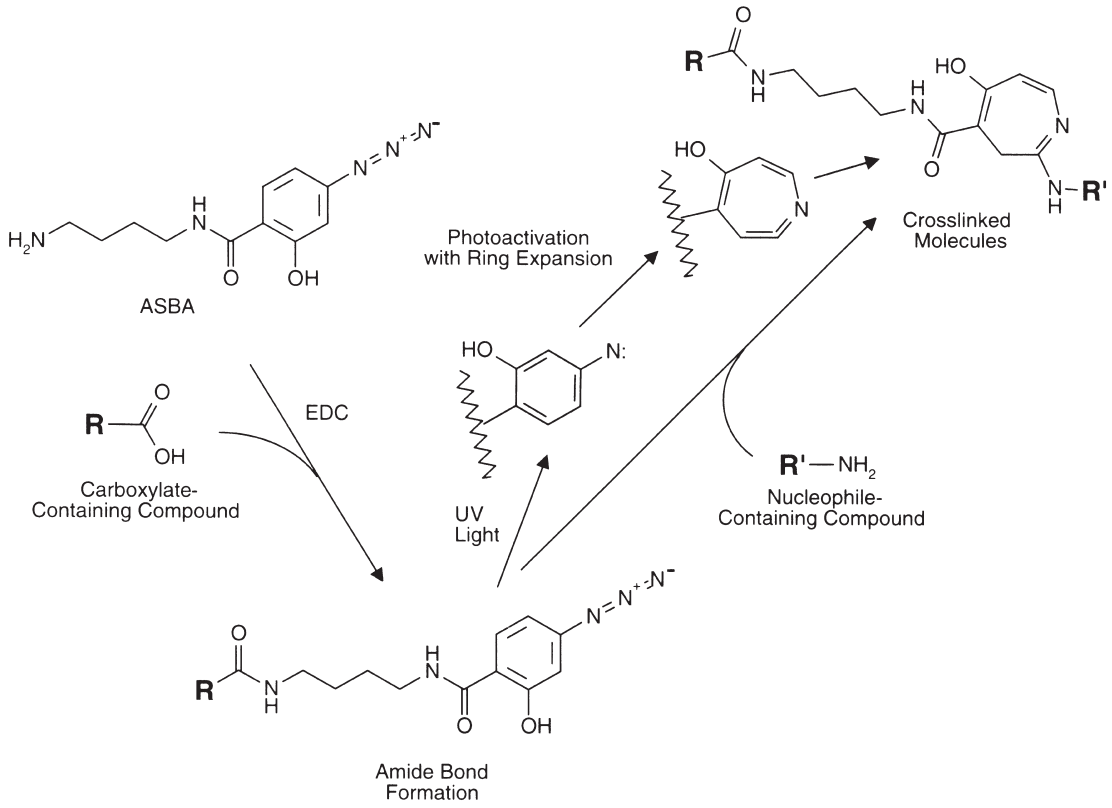
ABH is relatively insoluble when directly added to water or buffer, and therefore it should be pre-dissolved in DMSO prior to addition of an aliquot to an aqueous reaction medium. Stock solutions at a concentration of 50-m*M* ABH in DMSO work well. Since both reactive groups on ABH are stable in aqueous environments as long as the solution is protected from light, a secondary stock solution may be made from the initial organic preparation by adding an aliquot to the hydrazide reaction buffer (0.1-*M* sodium acetate, pH 5.5) (O'Shannessy and Quarles, 1985; O'Shannessy *et al.*, 1984). Make a 1:10 dilution of the ABH/DMSO solution in the reaction buffer. This solution may be stored in the dark at 4°C without decomposition.

6. CARBOXYLATE-REACTIVE AND PHOTOREACTIVE CROSSLINKERS

A carboxylate-reactive crosslinking compound typically contains a primary amine functional group that can be coupled to a carboxylic acid group in a protein or other molecule through the use of a suitable activating agent, such as a carbodiimide. The carbodiimide forms an active ester intermediate that then reacts with the amine to create an amide bond (Chapter 4, Section 1). Reported use of diazoalkyl derivatives that spontaneously react with carboxylates have been tried with fluorescent probes, but not yet applied to heterobifunctional crosslinking agents (DeMar *et al.*, 1992; Schneede and Ueland, 1992) (Chapter 3, Section 3.1). The following heterobifunctional reagent is the only carboxylate-reactive photosensitive crosslinker currently available commercially.

6.1. ASBA

ASBA, 4-(*p*-azidosalicylamido)butylamine, is a carboxylate-reactive crosslinking agent containing a primary amine on one end and a photosensitive phenyl azide group on the other (Thermo Fisher). The crosslinker is not spontaneously reactive with carboxylates, but must be used with another activating agent that facilitates bond formation. For instance, it can be used in conjunction with a carbodiimide or other such reagent system that can initiate covalent bond formation with a carboxylic acid. A water soluble carbodiimide like EDC (Chapter 4, Section 1.1) is able to activate the carboxylates on a target molecule, forming active ester



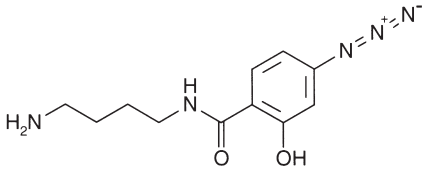


FIGURE 6.33 ASBA contains a primary amine group that may be conjugated to carboxylate compounds using the carbodiimide EDC. Subsequent exposure to UV light initiates the photoreaction leading to covalent crosslinks.

intermediates (Figure 6.33). In the presence of ASBA, derivatization will occur, resulting in amide bond formation and thus leading to modification of the carboxylate-containing molecule with a photoreactive group.

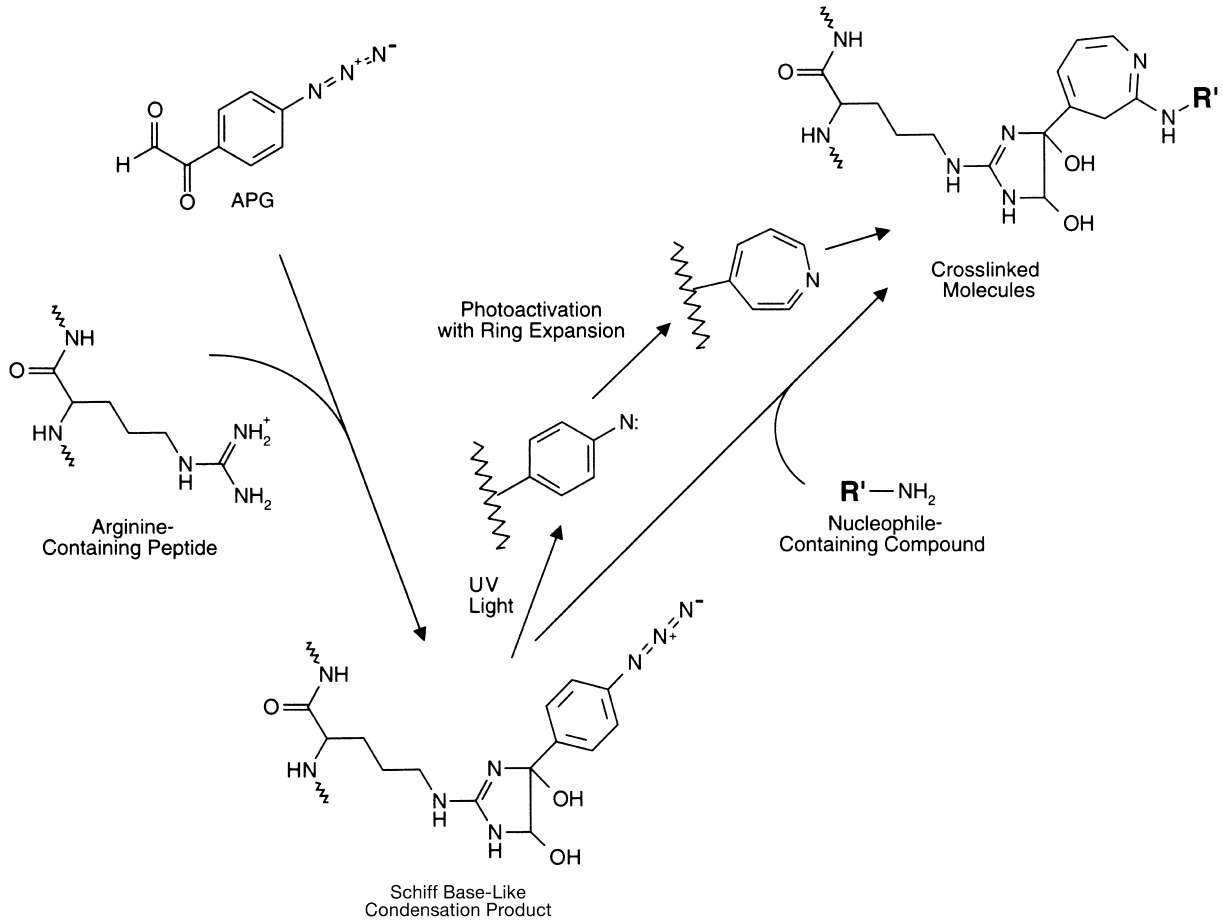
ASBA
4-(*p*-Azidosalicylamido)
butylamine
MW 249.27
16.3 Å

The cross-bridge of ASBA provides a reasonably long spacer (16.3 Å). The phenyl azide portion is constructed from a salicylic acid derivative and thus possesses a ring-activating hydroxyl group. The presence of this group allows radioiodination of the ring prior to crosslinking (Chapter 12, Section 2.5). Before the photolyzing step is initiated, the reagent should be handled in the dark or protected from light to avoid decomposition of the phenyl azide group.

ASBA has been used to identify parasite adhesive proteins (Gowda *et al.*, 2007), for active site-directed labeling of glucosidase I (Romaniouk *et al.*, 2004), and to study interactions with the proteasome (Qureshi *et al.*, 2003).

7. ARGININE-REACTIVE AND PHOTOREACTIVE CROSSLINKERS

The guanidinyl group on arginine's side chain can be specifically targeted by the use of 1,2-dicarbonyl reagents, such as the diketone group of glyoxal (Chapter 3, Section 5.2). Under alkaline conditions, this type of group can condense with the guanidinyl residue to form a Schiff base-like complex. The presence of other chemical compounds in the reaction can cause further structural rearrangements, such as stabilization by boronate (Pathy and Smith, 1975). Derivatives such as phenylglyoxal and *p*-nitrophenylglyoxal can be used to block or quantitatively determine the amount of arginine in a protein (Yamasaki *et al.*, 1981). Studies have shown that if the reaction is performed with a 2:1 ratio of glyoxal compound to arginine residues, then the modification that



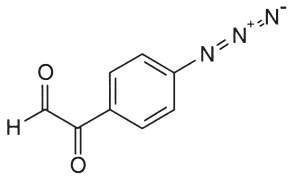


FIGURE 6.34 APG can be used to label specific arginine residues in proteins, producing stable, cyclic Schiff base-like bonds with the side-chain guanidino groups. Photoactivation with UV light then causes ring expansion of the phenyl azide group, initiating covalent bond formation with amines.

results is reversible (Takahashi, 1968). However, if the modification is performed at a 1:1 stoichiometry, then it is irreversible (Konishi and Fujioka, 1987).

The ability to direct conjugation or modification specifically through arginine residues using this chemistry has been exploited in the availability of the only photoreactive glyoxal derivative, APG.

7.1. APG

APG, *p*-azidophenyl glyoxal, is a heterobifunctional crosslinker containing an arginine-specific diketone group on one end and a photosensitive phenyl azide group on the other end (Thermo Fisher). The reagent is a derivative of phenylglyoxal, a compound long used as an arginine guanidinyl modifier. Reaction of APG with proteins at pH 7 to 8 results in selective modification of arginine, leaving photoreactive groups available for subsequent crosslinking with interacting molecules (Figure 6.34). Exposure to UV light effects the final crosslink. The cross-bridge of an APG crosslink is only 9.3 Å in length, allowing proximity interactions to be studied or the irreversible labeling of arginine areas in proteins.

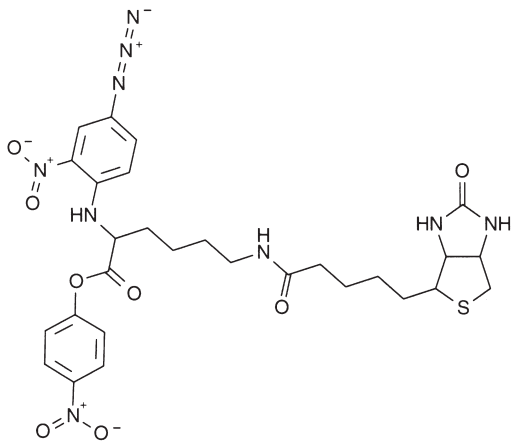
APG
p-Azidophenyl glyoxal
MW 193.16
(as the monohydrate)
9.3 Å

APG has been used to investigate the binding step in collagen phagocytosis (Chong *et al.*, 2007); to inhibit bovine heart lactic dehydrogenase, egg white lysozyme, horse liver alcohol dehydrogenase, and yeast alcohol dehydrogenase (Ngo *et al.*, 1981); to crosslink RNA–protein interactions in *E. coli* ribosomes (Politz *et al.*, 1981), and to identify regions of brome mosaic virus coat protein chemically crosslinked *in situ* to viral RNA (Sgro *et al.*, 1986).

CHAPTER

7

Trifunctional Crosslinkers



Trifunctional crosslinkers represent a relatively small but important category of bioconjugation reagents, possessing three different reactive or complexing groups per molecule. The design of this type of reagent is more elaborate than multifunctional crosslinkers built off polymers such as polyaldehyde dextran (Chapter 18, Section 2.2) or small organic molecules like trichloro-*s*-triazine (Chapter 18, Section 2.1) which merely contain more than two groups of the same functionality per molecule. The trifunctional approach incorporates elements of the heterobifunctional concept wherein two ends of the linker contain reactive groups able to couple with two different functional groups on target molecules. A trifunctional reagent, however, has a third arm terminating in yet another group able to specifically link to a third chemical or biological target.

A convenient molecule from which to build trifunctionals is the amino acid, L-lysine. Its three functional groups, α-carboxy, α-amino, and ε-amino, can be derivatized independently to contain three arms. Each arm can be designed to terminate in a complexing group able to participate in a particular type of conjugation reaction or affinity interaction.

The initial attempts at producing trifunctional reagents used biocytin as the core compound. Biocytin is the lysine derivative of biotin having its valeric acid side chain amide-bonded to the ε-amino group of the amino acid (Chapter 11, Section 6.2). Thus, crosslinkers built on this compound have one of their trifunctional arms ending in a biotin label which is able to specifically complex with avidin or streptavidin probes. The creation of two additional reactive arms from the α-carboxy and α-amino groups of biocytin results in the completed trifunctional. The following two crosslinkers are examples of this approach.

1. 4-AZIDO-2-NITROPHENYLBIOCYTIN-4-NITROPHENYL ESTER

Wedekind *et al*. (1989) designed a trifunctional reagent for studying the hormone binding site of the insulin receptor. The crosslinker, 4-azido-2-nitrophenylbiocytin-4-nitrophenyl ester (ABNP) contains a nitrophenyl ester group that can react with amine functions in proteins and peptides, similar to the reaction of *N*-hydroxysuccinimide (NHS) esters with amines (Chapter 3, Section 1.4). This group can be used to modify a ligand (such as insulin) prior to its binding to a specific receptor molecule. The second chemically reactive functional group on ABNP is a photosensitive phenyl azide group capable of being activated by exposure to UV light. After the labeled ligand is allowed to interact with its receptor, forming an interaction complex, the mixture is photolyzed to effect a covalent attachment point (Figure 7.1). The third arm of the trifunctional reagent is the biotin handle (from biocytin). This component allows the complex to be purified by affinity chromatography on immobilized avidin or immobilized streptavidin (Chapter 15, Section 2.5). Alternatively, the biotin group can be used to visualize the binding of the ligand to its receptor using labeled avidin or streptavidin reagents (Chapter 11, Sections 1–5).

4-Azido-2-nitrophenylbiocytin-4-nitrophenyl ester

ABNP is soluble in dimethylformamide (DMF) but insoluble directly in aqueous solution. Insulin

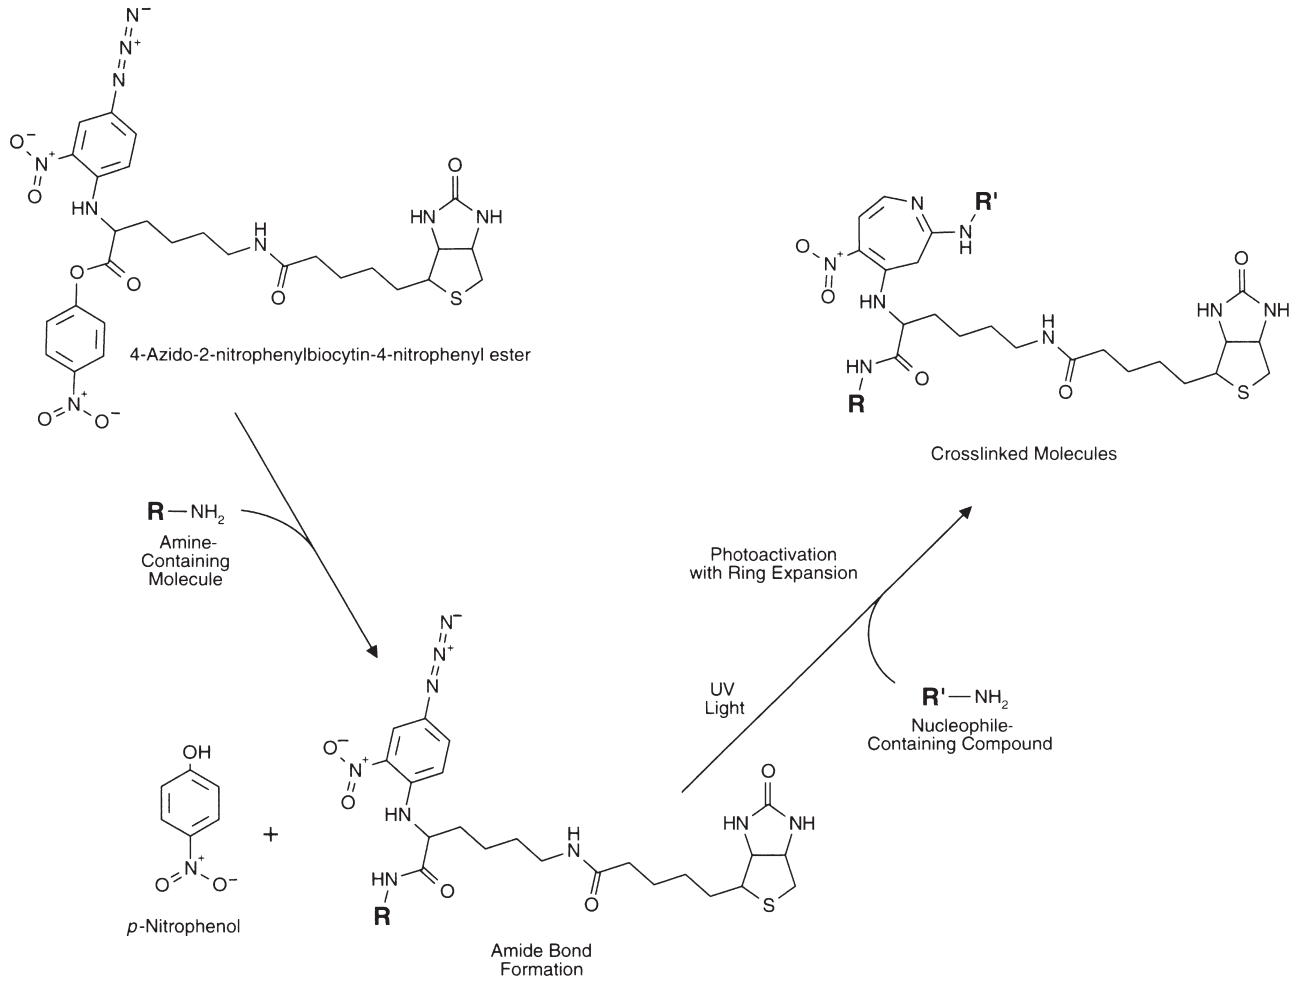

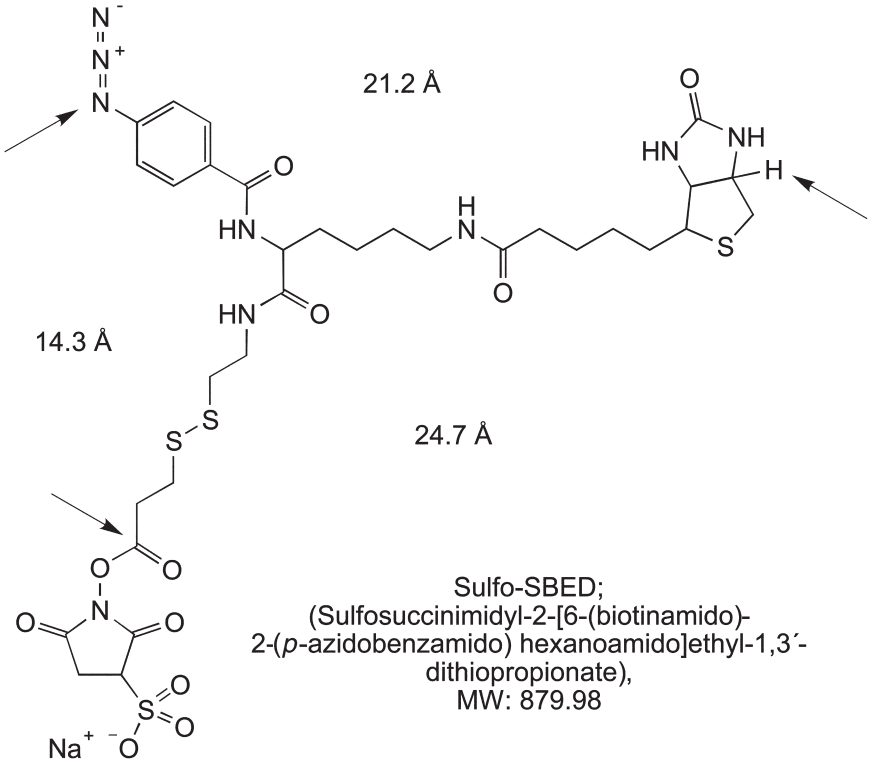

FIGURE 7.1 The Wedekind trifunctional crosslinker can react with amine groups via its *p*-nitrophenyl ester to form amide bond linkages. The phenyl azide group then can be photoactivated with UV light to generate covalent bond formation with a second molecule. The biotin side chain provides binding capability with avidin or streptavidin probes.

labeling was done in DMF:water at a ratio of 9:1. For molecules not soluble in organic solvent, such as proteins, the trifunctional may first be dissolved in DMF and a small aliquot added to an aqueous reaction medium. The nitrophenyl ester reactive group can be coupled to amine groups at alkaline pH (7–9) and in buffers containing no extraneous amines (avoid Tris). Unfortunately, ABNP is not commercially available at the time of this writing.

2. SULFO-SBED

Another trifunctional crosslinking agent is sulfo-SBED or sulfosuccinimidyl-2-[6-(biotinamido)-2- (*p*-azidobenzamido) hexanoamido]ethyl-1,3′-dithiopropionate, developed by Ed Fujimoto at Pierce Chemical (now Thermo Fisher). Similar to ABNP discussed previously, sulfo-SBED is built on a biocytin backbone. Thus, one arm of the trifunctional compound consists of a biotin handle that can be used for purification or detection purposes using avidin or streptavidin probes. The chemically reactive groups of sulfo-SBED include a sulfo-NHS ester and a phenyl azide group. The sulfo-NHS ester provides amine-coupling capability, forming amide bond linkages with target molecules (Chapter 3, Section 1.4). The phenyl azide is photosensitive and may be activated by exposure to UV light at wavelengths >300 nm. Most phenyl azides react by ring expansion to dehydroazepines with subsequent reactivity toward nucleophiles, especially amines (Chapter 3, Section 7.1) (Figure 7.2).

Sulfo-SBED;
(Sulfosuccinimidyl-2-[6-(biotinamido)-
2-(*p*-azidobenzamido) hexanoamido]ethyl-1,3´-
dithiopropionate),
MW: 879.98

The sulfo-NHS ester of sulfo-SBED is negatively charged and provides a degree of water solubility (about 5-m*M* maximum concentration) for the entire molecule. Limited water solubility is all that can be expected due to the large size of the trifunctional, most of it consisting of relatively hydrophobic structures. However, the reagent is much more soluble in organic solvents such as DMF (170 m*M*) and dimethyl sulfoxide (DMSO) (125 m*M*). Concentrated stock solutions may be prepared in these solvents prior to addition of a small aliquot to an aqueous reaction mixture.

Since the active ester end of the molecule is subject to hydrolysis (half-life of about 20 min in phosphate buffer at room temperature conditions), it should be coupled to an amine-containing protein or other molecule before the photolysis reaction is carried out. During the initial coupling procedure, the solutions should be protected from light to avoid decomposition of the phenyl azide group. The degree of derivatization should be limited to no more than a 5- to 20-fold molar excess of sulfo-SBED over the quantity of protein present to prevent possible precipitation of the modified molecules. For a particular protein, studies may have to be done to determine the optimal level of modification.

An additional feature of sulfo-SBED is the presence of a cleavable disulfide group in the cross-bridge of the NHS ester arm of the molecule. After a conjugation reaction has taken place, the complexes first may be purified using immobilized avidin or immobilized streptavidin and then the conjugates released by treatment with a disulfide reducing agent. This allows analysis of the complexed molecules, for example, after the binding of a ligand to its receptor. Alternatively, the disulfide group may be cleaved after interaction and capture of unknown proteins, thus transferring the biotin label to the prey protein. The unknown interacting protein may then be detected or purified using the biotin tag. Such label transfer procedures are important options for studying protein–protein interactions (Chapter 24).

Since sulfo-SBED has three functional arms, the length of each portion should be considered when doing conjugation studies involving interacting proteins. The biotin handle has an effective length of 19.1 Å, including the side-chain length for the lysine component. The sulfo-NHS ester arm is approximately 13.7 Å long, measuring from the same point in the lysine group. The phenyl azide arm is the shortest, only 9.1 Å long. The structure for sulfo-SBED shown in this section includes molecular distance measurements somewhat different from these numbers in that the total distances between the three arms are given, which reflects the intramolecular distances between the terminal reactive groups or interacting group on biotin (indicated by the arrows).

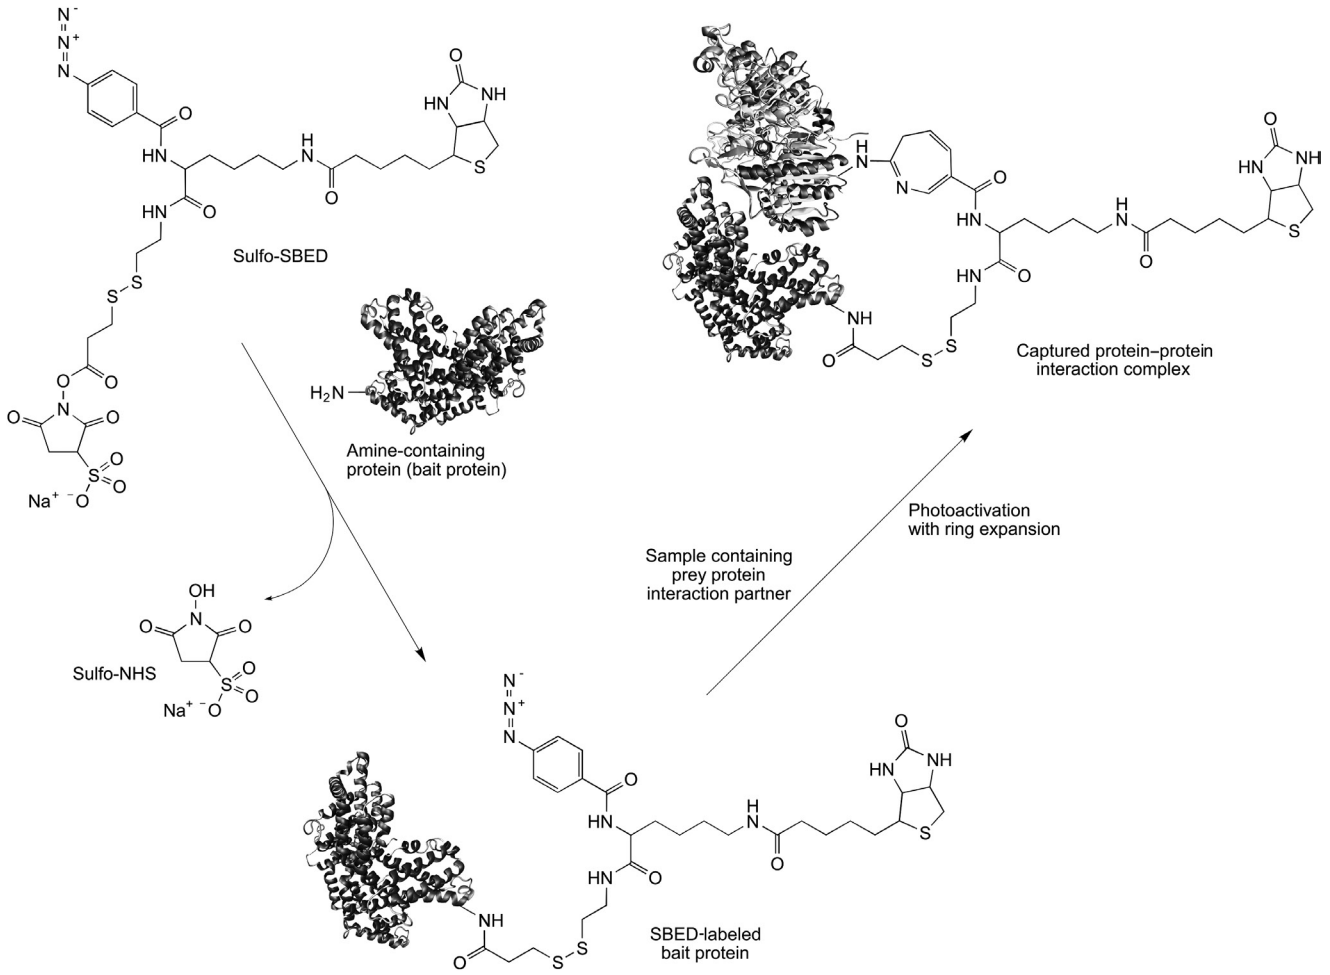

FIGURE 7.2 The trifunctional reagent sulfo-SBED reacts with amine-containing bait proteins via its NHS ester side chain. Subsequent interaction with a protein sample and exposure to UV light can cause crosslink formation with a second interacting protein. The biotin portion provides purification or labeling capability using avidin or streptavidin reagents. The disulfide bond on the NHS ester arm provides cleavability using disulfide reductants, which effectively transfers the biotin label to an unknown interacting protein.

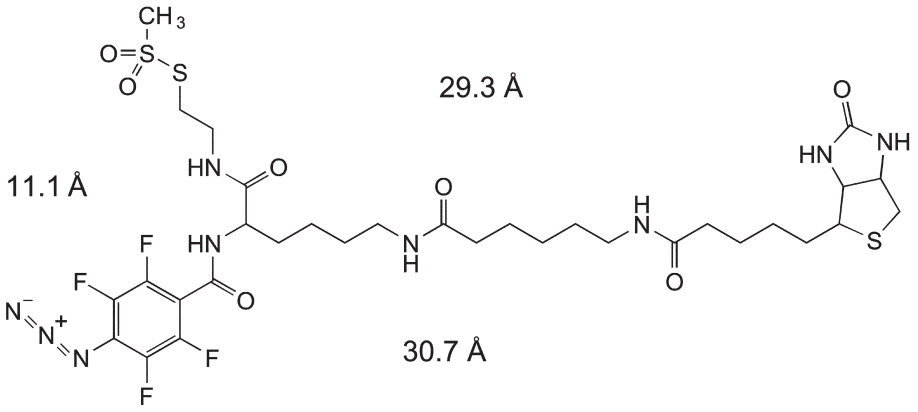
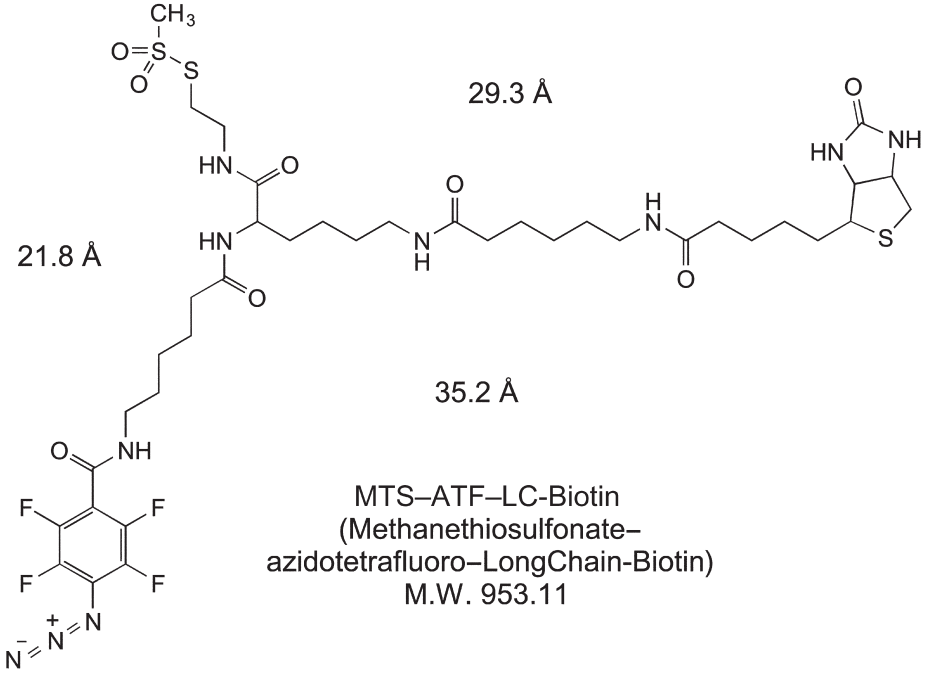
Sulfo-SBED has been used to confirm the interaction between human frataxin and the scaffold protein ISU with mass spec detection (Watson *et al.*, 2012), to investigate the binding of receptor tyrosine kinase TrkB to the neural cell adhesion molecule (NCAM) (Cassens *et al.*, 2010), and in a host of other applications designed to identify protein interactions (see Chapter 24, Section 3.1, for additional information on the use of sulfo-SBED in capturing interacting partners).

The following suggested protocol was developed by Barb Olson at Thermo Fisher for the labeling of soybean trypsin inhibitor with its subsequent complexation with trypsin. Modifications to this procedure may have to be done to study other proteins.



Protocol

1. Dissolve 5 mg of soybean trypsin inhibitor (STI) in 0.5 ml 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
2. In a fume hood, dissolve 1.12 mg of sulfo-SBED in 25 µl of DMSO. Prepare fresh and protect from light.
3. Add 11 µl of the sulfo-SBED solution to the STI solution. Mix well.
4. React for 30 min at room temperature or for 2 h at 4°C.
5. If some precipitation occurs, clarify the solution by centrifugation using a microfuge. Remove excess reactant by gel filtration using a desalting resin.
6. Mix the purified sulfo-SBED-modified STI with 5 mg of trypsin dissolved in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.
7. Incubate at room temperature for 3.5 min to allow the specific binding of the two molecules to occur.
8. Photolyze the solution with long UV light (about 365 nm) at a distance of about 5 cm for 15 min. This process may be done with the solution on ice to prevent heating of the sample.



Isolation of complexed molecules may be done by affinity chromatography using a column of immobilized avidin or immobilized streptavidin. Cleavage of the disulfide bond of the crosslinker may be done by treatment with 50-m*M* dithiothreitol (DTT). For additional information on the use of sulfo-SBED in the study of protein interactions, see Chapter 24, Section 3.1.

3. MTS–ATF–BIOTIN AND MTS–ATF–LC-BIOTIN

MTS–ATF–Biotin and MTS–ATF–LC-Biotin are trifunctional crosslinkers similar in design to sulfo-SBED discussed previously, but in addition to the biotin handle, they contain a thiol-reactive group and an enhanced photoreactive, perfluorinated phenyl azide group. The two reagents differ only in the length of the cross-bridge in the photoreactive arm, with the LC version containing an extended aminocaproyl spacer. Relative to the spacing possible between the reactive groups on these compounds, the LC version therefore provides nearly twice the maximal molecular distance over its shorter analog (21.8 Å *versus* 11.1 Å). Thus, interacting proteins may be captured through use of either a long or short crosslink, depending on the optimal distances between the proteins—or at least to the nearest thiol on the bait protein.

MTS–ATF–Biotin
(Methanethiosulfonate–
azidotetrafluoro–Biotin)
M.W. 839.95

MTS–ATF–LC-Biotin
(Methanethiosulfonate–
azidotetrafluoro–LongChain-Biotin)
M.W. 953.11

Both MTS–ATF–Biotin and MTS–ATF–LC-Biotin contain a methanethiolsulfonate group (MTS) on one arm, which is able to couple with thiols. This reaction proceeds with loss of the methyl sulfonate leaving group (sulfinic acid) and forms a disulfide linkage (Figure 7.3). Unlike a pyridyl disulfide group, however, which also reacts with thiols to form disulfide linkages, the MTS group is unstable to hydrolysis in aqueous solution,

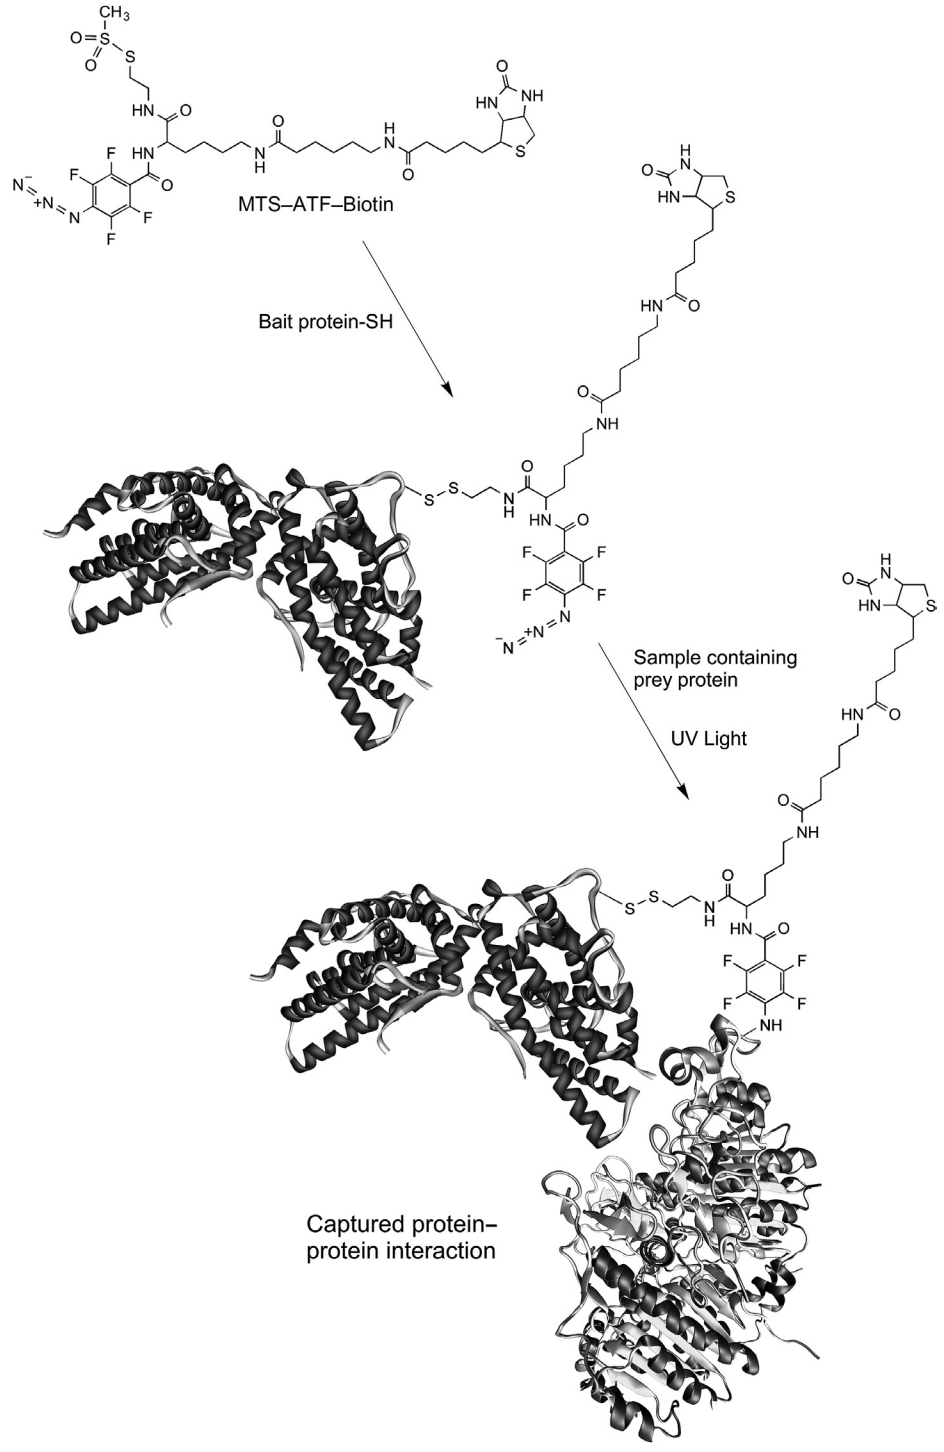


FIGURE 7.3 Mts–Atf–Biotin can be used to label bait proteins at available thiol groups using the methanethiolsulfonate group, which forms a disulfide linkage after reaction. The modified protein is then allowed to interact with a protein sample and photoactivated with UV light to cause a covalent crosslink with any interacting proteins. Cleavage of the disulfide bond effectively transfers the biotin label to the unknown interacting protein.

especially if other strong nucleophiles are present. Therefore, most MTS compounds dissolved or brought into PBS buffer at physiological pH will hydrolyze with a half-life on the order of 10 to 15 min. However, they also have very rapid reactivity with thiols (Stauffer and Karlin, 1994; Holmgren *et al*., 1996; Liu *et al*., 1996). The reaction of an MTS group with a thiol on a bait protein can take place with high yields in just a matter of minutes. Both of these trifunctional label transfer compounds are hydrophobic, so their MTS reactivity in the aqueous phase may be somewhat slower than corresponding hydrophilic MTS reagents.

For use in studying protein interactions, these compounds are first reacted with a thiol on a purified bait protein to form a disulfide bond. Since the reagents are water insoluble, they must be dissolved in an organic solvent such as DMF or DMSO and then an aliquot added to the bait protein in an aqueous buffer to initiate the reaction. Once modified, the biotinylated bait protein is then incubated with a sample containing potentially interactive prey proteins. After an incubation period, initiating the photoreaction by exposure to UV irradiation captures the interacting proteins. Any interaction complexes thus formed can be isolated or detected using the biotin handle. In addition, the disulfide bond formed with the bait protein during the crosslinking reaction can be reduced to cleave the conjugates and transfer the biotin label to the unknown interacting prey proteins. This is a powerful way of labeling unknown interacting proteins for subsequent analysis.

MTS–ATF–Biotin and MTS–ATF–LC-Biotin have been used to investigate protein interactions involving the SufBCD Fe-S scaffold complex binding with SufA for Fe-S cluster transfer (Chahal *et al*., 2009), in the characterization of carriers and receptors of the Lewis^X glycan (Katagihallimath, 2008), and for study of the piccolo NuA4 catalyzed acetylation of nucleosomal histones (Huang and Tan, 2012). A protocol for the use of these compounds in the study of protein interactions can be found in Chapter 24, Section 3.2.

4. HYDROXYMETHYL PHOSPHINE DERIVATIVES

Although phosphine compounds are often used as disulfide reducing agents in bioconjugate chemistry (Chapter 2, Section 4.1), there are classes of organo-phosphine reagents containing three hydroxymethyl groups that can act as trifunctional bioconjugation agents for coupling or crosslinking purposes. Tris(hydroxymethyl) phosphine (THP) and β-[tris(hydroxymethyl)phosphino] propionic acid (THPP) (Thermo Fisher) are small trifunctional compounds that spontaneously react with nucleophiles, such as amines, to form covalent linkages (Henderson *et al*., 1994; Katti, 1996; Katti *et al*., 1999). Nucleophiles react with the hydroxymethyl arms by attack on the electron-deficient carbon atom with loss of water to form secondary or tertiary amine bonds (Figure 7.4).

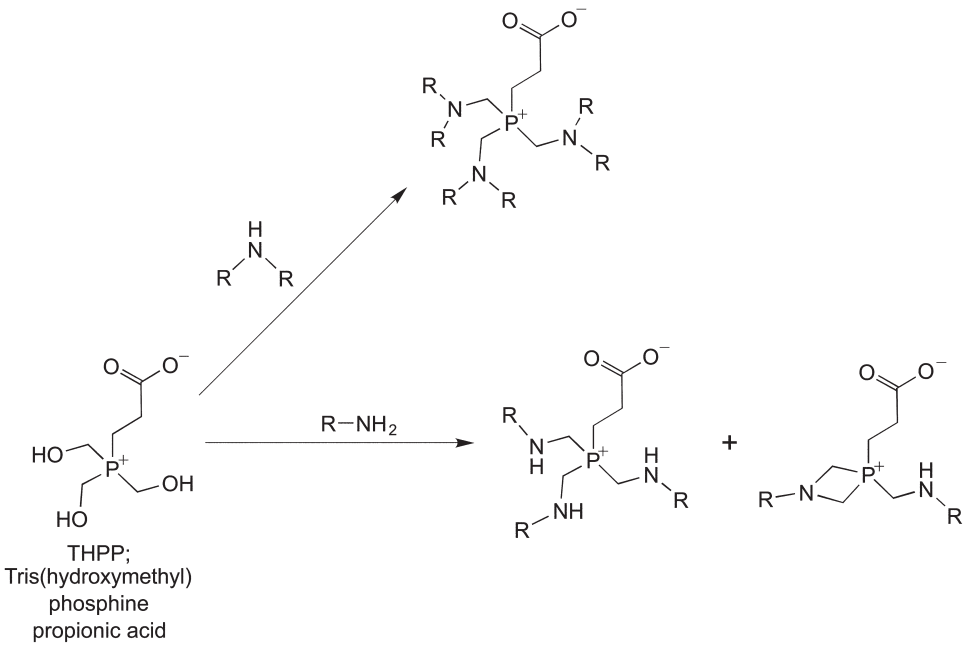

FIGURE 7.4 THPP reacts with amine-containing molecules to form secondary or tertiary amine bonds.

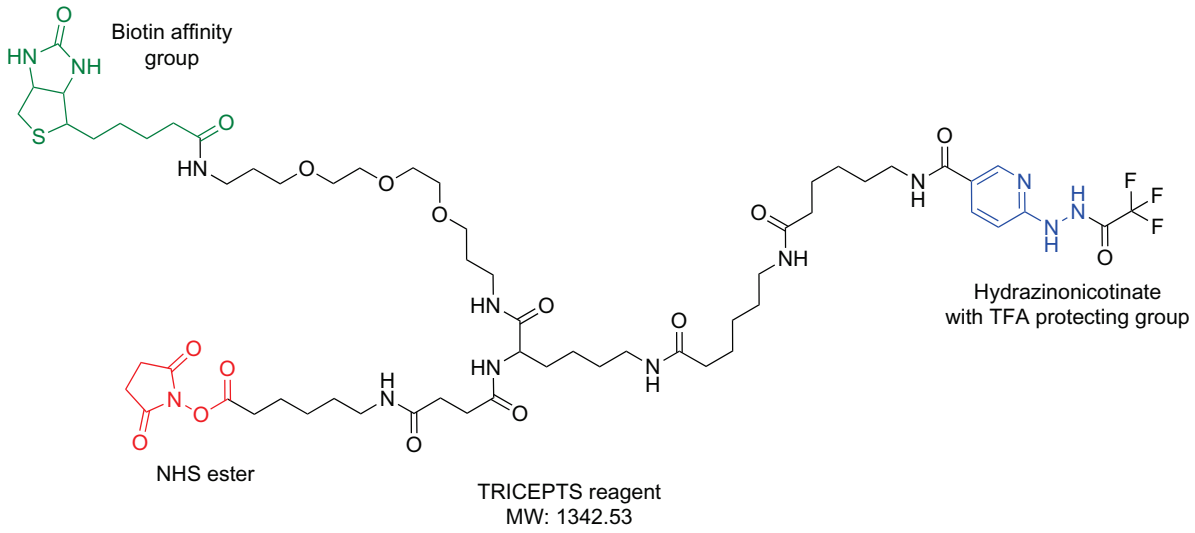

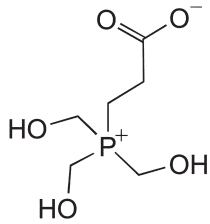

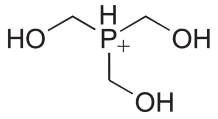

FIGURE 7.5 The TRICEPTS reagent contains an amine-reactive NHS ester to couple with a ligand that can interact with a cell surface receptor. The hydrazinonicotinate end of the compound is able to form hydrazone bonds with glycans on these receptors if the carbohydrate has been previously oxidized with sodium periodate to form aldehyde residues. The trifluoroacetyl protecting group on the hydrazine spontaneously hydrolyzes off during this reaction. Thus, receptors that are able to bind to the labeled ligand become permanently labeled with the TRICEPTS reagent and now contain a biotin affinity handle for detection or purification purposes. Receptors so labeled can be detected using streptavidin conjugates or enriched on immobilized streptavidin columns and analyzed by mass spectrometry.

THPP;
Tris(hydroxymethyl)
phosphine propionic acid

THP;
Tris(hydroxymethyl)
phosphine

THP has also been used as a reducing agent in organic synthesis for some time and it is able to form coordination complexes with metals to create potent hydrogenation catalysts (James and Lorenzini, 2010). Both THP and THPP are stable in aqueous solution, as the only potential product of hydrolysis is the reformation of the hydroxymethyl groups. It is unusual for an amine-reactive functional group to have long-term stability in water or buffer, which makes these reagents uniquely suitable for creating reactive surfaces or reactive molecules for subsequent conjugation with proteins or other amine-containing compounds. Hydroxylic chromatographic supports have also been activated with hydroxymethyl phosphine derivatives for immobilization of enzymes (Petach *et al*., 1994).

Hydroxymethyl phosphines are susceptible to oxidation to form the phosphine oxide. Therefore, avoid excess oxygen, oxidizing agents, or azide compounds, which react with phosphines in the Staudinger reaction (Chapter 17, Section 6). In addition, metallic surfaces can be modified via the phosphine group to result in hydroxymethyl group substitutions.

5. TRICEPTS REAGENT

Frei *et al*. (2012) reported on a new trifunctional crosslinker design, which they termed TRICEPTS, a descriptive name that depicts its three arms capable of binding three different components (Figure 7.5). Similar in design to the trifunctional reagents described previously in Sections 1 to 3, this compound was specifically constructed to capture interacting molecules associated with receptor–ligand binding events. One arm of this reagent contains a terminal NHS ester group that can be used to label a protein or ligand that interacts with a receptor through the formation of an amide linkage. A second arm of the compound contains a trifluoroacetyl-protected hydrazine group that is capable of binding to glycans on cell surface receptors after they have been treated by mild oxidation with sodium periodate to produce aldehydes (Chapter 2, Section 4.4). The hydrazine group can spontaneously form a hydrazone linkage with an aldehyde on these glycoproteins, thus locking the ligand to its receptor after the interaction has occurred. The third arm of the TRICEPTS

compound contains a long biotin affinity group that can then be used to detect or isolate the interacting ligand–receptor complexes using streptavidin conjugates or immobilized streptavidin.

The TRICEPTS reagent was used to successfully detect interactions between ligands and receptors using labeled insulin, transferrin, apelin, and epidermal growth factor (EGF), as well as therapeutic antibodies able to interact with receptors on tumor cells. Fluorescently labeled streptavidin could be used to detect the crosslinked complex on cell surfaces. In addition, the complexes captured on immobilized streptavidin could be analyzed by mass spec to determine the identities of the receptors being bound.

CHAPTER

8

Dendrimers and Dendrons

1. DENDRIMER CONSTRUCTION

The science of nanotechnology has employed many different constructs having low nanometer dimensions, including inorganic scaffolds, biological macromolecules, and various forms of polymers and particles. One of the most defined nanoparticle constructs is a unique polymeric assemblage called a dendrimer. First described in 1983 by Tomalia and Dewald in the application to U.S. patent 4,507,466 and again in 1985 by Tomalia *et al.* and Newkome *et al.*, dendrimers are monodisperse, globular macromolecules grown by successive synthetic steps from a central core molecule. Each step, called a generation, adds a distinct layer to the previous one so that a dendrimer grows out from the core like the branches of a tree. In fact, the name dendrimer comes from the Greek word for tree, or "dendron." The result is a polymeric molecule having a fractal dimensional quality with properties and shape that are determined by the types of monomers used to grow the branches.

Each step in dendrimer synthesis occurs independently of the other steps; therefore, a dendrimer can take on the characteristics defined by the chemical properties of the monomers used to construct it. Dendrimers thus can have almost limitless properties depending on the methods and materials used for their synthesis. Characteristics can include hydrophilic or hydrophobic regions, charged or uncharged parts, the presence of functional groups or reactive groups, metal-chelating properties, core/shell dissimilarity, electrical conductivity, hemispherical divergence, biospecific affinity, and photoactivity, or the dendrimers can be selectively cleavable at particular points within their structure.

Dendrimers have been used for many diverse applications within the biological, chemical, polymer, and nanotechnology fields. Some major applications include their use as multivalent bioconjugation scaffolds, for enhancement of signals in assays, to solubilize hydrophobic molecules in aqueous environments by internal entrapment, to functionalize surfaces and particles for conjugation, as transfection agents for cells, to create targeted therapeutic constructs for the treatment of disease, as carriers of affinity ligands, and as additives for other polymer mixtures. For excellent reviews of dendrimer technology, see Fréchet and Tomalia (2002), as well as Boas *et al*. (2006) and Menjoge *et al*. (2010).

The synthesis and structure of a dendrimer can be illustrated by the well-known poly(amidoamine) type (called PAMAM), which describes the monomers making up the complete polymer. The synthesis starts from a core diamine (or ammonia) molecule. The diamine can be of various lengths and spacer arm properties and even contain cleavable components. Typically, the core is a short diamine, such as ethylenediamine. The first reaction that is done to form a PAMAM dendrimer is reacting the core with methyl acrylate to form the Michael addition product, a tetra-methyl ester branched molecule. Next ethylenediamine is again added in large excess to the tetra-methyl ester intermediate, which undergoes amidation to form the tetra-amidoethylamine generation-0 (G-0) product containing four pendent amines. Another round of methyl acrylate addition followed by ethylenediamine yields the eight-amine generation 1 (G-1) PAMAM dendrimer (Figure 8.1).

Similar successive additions of methyl acrylate and ethylenediamine result in progressively higher-generation dendrimers, which branch out to larger diameters and contain greater numbers of amines on their surface. For dendrimers of the classic PAMAM type, each additional generation results in doubling the number of pendent amine groups decorating its surface, because alkylation of each terminal amine can be done twice with two molecules of methyl acrylate. Since each step in dendrimer synthesis adds greater branching of monomer units as they grow out from the core, the design has become known as "starburst" dendrimers. Figure 8.2 illustrates graphically how the growth of dendrimers built from a bifunctional core results in ever more branching as the generational size increases. The corresponding G-3 and G-4 PAMAM dendrimer chemical structures are shown in Figures 8.3 and 8.4.

Bioconjugate Techniques, *Third Edition*.
DOI: http://dx.doi.org/10.1016/B978-0-12-382239-0.00008-X

© 2013 Elsevier Inc. All rights reserved.

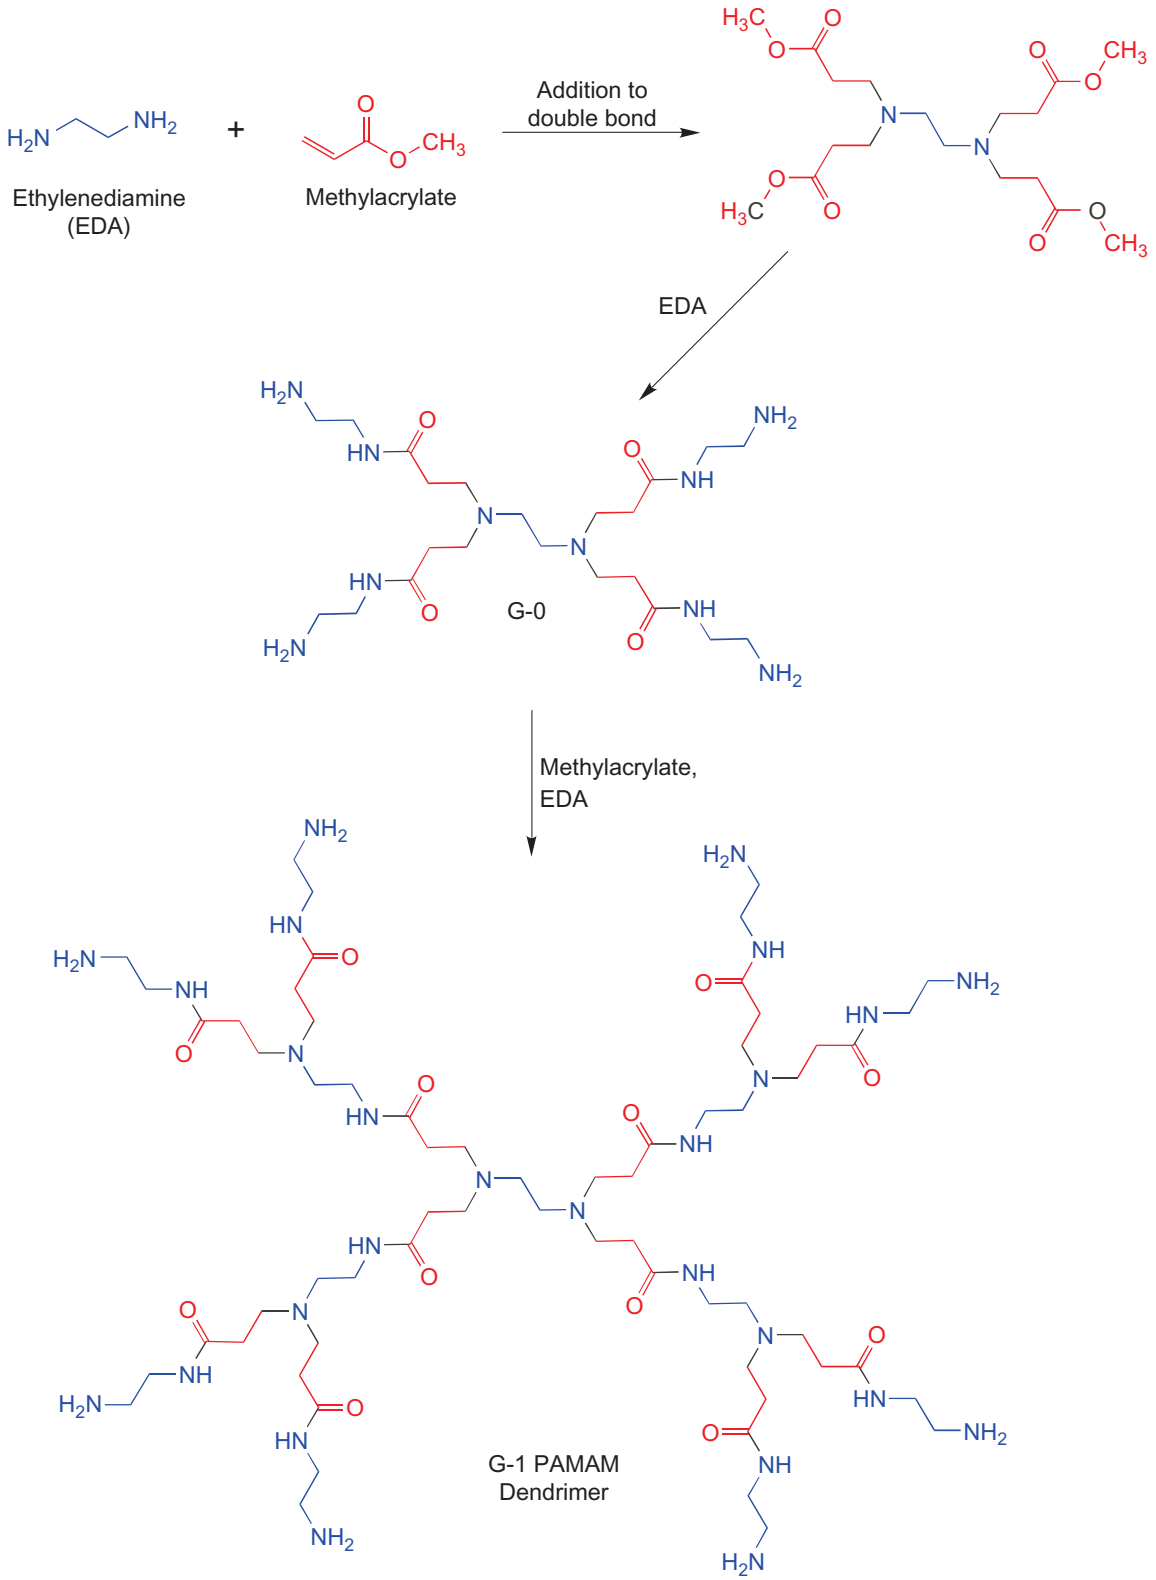

FIGURE 8.1 The synthesis of a PAMAM-type dendrimer proceeds from a diamine core (e.g., ethylene diamine, or EDA) by initial addition of the amines to the double bonds of methacrylate. Subsequent reaction of the methyl ester groups with EDA produces a G-0 dendrimer with four pendent amine groups. Another round of methacrylate and EDA additions results in a G-1 PAMAM dendrimer containing eight primary amines.

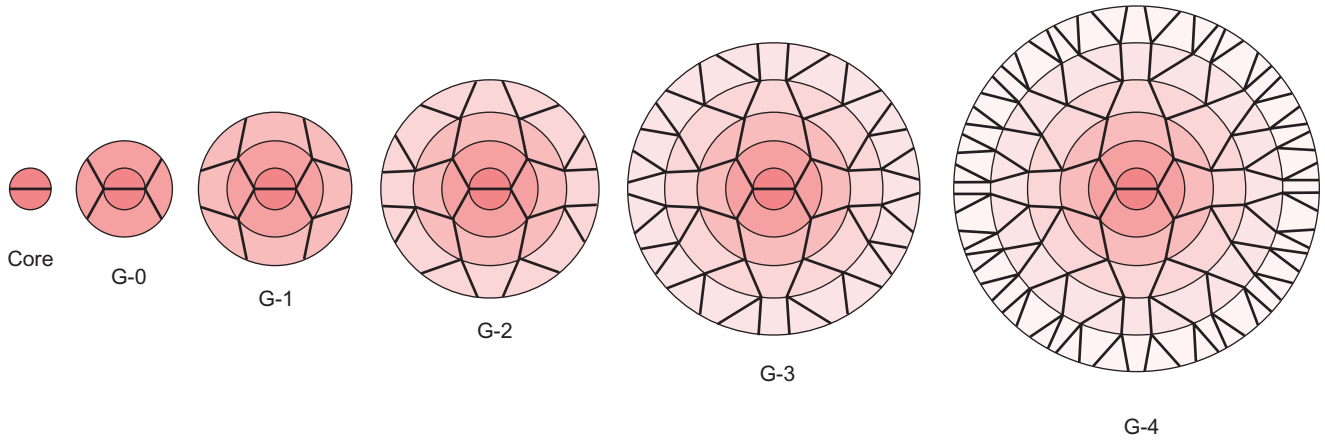

FIGURE 8.2 A graphical illustration of the growth of dendrimer structures from an initial bifunctional core to a G-4 dendrimer containing 64 terminal groups on its outer surface.

Although a two-dimensional depiction of this dendrimer structure may look like the molecule has nearly perfect circular symmetry, its true three-dimensional structure actually appears more asymmetrical for lower-generation dendrimers and like a complex globular protein (Figure 8.5) for generations above G-4.

There are two main methods of synthesizing dendrimers: (1) the divergent method, which involves building the core outward in successive steps or generations as described above for PAMAM dendrimers; and (2) the convergent method (Hawker and Fréchet, 1990; Hodge, 1993; Grayson and Fréchet, 2001), which consists of building a single-branched tree as it would grow out from the core in the divergent method, but in this case, after synthesis of individual trees, they are linked to the core structure as single units (Figure 8.6). Thus, convergent dendrimers are constructed from the outside in. One advantage of the convergent synthesis strategy is that different dendritic starting materials (dendrons) can be built and combined to form a segment-block dendrimer or a layer-block dendrimer, which consists of polymers of different types within the same dendrimer structure. The only major disadvantage of using the convergent approach to making dendrimers is that the result is limited to rather small dendritic molecules, because as the size of the building blocks increases, steric crowding prevents efficient reaction of all the dendrons with the core.

A third method of constructing dendrimers is through self-assembly of engineered building blocks. When the blocks are put together under the correct conditions in solution, they spontaneously assemble into dendritic structures, thus dramatically simplifying an often tedious, multi-step production process (Walter and Malkroch, 2012). For instance, dendrimers have been assembled through use of chelating components, which assemble into dendritic structures upon addition of the appropriate metal ions (Denti *et al.*, 1992; Balzani *et al.*, 1996; Kawa and Fréchet, 1998). Oligonucleotide dendrimers also have been formed by using intelligently designed sequences that hybridize to other oligos in such a way that dendritic molecules are spontaneously created in solution (Genisphere technology). In addition, dendrimers have been made from dendron trees containing interior groups that can self-assemble through hydrogen bonding with groups on neighboring trees, thus forming the complete dendrimer as the adjacent groups interact at the core (Hudson *et al.*, 1997; Percec *et al.*, 1998).

Finally, dendrimers have been synthesized using solid-phase peptide synthesis resins, wherein the core is linked to the resin and the half-dendrimer (dendron) is built out from it in sequential steps (March *et al.*, 1996; Swali *et al.*, 1997; Wells *et al.*, 1998). The advantage of this method is the ease with which reactants are added and the growing dendron is purified from reaction by-products. This method also can be used to add terminal peptides onto the dendron for affinity-targeting purposes. Monaghan *et al.* (2001) used this approach to make peptide–dendrimer conjugates for the investigation of integrin binding.

One of the most important advances in synthesizing dendrimers is the use of the cycloaddition reaction between azides and alkynes, which has become known as "click chemistry" (Chapter 17, Section 5). The copper I-catalyzed conjugation reaction forms cyclic 1,2,3-triazoles in very high yield. Using the appropriate monomers, the click chemistry-mediated assemblage of dendrimers has provided dramatic improvement to both the yield and the ease of synthesis and thus

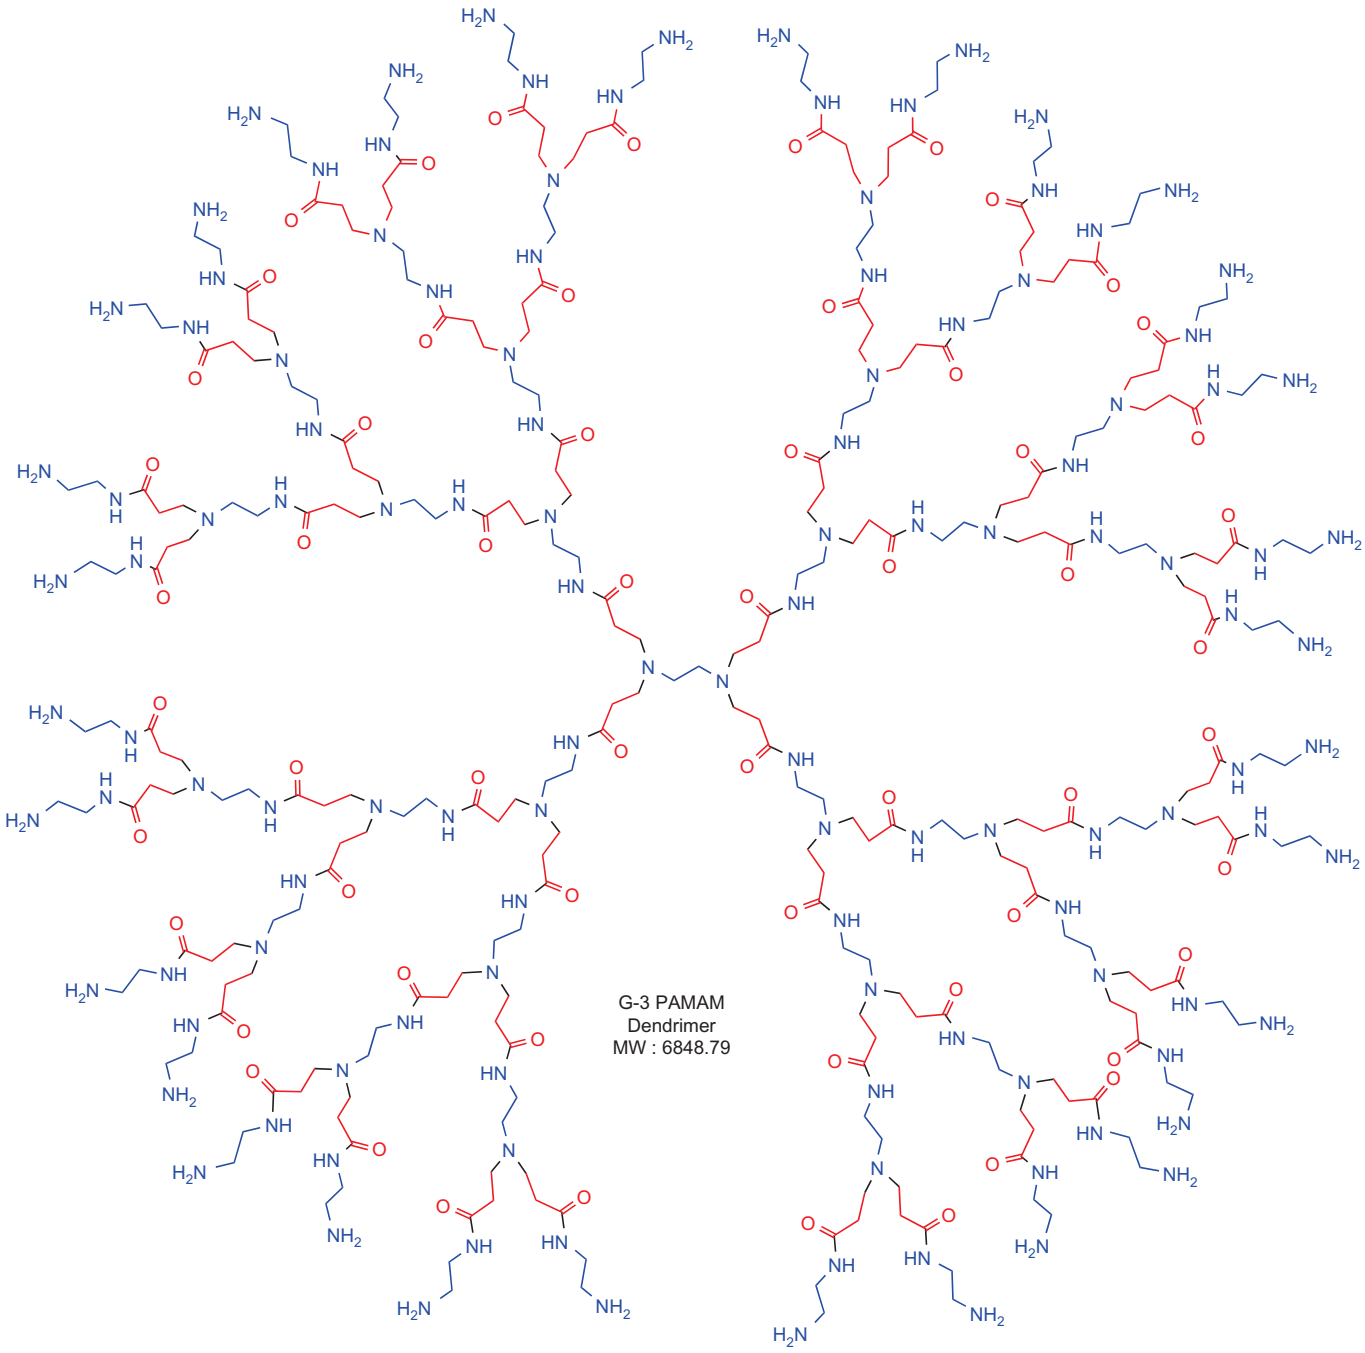

FIGURE 8.3 The chemical structure of a G-3 PAMAM dendrimer.

has dramatically decreased the cost of making bulk amounts of dendritic molecules (Rouhi, 2004; Wu *et al.*, 2004; Joralemon *et al.*, 2005; Lee and Kim, 2005; Wu *et al.*, 2005; Huang et al., 2012) (Figure 8.7). Even unsymmetrical dendrimers can be prepared using a convergent synthesis approach between propargyl-functionalized PAMAM dendrons and azido-functionalized PAMAM dendrons (Lee *et al.*, 2007).

Regardless of how they are made, the higher the dendrimer generation the greater the density of its branching becomes. Dendrimers of small size have an internally open configuration that freely permits the flow of small molecules within their inner structure. As dendrimers increase in diameter from G-0 through G-7, their appearance and size become more and more similar to those of globular proteins of corresponding mass.

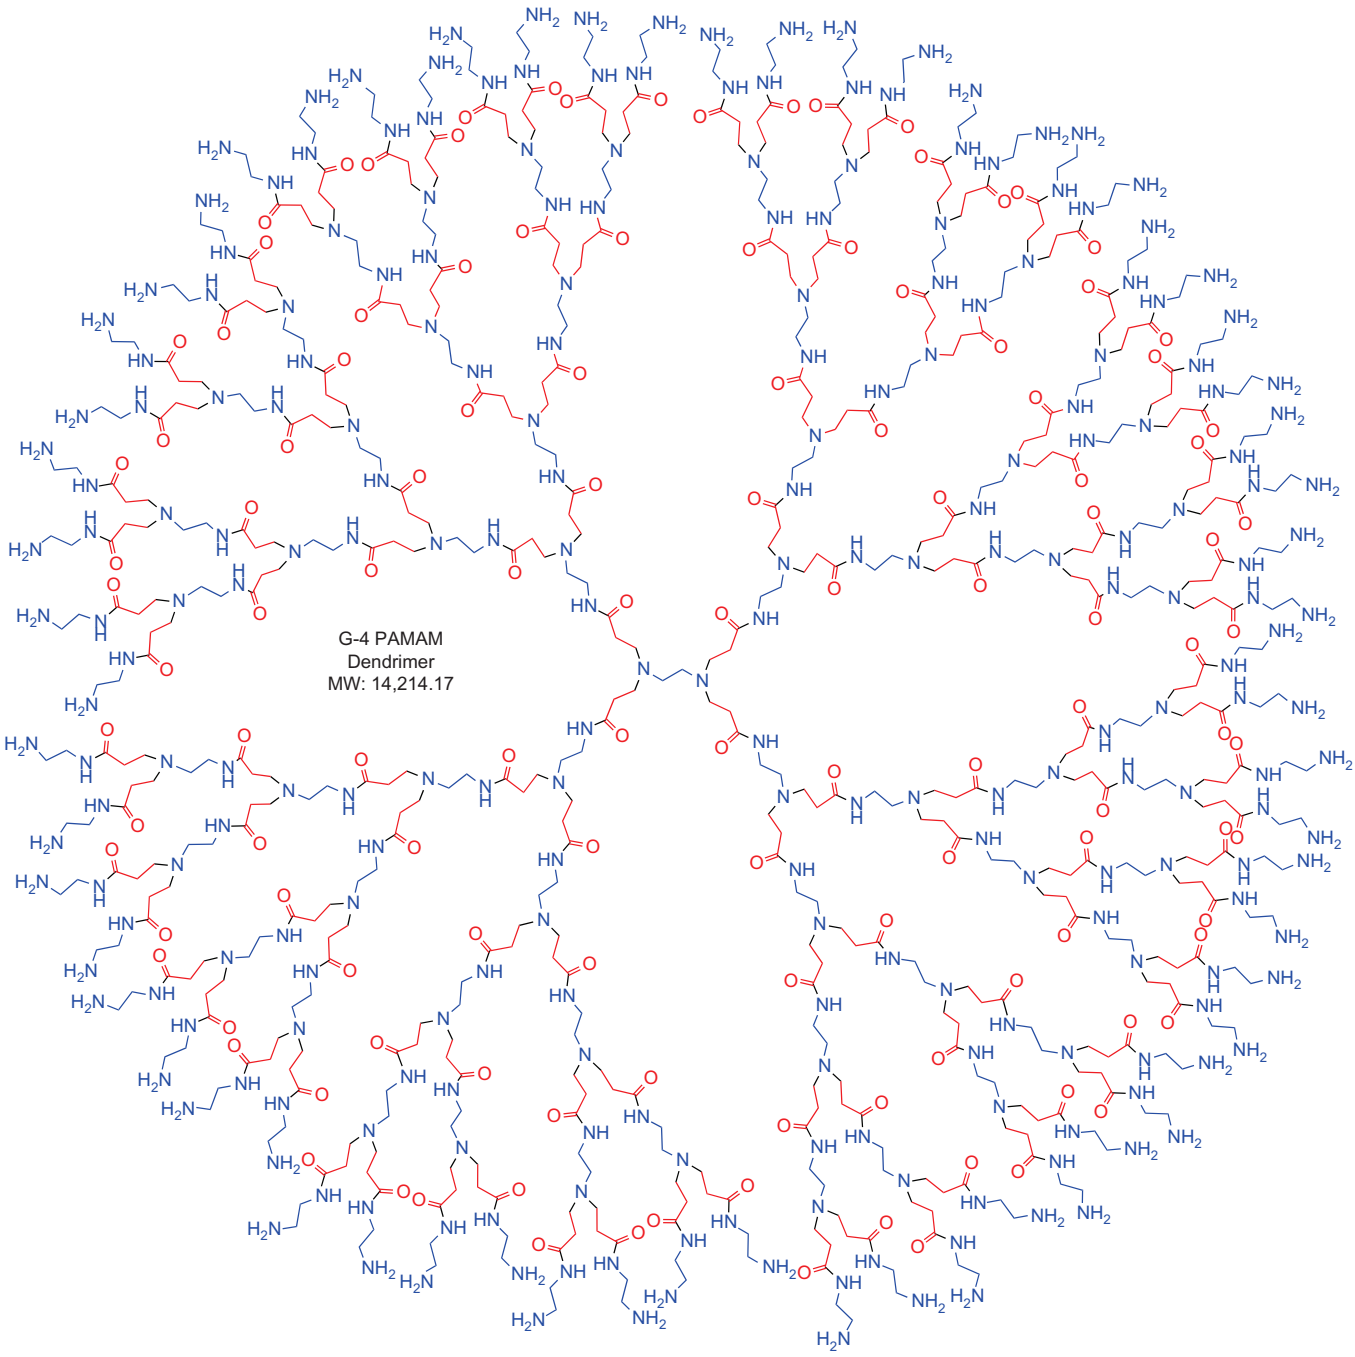

FIGURE 8.4 The chemical structure of a G-4 PAMAM dendrimer.

For instance, a G-0 PAMAM dendrimer has a molecular weight of 517 and a diameter of about 1.5 nm, whereas a G-7 dendrimer has a mass of 116,493 and a diameter of 8.1 nm, which are very similar in mass and diameter to peptides and proteins of comparable sizes (Eichman *et al.*, 2001). Unlike proteins, however, the surfaces of dendrimers become increasingly dense as their size increases. This is due to the doubling of branches and pendent groups on the outer surface for each generation increase in size. As the dendrimer generation and size increase, the molecules become more symmetrical and spherical in shape due to the dense outer branch packing. At a certain point, surface crowding becomes so great that no further access to the internal structure is possible and the dendrimer becomes a rigid ball. As dendrimer size increases, it also becomes increasingly

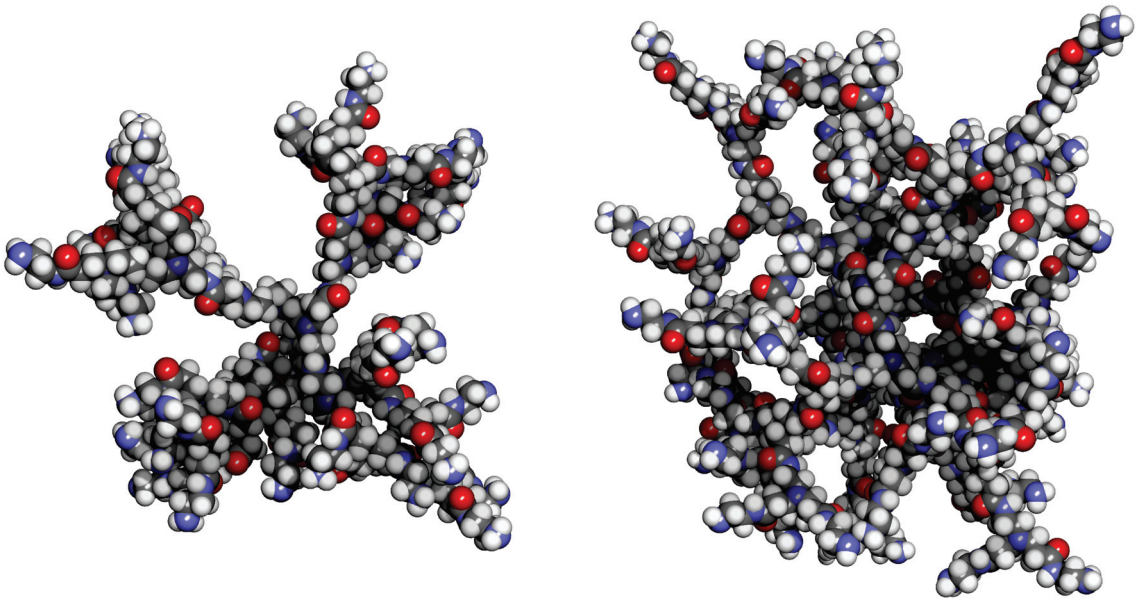

FIGURE 8.5 The G-3 and G-4 PAMAM structures shown in Figures 8.3 and 8.4 are illustrated here as space-filling molecular models. The structures were energy minimized and then allowed to go through molecular dynamics to give the three-dimensional configurations seen here. The G-4 level begins to show similarity to globular proteins as the number of pendent arms becomes great enough to create an almost fully filled core.

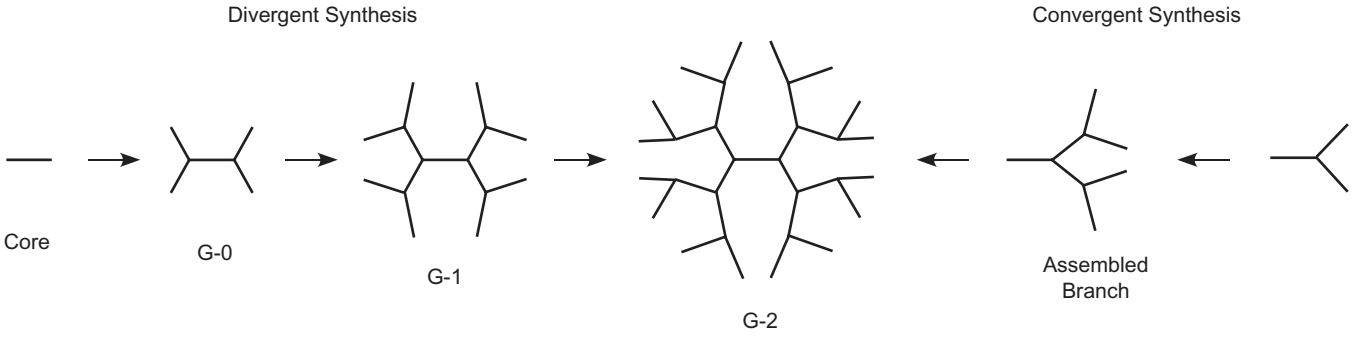

FIGURE 8.6 The divergent and convergent synthesis methods of dendrimer formation.

difficult to add another layer of monomers to the surface due to steric hindrance.

In general, dendrimers of size G-0 through G-3 have open, asymmetric, and flexible structures with effectively no protected internal areas, due to a large freedom of motion in their branches, and they can readily accommodate additional covalent attachments to their surfaces. See Figures 8.3 to 8.5 for illustrations of the 2D and 3D structure of a G-3 and G-4 dendrimer, in which G-3 dendrimers can be seen to have a great deal of internal space. However, G-4 through G-6 dendrimers display a more globular structure and contain internal void areas, which can hold guest molecules, such as delivery agents or drugs. Above this size, G-7 and greater, dendrimers are more like solid spheres or particles with inaccessible interiors and highly dense surfaces, and they appear upon imaging much like polymer nanoparticles of similar size (Chaper 14).

Unlike linear or ordinary branched polymers, dendrimers display intrinsically low viscosity, even at high mass. As standard polymeric molecules increase in mass and size, their viscosity normally increases

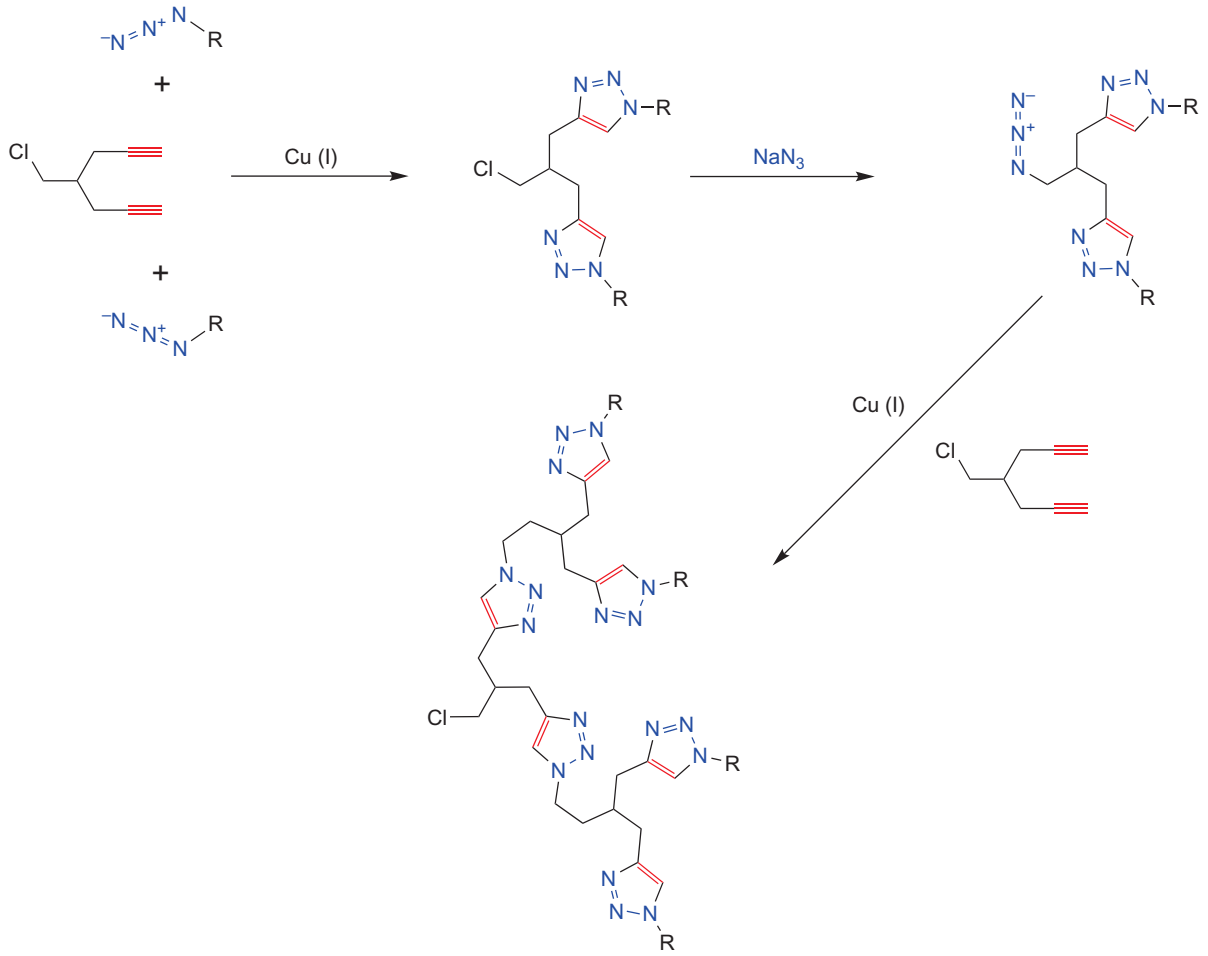

FIGURE 8.7 The synthesis of dendrimer molecules using click chemistry proceeds with high yield. Each step results in the cycloaddition reaction between azide-containing molecules and alkyne molecules to form triazole linkages.

continually. With dendrimers, viscosity increases only up to about the fourth generation, after which it actually begins to decline (Mourey, 1992; Fréchet, 1994). In addition, with control over the type of pendent groups that adorn the surface, dendrimers can maintain high solubility regardless of size.

Dendrimer molecules of the mid-size range have been found to be excellent carriers of guest molecules for solubilization and drug delivery. Wang *et al.* (2012) studied the host–guest chemistry of dendrimer–cyclodextrin conjugates in detail using NMR to determine what types of molecules are best contained within the structures for drug delivery purposes. In addition, certain groups added to the surface of such dendrimers can aid in the entrapment of molecules within the dendrimer cores. Such a construct, called a dendrimer box, can be designed to release the guest molecules upon certain conditions being met, such as pH-facilitated hydrolysis or a photoreaction of the surface capping groups. In this case, the capping groups are reversible and thus the dendrimer can be induced to release its cargo by cleavage (Jansen *et al.*, 1994; Jansen and Meijer, 1995). Miklis *et al.* (1997) used molecular dynamics to investigate the encapsulation of rose bengal molecules in a dendrimer box, which was formed by the coupling of tBOC-L-Phe cap molecules to the 64 terminal primary amines of a G-5 poly(propyleneimine) dendrimer. It was discovered that without the capping groups, the rose bengal molecules were in equilibrium between the solvent, surface, and interior of the dendrimer. However, forming a dendrimer box with the tBOC-L-Phe caps stably was found to keep the guest molecules within the dendrimer interior without leakage.

In some cases, a dendrimer box can be designed to provide a slow release of a drug by capping the branched structure with hydrophilic PEG groups. The internal structure is designed to effectively dissolve the organic drug and sequester it, while the PEG capping groups provide extreme dendrimer solubility and inhibit the movement of the drug out of the interior

dendritic space. Liu *et al.* (2000) used this design to entrap indomethacin within the hydrophobic branches of a dendrimer built from phenyl-group-containing monomers and provided an $mPEG_{16}$ cap to allow a time-release effect for the drug *in vivo*.

In addition to the PAMAM variety, many different chemical constituents have been used as monomer units to build a dendritic molecule. Some have used trifunctional aromatic units, rigid monomers to keep the branches from bending, polyethers, polyhydroxyls, heterocyclic compounds, etc. In some dendrimer types, the interior structure is hydrophobic and can be used potentially to carry small organic molecules, while the surface groups are made to be hydrophilic to promote overall solubility. The potential variety of dendrimer construction is limited only by the imagination of organic or inorganic building blocks that can be conceived and linked together.

2. CONJUGATION TO DENDRIMERS

Many of the applications of dendrimers involve the covalent coupling of other molecules to the dendrimer surface or to points within the branched structure. These attached molecules can function as detection agents, affinity ligands, targeting components, radioligands, imaging agents, or pharmaceutically active compounds. The methods used for dendrimer conjugation are similar to the procedures used with other macromolecules and particles. The essential elements in designing a dendrimer conjugate are the functional groups that are present on the dendrimer and the functional groups on the molecule to be coupled.

Dendrimers are commercially available containing a variety of dendron structures and pendent groups on their surface (Dendritic Nanotechnologies; Dendritech). Some of the functionalities available allow for bioconjugation reactions to be done, but others are designed to create certain solubility properties and cannot be used directly for coupling other ligands. Figure 8.8 shows some of the available surface groups for traditional PAMAM-based dendrimers, including amine, carboxylate, hydroxyl, methyl ester, mPEG, and a hydrophobic C_6 chain. Selections of different diamine cores also are available with these surface functionalities, including the chain lengths C_2, C_4, C_6, and C_{10}, and a disulfide cleavable cystamine core. Most dendrimers of the PAMAM type are commercially available in sizes up to G-6, but can be custom ordered in higher generations, which are more difficult to synthesize and more expensive.

The Priostar dendrimers originally available from Dendritic Nanotechnology (now Starpharma) are created using a new manufacturing process and provide greater flexibility in dendrimer design and much better stability in the final product. These dendrimers are stable at room temperature, unlike PAMAM dendrimers, and can withstand extremes in pH or temperature without hydrolyzing or decomposing. In addition, the dendritic structures can be formed to have internal functional groups along their branches for conjugation, including secondary amines and hydroxyls. Therefore, fluorescent molecules or other organic molecules can be attached at internal locations, leaving the surface groups available for additional conjugation sites.

Priostar dendrimers are available with amine, hydroxyl, carboxylate, or epoxy functionalities on their

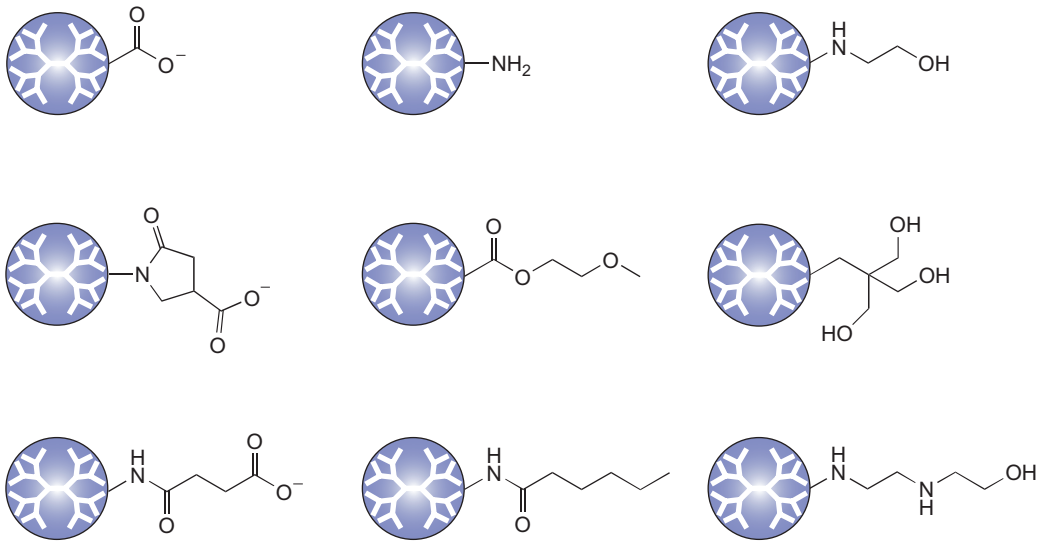

FIGURE 8.8 The pendent groups available on the surface of dendrimer molecules are highly varied. Some groups provide functional or reactive groups for bioconjugation, while other groups create unique solubility characteristics for the dendrimer.

surface for bioconjugation reactions. Also, due to the monomers used for synthesis, each generation of this dendrimer contains more surface functionalities than the corresponding PAMAM dendrimer. For example, PAMAM dendrimers with ethylenediamine cores have 4, 8, 16, and 32 pendent groups present for generations G-0, G-1, G-2, and G-3, respectively. By contrast, Priostar dendrimers have 4, 12, 30, and 100 pendent functionalities on their surface for G-0, G-1, G-2, and G-3, respectively. The result is much greater surface functionality at much lower generation number and size; therefore, surface functionality can be maximized without growing the dendrimer so large that it no longer can accommodate guest molecules within its core structure.

Other than the epoxy groups available on one Priostar dendrimer type and a methyl ester available on a PAMAM dendrimer, the commercial suppliers generally do not offer a selection of spontaneously reactive dendrimers for bioconjugation purposes. For this reason, most of the applications published for coupling biomolecules to dendrimers have used various modification or activation steps to create the appropriate reactive groups for conjugation (e.g., Leon *et al.*, 1996).

Due to the multivalent nature of dendrimers, the first consideration for conjugating molecules to them is to decide how many modifications should occur on the surface. For some molecules, maximizing the ligand:dendrimer modification ratio may be desirable. An example is in creating sugar–dendrimer derivatives to interact with carbohydrate binding proteins on cell surfaces. Since many sugar–lectin associations are of low affinity, creating a dendrimer conjugate having numerous sugar molecules attached to its surface is advantageous to form multiple interaction points. This approach results in the sugar–dendrimer complex binding to the cell surface with higher avidity than a single sugar derivative would be able to achieve.

However, for other bioconjugation applications, the optimal number of molecules attached to a dendrimer may have to be determined by experimentation. Too many modifications may result in decreased activity of the final conjugate as compared to a similar conjugate made without the use of a dendrimer. For instance, numerous fluorescent molecules can be attached to a G-3 amine-containing dendrimer to provide an enhanced fluorescent conjugate, which is brighter than a single fluorescent molecule for labeling proteins. However, if too many fluorescent molecules are attached, fluorescence quenching may take place and obviate any benefit the use of a multivalent dendrimer may provide toward signal enhancement. Therefore, for any given dendrimer conjugate preparation, some thought must be given to optimizing the number of modifications (or the ligand:dendrimer ratio) to obtain the best possible conjugate activity in the intended application.

In addition, if a dendrimer is to be labeled with one molecule and then ultimately attached to another molecule to form the complete complex, then the second conjugation step also must be planned from the beginning. Are some surface groups going to be used for coupling the first molecule and then the remaining groups used for coupling to the second one or will a disulfide dendritic core be used for coupling to the second molecule after cleavage of the modified dendrimer? Such decisions will affect the conjugation strategies used with dendrimers and often govern the usefulness of the resultant conjugate.

Dendrimer conjugates are being used more frequently in the development of multivalent constructs for delivering drugs to discrete sites *in vivo*. Dendrimers have been used to target cancer cells using biotin–dendrimer conjugates (Yang *et al.*, 2009), modified with folate and PEG polymers to carry DNA to tumor cells (Arima *et al.*, 2012), and loaded with DTPA–gadolinium chelates and folate in a PEG-dendrimer for high-contrast imaging of tumors (Chen *et al.*, 2010). In addition, a doxorubicin–dendrimer conjugate was designed to carry increased dosages of the chemotherapeutic agent to cancer cell targets (Chandra *et al.*, 2011).

The following methods of linking molecules to dendrimers present options for deciding the best reactions to exploit in creating a conjugate. In all cases, the ratio of reactants and the nature of the final conjugate should be carefully considered. In the end, running a series of trial conjugations to optimize the final conjugate will result in a method that is appropriate to the intended application and consistent in performance from batch to batch.

2.1. Coupling to Amine-Containing Dendrimers

PAMAM amine-containing dendrimers have surfaces that are adorned with many primary amine groups, the number of which is dependent on the generational size of the dendritic structure. For instance, a G-3 PAMAM dendrimer has 32 amine groups on the outer ends of its branches, a G-4 has 64 amines, and a G-5 has 128 amines. As long as the dendrimer size is within the mid-range where crowding of surface components is not severe, then the reactivity of these pendent amines is much greater than the amines on a globular protein. This is due to the fact that with protein molecules solvent accessibility of amines is dependent on the relative exposure of the side-chain lysine amines to the environment. For many globular proteins, a percentage of amines are highly accessible and react quickly, but for another population of amines, they are somewhat buried below the surface polypeptide structure and do not react as readily (Chapter 2, Section 1.1).

With dendrimers, the pendent amine groups are all approximately equally accessible and very reactive for bioconjugation or modification reactions (Fréchet, 1994). The only potential limitation for coupling to a dendrimer surface would be steric crowding, which would restrict the number of large molecules from coupling to every functional group on the dendrimer. For the coupling of small molecules such as sugars or biotin derivatives, the total number of possible modifications will approach the total number of amine groups on the surface, providing the dendrimer is not so large that there is already severe surface crowding of the branches. For globular protein coupling, however, the number of potential coupling points may be much less than the total number of functional groups available, because each protein molecule will overlap and block some functional groups as it is coupled to the dendrimer surface.

Modification of Amine-Containing Dendrimers with Sulfo-NHS-LC-SPDP

The amines of a PAMAM dendrimer may be reacted with any heterobifunctional crosslinker that contains an amine-reactive group on one side and another end having different reactivity. The result will form a reactive dendrimer that is useful for coupling proteins and other ligands, that have functional groups able to form a covalent linkage with the second reactive group on the crosslinker. Sulfo-NHS–LC-SPDP contains a sulfo-NHS ester that will couple with the pendent amine groups on the dendrimer and a pyridyl disulfide at its other end to couple with thiol-containing ligands (Chapter 6, Section 1.1). Reaction of this reagent with an amine-containing dendrimer yields a reactive intermediate containing a long aliphatic spacer arm and terminating in reactive pyridyl disulfide groups (Figure 8.9). A disulfide linkage can be formed by reaction of the pyridyl disulfide end with a thiol-containing ligand, which is reversible by reduction with DTT or TCEP.

Another strategy using this crosslinker is purposely to reduce the pyridyl disulfide end after dendrimer modification to create a free thiol on the dendrimer. Singh (1998) used this process to thiolate dendrimers for subsequent coupling with protein molecules containing a group reactive to thiols, such as sulfo-SIAB (or sulfo-SMCC)-activated antibodies. After the initial activation, SPDP-PAMAM dendrimers may be stored indefinitely either lyophilized or frozen, because the thiol-reactive group is stable to hydrolysis or degradation. The modified dendrimers also may be treated with DTT to release pyridine-2-thione and create free sulfhydryls on the dendrimer surface. A thiolated dendrimer should be kept in the presence of at least 10-m*M* EDTA and used immediately for bioconjugation to prevent oxidation of the thiols, which could form oligomers over time if disulfides are formed between dendrimer molecules.

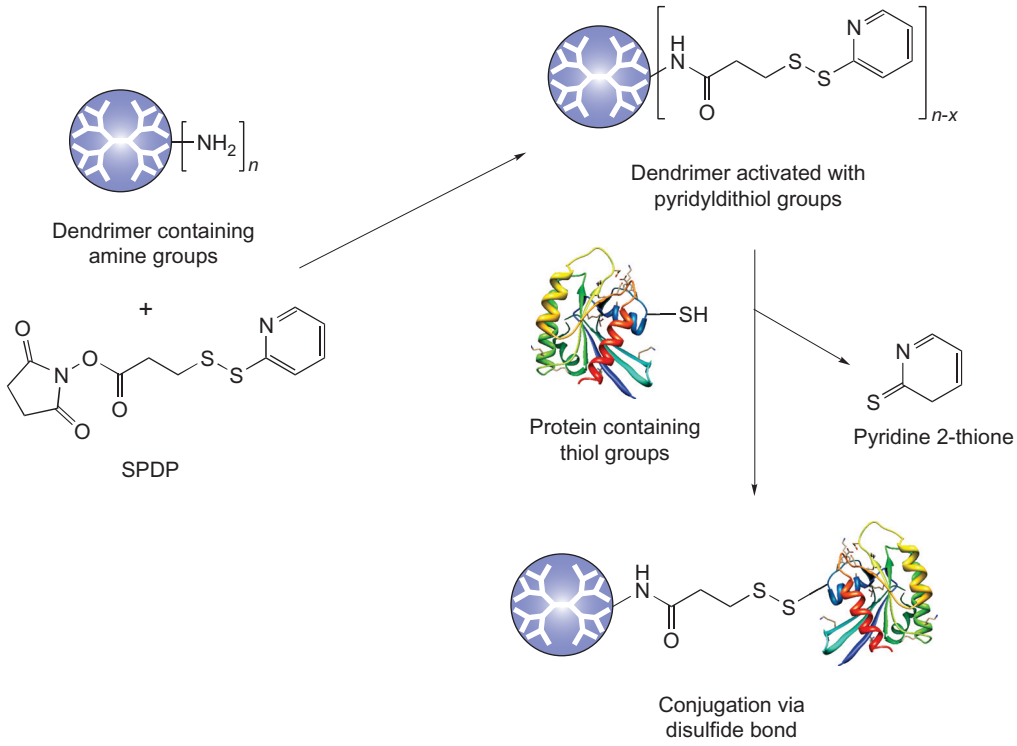

FIGURE 8.9 Amine-containing dendrimers can be activated with SPDP to create thiol-reactive derivatives. Alternatively, the pyridyl dithiol group may be reduced to create free thiols on the dendrimer surface for subsequent conjugation.

Use of sulfo-NHS–LC-SPDP or other heterobifunctional crosslinkers to modify PAMAM dendrimers may be done along with the use of a secondary conjugation reaction to couple a detectable label or another protein to the dendrimer surface. Patri *et al.* (2004) used the SPDP activation method along with amine-reactive fluorescent labels (FITC or 6-carboxytetramethylrhodamine succinimidyl ester) to create an antibody conjugate that also was detectable by fluorescent imaging. Thomas *et al.* (2004) used a similar procedure and the same crosslinker to thiolate dendrimers for conjugation with sulfo-SMCC-activated antibodies. In this case, the dendrimers were labeled with FITC at a level of five fluorescent molecules per G-5 PAMAM molecule. In addition, Bosnjakovic *et al.* (2012) prepared a dendrimer-based immunosensor for detection of tumor necrosis factor-alpha-cytokine by activation with SPDP.

Reaction of a G-3 PAMAM dendrimer with only a 4- to 10-fold molar excess of sulfo-NHS–LC-SPDP was found to yield a partially modified surface containing only a few pyridyl disulfide groups and leaving the rest of the amines available for further conjugation (Singh, 1998). To create seven to ten thiols per dendrimer, the reaction can be carried out using a 20-fold excess of sulfo-NHS–LC-SPDP. The following protocol should be optimized to incorporate the level of thiolation best suited for the application of the final conjugate.

Protocol

1. Dissolve the amine-containing PAMAM dendrimer in methanol or a buffered aqueous medium at a pH of 7 to 9 (e.g., 50-m*M* sodium phosphate, pH 7.5) and at a concentration of at least 10 mg/ml. Note that Singh (1998) used a concentration of 110 mg/ml in methanol, but other dendrimer concentrations should work equally well. For nonaqueous reactions, the addition of a proton acceptor may aid in driving the reaction to maximal yields (e.g., triethylamine or dimethylaminopyridine).
2. Dissolve sulfo-NHS–LC-SPDP at a concentration of 20-m*M* (5.2 mg/ml) in DMSO or water. If water is used, the solution must be used immediately to prevent hydrolysis of the sulfo-NHS ester.
3. With mixing, add an aliquot of the crosslinker to the dendrimer solution to provide the desired molar excess of reagent. For many applications, less than 10 pyridyl disulfide groups are needed per dendrimer molecule; therefore, molar ratios in the range of 5–20×excess of crosslinker over the amount of dendrimer present typically are used.
4. React with mixing for at least 30 min at room temperature. Longer reactions may be used without problems.
5. Purify the derivatized dendrimer using gel filtration (size exclusion chromatography) on a desalting column or through use of ultrafiltration spin-tubes (for G-4 and above). For smaller dendrimers, the derivatives may be purified by repeated precipitation from a methanolic solution by addition of ethyl acetate, dioxane, or benzene. The SPDP-dendrimer may be dried by lyophilization (if in water or buffer) or by solvent evaporation in vacuo (if the precipitation method was used).

   The SPDP-modified dendrimer of step 5 may be further derivatized with an amine-reactive fluorescent molecule for use in fluorescence detection applications. The fluorophore modification may be done prior to coupling an antibody or other molecules to the dendrimer for targeting purposes. The following steps illustrate the procedure used to obtain the fluorescently labeled dendrimer and then to use the SPDP-modified dendrimer to form thiols on the surface through reduction or to link to another molecule containing a thiol. Step 6 is optional for adding fluorescence detection capabilities, and the protocol of either step 7 or 8 may be used to conjugate the SPDP-reactive group to another protein.
6. Dissolve the purified SPDP-modified dendrimer of step 5 in 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, or in DMSO at a concentration of at least 10 mg/ml. Add a 10–20×molar excess of an amine-reactive fluorescent molecule (i.e., NHS-rhodamine or a hydrophilic NHS-Cy5 derivative—see section on fluorescent probes). React with mixing for 1 h at room temperature. Purify the fluorescently labeled SPDP-modified dendrimer using gel filtration or ultrafiltration. Follow the method of either step 7 or 8 to conjugate the dendrimer to another protein or molecule.
7. To create a thiolated dendrimer, the pyridyl disulfide groups may be reduced by addition of 50-m*M* DTT or TCEP in 50-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5, which will release pyridine-2-thione groups and leave sulfhydryls on the dendrimer surface. Remove excess reducing agent by gel filtration on a column of Sephadex G-25 or the equivalent. The thiolated dendrimer should be used immediately to conjugate to a protein or another molecule containing a thiol-reactive group, such as a maleimide or iodoacetyl group.
8. Alternatively, a thiol-containing protein may be directly conjugated to the SPDP-modified dendrimer to create a disulfide linkage. Add a sulfhydryl-containing protein or other molecule to the purified SPDP-modified dendrimer in 50-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.5. The amount of the thiol-containing protein to be added to the dendrimer should be determined experimentally to be optimal for the intended application of the

conjugate. Typically, an excess of thiol-containing protein over the number of SPDP groups per dendrimer is added to ensure that the number of proteins coupled will efficiently utilize the number of modifications initially made using sulfo-NHS–LC-SPDP. Thus, controlling the molar ratio used in the initial crosslinker reaction will control the molar ratio of protein-to-dendrimer in the final conjugate.

NHS–PEG$_n$–Maleimide Coupling to Amine-Containing Dendrimers

An alternative method to the use of sulfo-NHS–LC-SPDP for coupling thiol-containing proteins or antibodies to PAMAM dendrimers is to use a heterobifunctional crosslinker containing an amine-reactive NHS ester and a thiol-reactive maleimide group (Chapter 6, Section 1). Unlike the pyridyl disulfide reaction with a sulfhydryl as in the SPDP protocol described previously, a maleimide group forms a stable thioether linkage with a sulfhydryl-containing ligand, which is not cleavable by reduction.

A common choice of crosslinker for this type of reaction is sulfo-SMCC, which has been used extensively for antibody conjugation (Chapter 20, Section 1.1) and can also be used to conjugate molecules to dendrimers. Perhaps a better option for dendrimer conjugation, however, is to use a similar crosslinker design, but one that contains a hydrophilic PEG spacer arm to promote dendrimer hydrophilicity after modification. Derivatization of an amine dendrimer with an NHS–PEG$_n$–maleimide can create an intermediate that is coated with water soluble PEG spacers. This modification helps to mask any potential for nonspecific interactions that the PAMAM surface may have, while providing terminal thiol-reactive maleimides for coupling ligands (Figure 8.10). Rong and Reinhard (2012) used this strategy in developing dendrimer reagents to study the lateral dynamics of ErbB1-enriched membrane domains in live cells.

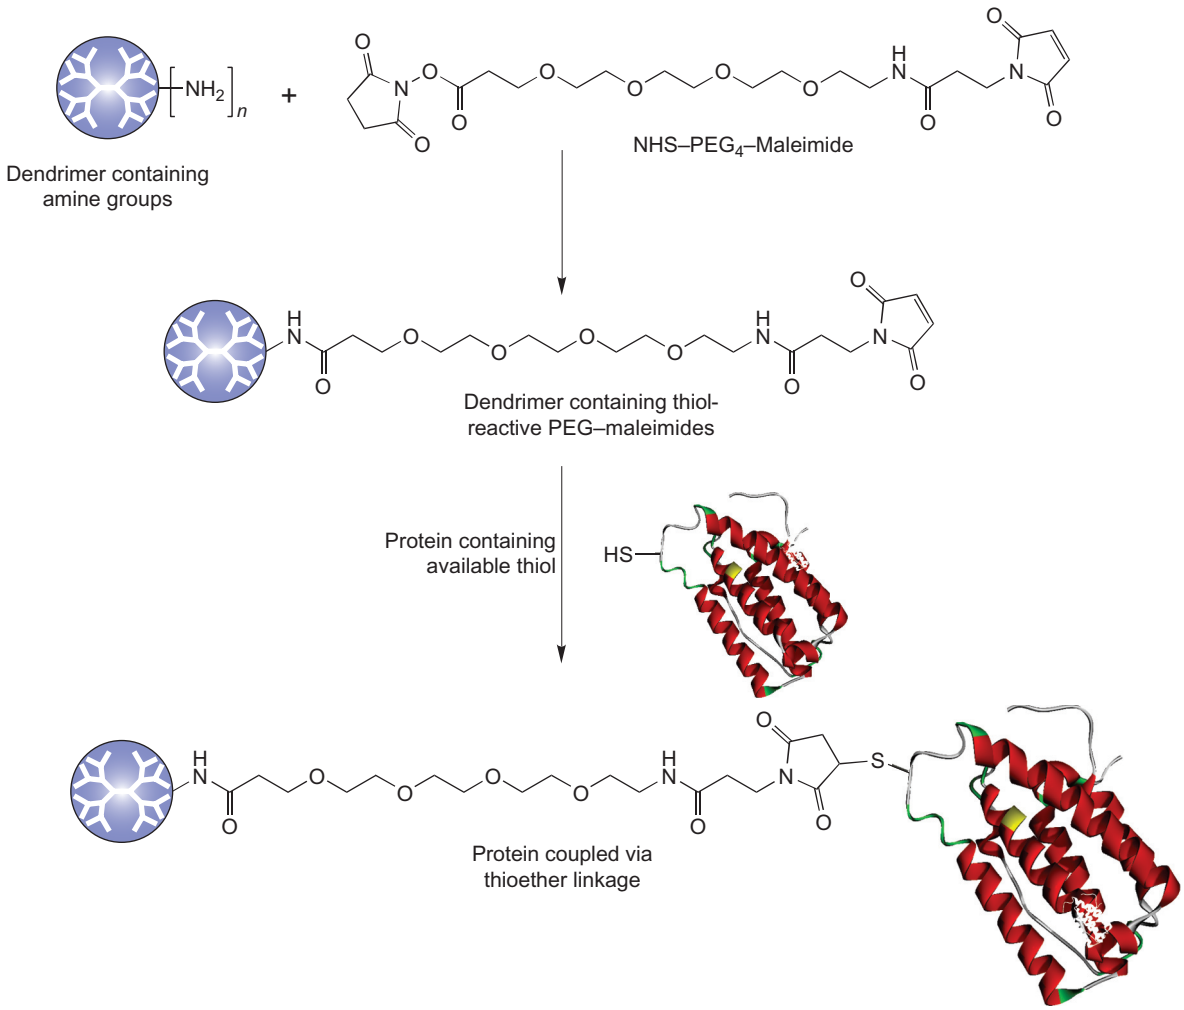

FIGURE 8.10 An NHS–PEG–maleimide compound can be used to functionalize dendrimers to provide a hydrophilic spacer terminating in thiol-reactive groups. Thiol-containing proteins then can be conjugated to this reactive intermediate to form covalent thioether bonds.

If an NHS–PEG_n–maleimide compound is used for this type of activation and coupling, the intermediate maleimide-activated dendrimer should be quickly purified of excess crosslinker and reaction byproducts and immediately used to couple ligand. This is due to the fact that the maleimide may hydrolyze in aqueous solution at a higher rate than when using a SMCC-type crosslinker, because of the extreme hydrophilicity of the PEG spacer arm compared to the cyclohexane spacer of SMCC.

NHS–PEG_n–maleimide crosslinkers are available in a number of spacer lengths depending on the size of the polymer chain in the PEG arm. Long-chain crosslinkers of this type use PEG polymers of molecular weight approximately 2000 to 5000, containing from about $n = 45$ to over $n = 100$ repeating polyethylene oxide units. Shukla *et al.* (2003) used PEG modifications to increase the half-life of folate receptor-targeted dendrimers for boron neutron capture therapy. However, a major deficiency of such full-length PEG polymers is that they are extremely polydisperse and consist of a broad range of polymer lengths, which makes reproducing the size of the conjugate difficult to achieve. Modifying a dendrimer with this type of polymeric crosslinker results in high variability of the length of the PEG chains displayed on its surface, which may be detrimental for coupling some ligands. In addition, the use of full-length PEG polymers perhaps should be avoided if the resultant hydrodynamic volume of the dendrimer derivative becomes unacceptably large for some applications.

Alternatively, shorter, discrete crosslinkers containing PEG spacers of known chain length are now available (Thermo Fisher, Quanta BioDesign; see Chapter 18, Section 1.2). These reagents are designed to contain an exact number of PEG units, typically from between 2 repeating units to 24 repeating units. The PEG spacer chain increases the overall water solubility of modified molecules and decreases nonspecific binding potential of the final conjugate. The following protocol may be used with any of these discrete PEG crosslinkers with the appropriate adjustments in the quantity of reagent added to take into account differences in molecular weight due to the PEG length. The longer of these discrete NHS–PEG–maleimide crosslinkers will provide the greatest degree of hydrophilicity after modification of an amine-containing dendrimer surface. Intermediate-length NHS–PEG–maleimides probably provide a sufficient combination of hydrophilicity while maintaining a smaller conjugate size. One caution should be noted when using PEG-based reagents with amine-containing dendrimers. The polyether crossbridge of PEG compounds has the ability to hydrogen bond to the dendrimer surface, especially when using dendrimers with a high density of amines. Reactions performed at higher levels of PEG-containing reagents may be done to overcome this tendency. Alternatively, the amine surface may be partially blocked or derivatized with another molecule prior to using the PEG compound to avoid hydrogen bond interactions.

Protocol

1. Dissolve 10 mg of an amine-containing dendrimer into 1 ml of 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5 (coupling buffer), with mixing.
2. Dissolve NHS–PEG_6–maleimide (MW 601.6) into DMSO at a concentration of 20 m*M*. Short, PEG-type crosslinkers often exist as a thick oily mass, and preparing the solution typically involves dissolving an entire vial of the compound into DMSO to determine accurately the required concentration. Use only dry DMSO to avoid hydrolysis of the NHS ester.
3. Add 50 µl of the NHS–PEG_6–maleimide solution to the 1-ml dendrimer solution and mix thoroughly to dissolve. This represents approximately a 14-fold molar excess of crosslinker over the quantity of dendrimer present, if a G-3 PAMAM dendrimer is used with an ethylenediamine core. The optimum molar ratio of crosslinker-to-dendrimer should be determined experimentally for best performance of the resultant conjugate in its intended application. If enough material is available, carrying out a series of experiments at different mole ratios of crosslinker-to-dendrimer will help to optimize the resultant conjugate.
4. React for 1 h at room temperature with mixing.
5. Purify the derivatized dendrimer from excess crosslinker and reaction byproducts using gel filtration (size exclusion chromatography) on a 10-ml desalting column or through use of ultrafiltration spin-tubes. If a dendrimer of at least G-3 size is being modified, the separation should be done on a support with an exclusion limit of no more than 2500 to 5000 Daltons to avoid losing the derivatized molecule through the membrane or not obtaining sufficient separation during the chromatography.
6. Add 1 to 10 mg of a protein or antibody containing an available thiol group to the purified, modified dendrimer from step 5. Alternatively, add the protein to be coupled to the dendrimer suspension in an amount equal to 1–10×molar excess over the estimated number of maleimide groups on the modified dendrimer. The amount of maleimide functionality may be determined using the protocol in Chapter 19, Section 5. Creating thiol groups from disulfides in proteins may be done according to the procedures in Chapter 2, Section 4.1. Alternatively, the use of a thiolation reagent may be done to add

thiols to the protein surface for coupling to the maleimide groups. The optimal amount of protein to be added to the dendrimer should be determined experimentally.

7. React the protein with activated dendrimer for 2 h at room temperature with mixing. At the completion of the reaction, cysteine may be added at 50 m*M* to block excess maleimide reactive sites that are not coupled with protein.
8. Purify the conjugate and remove excess protein by gel filtration using a column with an exclusion limit that is able to accommodate both the protein being conjugated and the dendrimer–protein conjugate. If the conjugate elutes in the void volume while the protein is retained in the pores, this also will result in sufficient separation to purify the conjugate. Store the dendrimer conjugate frozen (especially if it's a PAMAM-type) or lyophilized. The addition of a stabilizing excipient to the freeze-dried conjugate may be done to protect the coupled protein during lyophilization (e.g., sucrose).

Coupling Glycoproteins to Amine-Dendrimers by Reductive Amination

The amines on the surface of PAMAM-type and other amine-containing dendrimers may be used to couple to aldehyde groups in other molecules, including those formed after periodate oxidation of sugar groups in glycosylated proteins. Mild treatment of glycoproteins with sodium meta periodate results in cleavage of diol carbon–carbon bonds with concomitant oxidation of the hydroxyls to aldehyde groups. These aldehydes can be used to conjugate the proteins to amine-containing dendrimers through Schiff base formation and reduction to secondary amine linkages using sodium cyanoborohydride (Chapter 2, Section 4.4, and Chapter 3, Section 5) (Figure 8.11).

The following protocol involves the conjugation to an amine-containing dendrimer of a periodate-oxidized glycoprotein, such as an antibody that has been treated to produce aldehydes according to the protocols in Chapter 2, Section 4.4. This type of conjugation reaction to dendrimers may be used even after the dendrimer

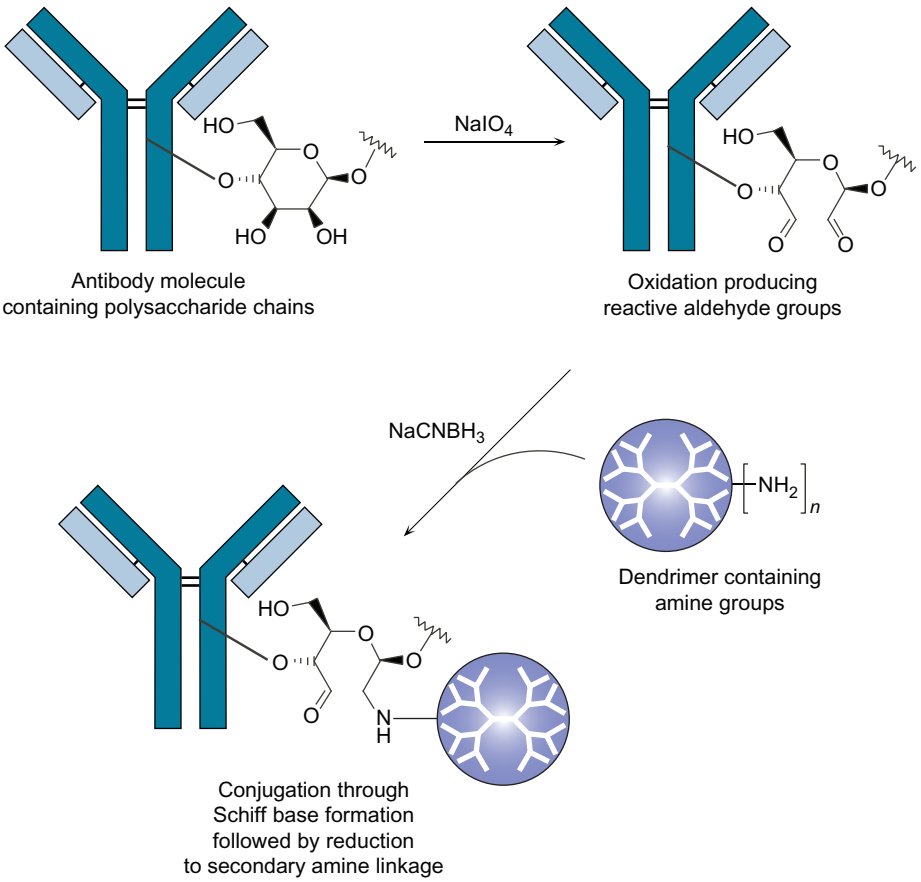

FIGURE 8.11 Oxidation of glycoproteins with periodate, such as glycosylated antibodies, results in the formation of aldehyde groups that can be used for conjugation to dendrimers containing amine groups. Reductive amination with sodium cyanoborohydride results in coupling *via* secondary (or tertiary) amine bonds.

has been initially modified with a limited number of heterobifunctional crosslinking molecules. Thus, an amine-containing dendrimer first may be reacted with crosslinkers such as sulfo-NHS–LC-SPDP or NHS–PEG_6–maleimide as described previously, and the remaining amines on the dendrimer surface used to couple with an oxidized glycoprotein. This would create a complex that contained a covalently linked glycoprotein with thiol-reactive groups available for further conjugation with another molecule containing a sulfhydryl group. Singh (1998) used this technique to produce a dendrimer conjugate containing alkaline phosphatase for detection and a Fab′ fragment of an antibody directed against creatine kinase MB isoenzyme. The phosphatase enzyme was coupled through its carbohydrates by reductive amination and the Fab′ fragment was coupled through a thiol group.

Protocol

1. Dissolve an amine-containing dendrimer in 50-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of at least 10 mg/ml. Note: The use of a buffer at pH 9–10 (e.g., 0.1-*M* sodium carbonate) for the initial Schiff base formation (step 2) will result in higher efficiency of conjugation. However, if a higher pH is used during this first stage, then the pH must be adjusted back down to more neutral conditions before the addition of reductant (step 4), as the reducing agent is not effective in the higher pH environment.
2. Add a quantity of a periodate-oxidized glycoprotein to the dendrimer solution (made according to Chapter 2, Section 4.4) to provide a molar ratio of protein-to-dendrimer of 1:1 to 10:1. Mix to dissolve. The optimal level of protein addition should be adjusted to provide maximal performance and activity in the intended application. If another protein also is to be attached to the dendrimer to make the final complex, then limiting the density of the periodate-oxidized protein may be necessary to leave room on the surface for additional protein coupling. In addition, some proteins with multiple glycosylation sites may cause dendrimer oligomerization if the conjugation reaction is done with too low of a protein-to-dendrimer ratio.
3. React for 2 h at room temperature with mixing.
4. In a fume hood, add 10 µl of 5-*M* sodium cyanoborohydride (Sigma) per ml of reaction solution. Caution: Cyanoborohydride is extremely toxic. All operations should be done with care in a fume hood. Also, avoid any contact with the reagent, as the 5-*M* stock solution is dissolved in 1-*N* NaOH. If a higher pH buffer was used for the Schiff base formation, then adjust the solution to pH 7.5 before adding the cyanoborohydride.
5. React for 30 min at room temperature in a fume hood.
6. Block unreacted aldehydes by the addition of 50 µl of 1-*M* ethanolamine, pH 7.5, per ml of reaction solution. Block for 30 min at room temperature with mixing.
7. Purify the conjugate from unreacted protein or unreacted dendrimer using gel filtration chromatography with a matrix having an exclusion limit appropriate to accommodate the size of the molecules being separated (e.g., a HiPrep 16/60 column packed with Sephacryl S-200 HR, GE Healthcare).

Blocking Amines on PAMAM Dendrimers

The number of amine groups on dendrimers of medium to large size (G-3 and above) often is many more than what is required to prepare a conjugate. Since amines can become protonated and carry a positive charge even under physiological conditions, they may interact nonspecifically with biomolecules. Ionic interactions can be a significant source of high backgrounds in assays or create off-target effects if using a dendrimer conjugate in the development of *in vivo* applications (cell-based or whole animal). In particular, nonspecific binding to the positively charged amine groups on dendrimers, if left unblocked, can be cytotoxic to normal cells *in vivo* especially if the conjugate is designed to carry chemotherapeutic components that can be used to kill cancer or diseased cells (Patri *et al.*, 2002; Kukowska-Latallo *et al.*, 2005). To overcome the positive charge character of amine-containing dendrimer excess amine groups can be covalently blocked to eliminate the possibility of ionic interactions. This blocking process can occur before activation of the dendrimer with a crosslinker or after modification, providing that the blocking agent used to couple with the remaining amines does not affect the activation chemistry.

Singh (1998) used succinylation with succinic anhydride to block excess amines and convert them into negatively charged carboxylates, which often have lower interaction potential with biomolecules than positive charges. Thomas *et al.* (2004) used acetic anhydride to acetylate and block the amines of a G-4 PAMAM dendrimer before or after activation with sulfo-NHS–LC-SPDP. Similarly, Patri *et al.* (2004) also used acetic anhydride to block amines on a G-5 PAMAM dendrimer prior to activation with sulfo-NHS–LC-SPDP, but the blocking step was done to eliminate about 80 of the 128 amine groups before effecting the conjugation with an antibody. In all these instances, the amine groups on the dendrimer are converted into amides, which carry no charge at physiological pH.

Reactions with succinic anhydride or acetic anhydride to block dendrimer amines can be done in

aqueous or methanolic solution. If organic solvent is used for the reaction, then it is typical to include triethylamine as a proton acceptor, which helps drive the reaction. Such reactions, however, cannot be done to dendrimer amines once a protein containing amines also has been conjugated, as the protein too will get modified.

Another method of blocking excess amines on dendrimers is to use small, hydrophilic blockers that contain hydroxyl or ether groups. Islam *et al.* (2005) used the short epoxy compound glycidol to modify amine groups to reduce nonspecific interactions in a dendrimer conjugate. The primary amine groups can be alkylated a maximum of two times with this reagent in methanol, resulting in four hydroxyl groups for each amino functionality (Shi *et al.*, 2007). The reaction with glycidol, however, was shown to be not as efficient in creating a homogeneous product as acylation with either succinic anhydride or acetic anhydride (Shi *et al.*, 2005). This likely is due to the formation of branched polymers off the dendrimer using glycidol (see Chapter 15, Section 2.1) as opposed to a single acylation product using either anhydride compound. Glycidol modification of an amine-containing dendrimer is done according to the following protocol.

Protocol

1. Dissolve the amine-containing dendrimer to be modified in methanol at a concentration of 10 mg/ml (all operations are done in a fume hood).
2. Add glycidol to the dendrimer solution in a 4-fold molar excess over the number of amines to be blocked (Shi *et al.*, 2007). The number of amines may be calculated from the generation number of the dendrimer and the degree of blocking desired. Obtaining the optimal molar ratio for a particular conjugate application may have to be done by experimentation using a series of different glycidol-to-dendrimer molar ratios.
3. Allow the reaction to continue for 24 h in the fume hood with mixing.
4. Dialyze the modified dendrimer against PBS buffer and then water to remove excess reactants.

Another option to limit the nonspecific binding character of amine-containing dendrimer is the use of PEG compounds. Amine-reactive PEG derivatives can be used to covalently link to excess amines on dendrimers and create a hydrophilic tether, which can dramatically limit nonspecific interactions with the exposed surface. For this purpose, PEG reagents containing an activated carboxylate (NHS ester) on one end and a methyl ether group (mPEG) on the other end work well (Chapter 18, Section 1.4). NHS–mPEG derivatives that are spontaneously reactive to the dendrimer surface amines will form amide bonds and eliminate the positive charge character of the pendent amino groups. Such PEG compounds may be a superior option to either succinylation or acetylation of amines to eliminate charge, because the PEG component also adds considerable hydrophilicity and low interaction potential to the resultant dendrimer derivative (Figure 8.12). PEG also is often added to dendrimers to increase their half-life in circulation for *in vivo* targeting. For instance, Zhu *et al.* (2012) created a multivalent dendrimer probe containing the integrin-binding RGD peptide and the antitumor drug doxorubicin and also modified with PEG to modulate its *in vivo* behavior.

Acylation reactions to block amine groups on PAMAM dendrimers with anhydride compounds are done in a similar manner to glycidol modification. The following protocol is based on the method of Majoros *et al.* (2005).

Protocol

1. Dissolve an amine-containing dendrimer in methanol at a concentration of 15 mg/ml with mixing. All operations should be done in a well-ventilated fume hood. A G-5 dendrimer was used in this reaction by Majoros *et al.* (2005) that contained 110 available amine groups.
2. Add to the dendrimer solution a quantity of acetic anhydride that represents a molar ratio of anhydride-to-amines of 0.72 : 1.0 (680 µl of acetic anhydride was added for the G-5 dendrimer). Using a molar quantity of anhydride that is less than the amount of amines present on the dendrimer ensures that only a portion of the amines will become blocked, so that further modification remains possible.
3. Add a quantity of triethylamine to the solution so that a 25% molar excess over the amount of anhydride will result (1.25 ml for the G-5 dendrimer).
4. React for 2 h at room temperature with mixing (in a fume hood).
5. Extensively dialyze the reaction mixture against water or buffer to remove excess reactants.

Preparation of Sugar–Dendrimer Derivatives

The multifunctional nature of an amine-containing dendrimer can be used to advantage to mimic multidentate interactions of molecules with cell surfaces or virus particles. For instance, the binding affinity of carbohydrate binding proteins (lectins) for individual sugar molecules typically is weak, of the order of $10^6\,M^{-1}$. In the native method used to increase the binding strength of these interactions, lectins on cell surfaces usually engage in multi-point attachments with carbohydrates or glycans. The conjugation of sugars to the pendent amine groups on dendrimers provides a scaffold for similar multi-site interactions with lectins, which effectively increases the avidity of the resultant

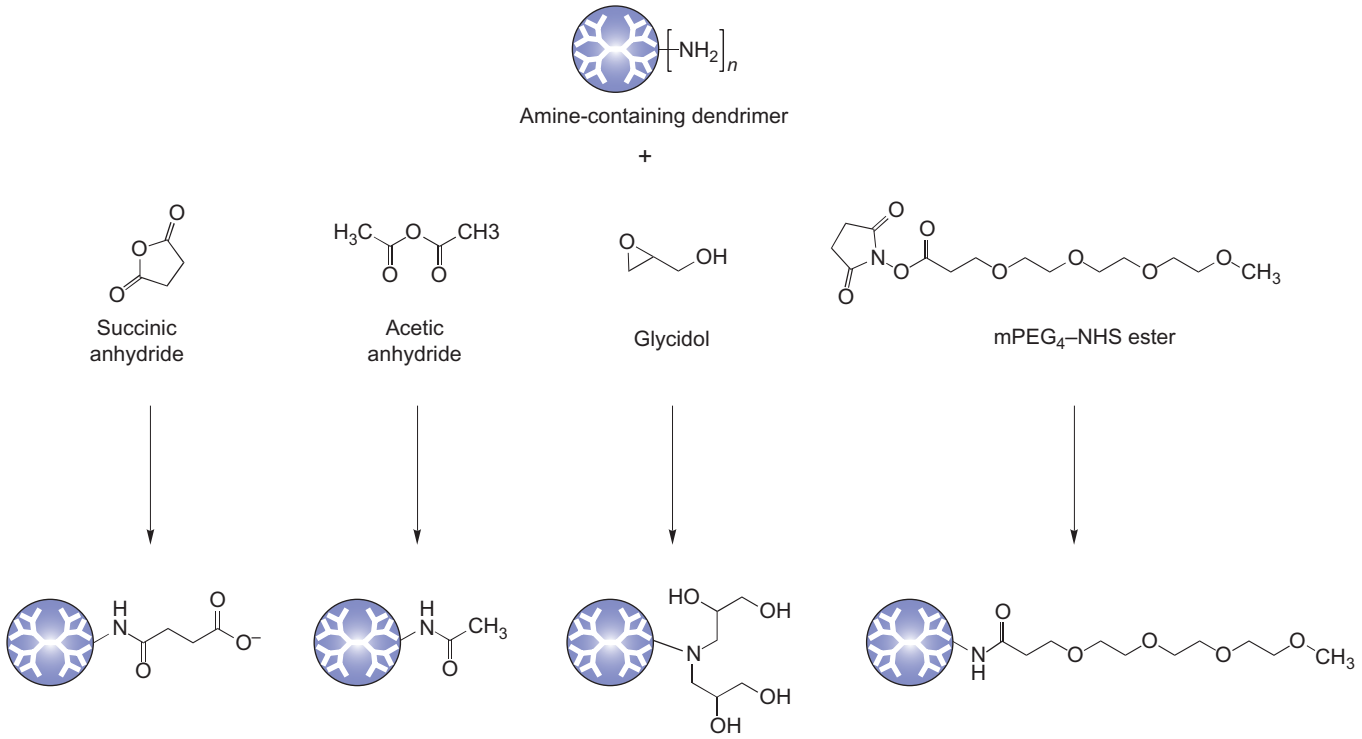

FIGURE 8.12 Amine-containing dendrimers can be modified using a number of common reactive modification agents. Excess amine groups can be blocked using acetic anhydride, glycidol, or an NHS–mPEG compound. Amines also can be converted into carboxylates using succinic anhydride.

binding complex (Aoi *et al.*, 1995; Bertozzi and Kiessling, 2001). This design is structurally similar to the multiple tree-branched structures of glycans on glycoproteins. The terminal sugar groups on such glycoconjugates are capable of interacting with more than one binding site or more than one receptor on cell surfaces. This effectively turns a single low-affinity interaction into a high-affinity binding event, which forms the basis for many life processes, including cellular recognition, adhesion, transport, and cell signaling (Clark and Wilson, 1988; Sharon and Lis, 1989). For a review of glycobiology, see the entire issue of *Science*: Carbohydrates and Glycobiology, Vol. 291, March 23, 2001, pp. 2263–2502.

A series of different mannose-dendrimers was synthesized to investigate their interaction with concanavalin A (Con A) (Woller and Cloninger, 2002; Woller *et al.*, 2003). It was discovered that the sugars on the dendrimer surface were able to bind to the Con A binding sites just like free methyl mannose in solution. However, as the size of the dendrimer increased and a number of multivalent mannose residues became available for binding to multiple Con A interaction sites, the affinity of the interaction dramatically increased. For a G-3 mannose–dendrimer derivative, the sugar complex was about 45 times more active than methyl mannose in solution. For larger-sized mannose–dendrimer complexes, the increase in activity of binding was up to 660-fold greater than free methyl mannose. However, the interaction potential for the mannose–dendrimer derivatives also was shown to be dependent on the degree of mannose loading. For large dendrimers, steric crowding of sugar molecules on the dendrimer surface decreased its binding activity toward Con A if the mannose loading was greater than about 50% of the amines modified. Thus, both dendrimer size and the level of modification must be carefully considered when designing sugar–dendrimer conjugates.

An amine-containing dendrimer's multivalent surface functionalities can accommodate a combination of carbohydrate modifications along with other groups placed on the surface to provide other activities. For instance, Lo Conte *et al.* (2011) prepared glycodendrimers by activating the surface amines to provide free-radical thiol-ene sites for coupling thiolated sugars by addition to carbon–carbon double bonds. The covalent attachment of mono- or disaccharides was easily done by irradiation at 365 nm for 1 h. On the same dendrimer, they also introduced PEG groups and glutathione molecules to create a G-4 dendrimer with the ability to avoid the reticuloendothelial system *in vivo*.

Such sugar–dendrimer complexes ("sugar balls") have been used to inhibit the interactions of viruses

with cell surfaces. Many viruses bind to particular carbohydrate residues on cell surfaces, which in turn facilitate their entry into cells and the resultant infection process. A virus particle presents a multi-dentate surface consisting of many carbohydrate-binding proteins able to interact with multiple cell surface carbohydrates. The surface of a dendrimer that is modified with sugar molecules is able to mimic the glycan-rich field on the surface of a cell. In this way, sugar–dendrimer complexes are able to interfere with virus binding to cellular targets. For instance, Borges *et al.* (2005) used dendrimers modified with a carbohydrate usually found on immune cell surface glycosphingolipids to function as an inhibitor of HIV-1 infection. The polyvalent nature of the sugar–dendrimer derivative was able to bind effectively to the virus particles with high avidity, thus preventing the virus from binding to the carbohydrates on the immune cell surface (Borges and Schengrund, 2005). The sugar–dendrimer complex in the vaginal ointment Vivagel, developed by Starpharma, is undergoing clinical trials as a preventative for HIV infection (Halford, 2005). The dendrimer formulation also is said to be active against other STDs, including chlamydia, herpes simplex virus, hepatitis B, and human papilloma virus.

Sugar–dendrimer complexes also may be used as affinity ligands for purification of carbohydrate- or sugar-binding proteins. Szwergold *et al.* (2001) used a polyvalent fructose–dendrimer derivative immobilized on a chromatography matrix to purify human fructosamine-3-kinase. The ligand was coupled to the support through excess amine groups on the dendrimers, which were not coupled with sugar molecules, and gel functioned with high affinity toward binding the enzyme out of complex samples.

The synthesis of sugar–dendrimer derivatives may be done using a number of reaction strategies. Aoi *et al.* (1995) used the lactone derivatives of lactose and maltose to react with the terminal amine groups on G-2 to G-4 PAMAM dendrimers. The reaction of a lactone with an amine involves nucleophilic attack on the lactone carbonyl with ring opening to form an amide bond (Figure 8.13). The conjugation was done in organic solvent (DMSO), but the reaction also may be done in aqueous buffers under alkaline conditions.

The preparation of sugar–dendrimer conjugates may encompass a variety of modification levels and sizes, depending on the generation of dendrimer used and the density of sugar molecules modifying its surface. Interactions with lectins vary according to the optimal sugar-to-sugar distance within the final complex. For instance, it is known that the three binding sites on the mammalian hepatic lectin for interaction with galactose and *N*-acetylgalactosamine are arranged on the protein in a triangle with a separation of 1.5 nm, 2.2 nm, and 2.5 nm (Lee *et al.*, 1984). Aoi *et al.* (1995) found that the molecular distances between sugar molecules on a G-3 PAMAM dendrimer prepared according to their protocol was between 1.3 and 2.9 nm. Thus, the sugar ball dendrimer had an optimal inter-sugar spacing to interact with the binding sites on the targeted lectin.

The following protocol represents the method of Aoi *et al.* (1995) for the coupling of lactone sugars to amine-dendrimers in organic solvent.

Protocol

1. In a fume hood, dissolve 270 mg of a G-4 dendrimer (PAMAM or other amine containing) in 2 ml of dry DMSO. Maintain a nitrogen blanket over the reaction to prevent oxidation. The use of a three-necked flask and a heating mantle is recommended to control mixing and the proper temperature.
2. Add with mixing a 300-fold molar excess of a sugar lactone derivative, such as *O*-β-D-galactopyranosyl-(1→4)-D-glucono-1,5-lactone (2.6 g) dissolved in 3 ml of DMSO.
3. React at 40°C for 9 h or overnight with stirring.
4. After cooling to room temperature, the sugar–dendrimer derivative may be precipitated with a large volume of methanol. The precipitate may be purified from reaction products by dialysis against water or buffer using a membrane with a molecular weight cutoff of 3500 Daltons. The final product may be stored frozen or lyophilized to a white powder.

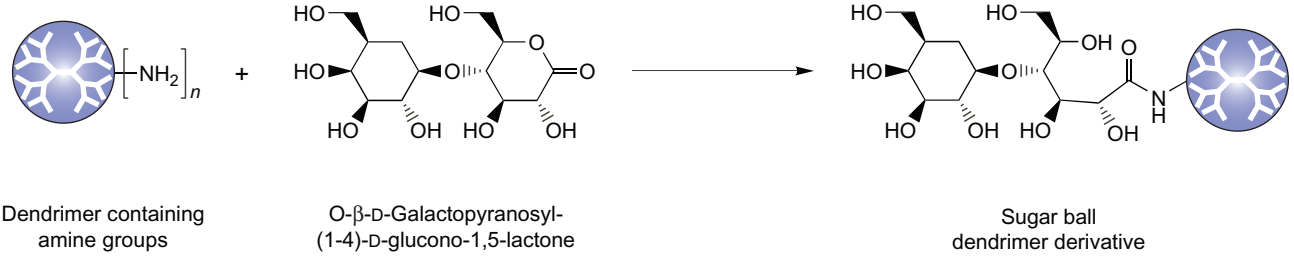

FIGURE 8.13 Lactone sugar derivatives can be used to react with amine-containing dendrimers, which results in coupling *via* amide bonds. The "sugar ball" dendrimers then can be used to specifically bind to carbohydrate binding proteins.

The modification of amine-containing dendrimer with lactose also can be done using mono(lactosylamido) mono(succinimidyl)suberate (Thermo Fisher). The amine-reactive compound contains a lactose group at the end of a suberate bridge and terminates at the other end in an NHS ester (Vetter *et al.*, 1995). The NHS ester spontaneously reacts with the amine groups on a dendrimer at neutral or slightly basic pH values to form an amide bond (Figure 8.14). The presence of the lactose disaccharide provides a hydrophilic modifying group that maintains the water solubility of the resultant conjugate.

Protocol

1. Dissolve mono(lactosylamido) mono(succinimidyl) suberate in dry DMF to prepare a concentrated stock solution. The compound is extremely soluble in DMF, and solutions of 100 mg/ml may be prepared.
2. Prepare the amine-containing dendrimer to be glycosylated in a buffer at a slightly basic pH (avoid amine-containing buffers, such as Tris or imidazole). The use of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, works well for NHS ester reactions. The concentration of the dendrimer in the reaction buffer should be at least 10 mg/ml. Other dendrimer concentrations also will work, but highly dilute solutions will result in less efficient modification yields.
3. With mixing, add a quantity of the mono(lactosylamido) mono(succinimidyl) suberate in dry DMF to the dendrimer solution to result in at least a 10- to 20-fold molar excess of reagent over the quantity of amines to be modified in the dendrimer. Depending on the desired application for the lactosyl-modified dendrimer, several different molar ratios may have to be tried to optimize the resulting modification level.
4. React for 30 to 60 min at room temperature with gentle mixing.
5. Purify the modified dendrimer away from reactants and reaction by-products using dialysis or size exclusion chromatography.

Another method for coupling carbohydrates or sugar derivatives to amine-containing dendrimer is to take advantage of the reducing end of sugars to reductively aminate the amines on the dendrimer surface. This reaction will form stable secondary amine linkages between carbon-1 of the sugars and the dendrimer (Figure 8.15). Saccharides with reducing ends have carbonyl groups that can be coupled to an amine-containing dendrimer in the presence of a reducing agent. However, since most reducing ends of sugars or glycans exist mainly in an acetal (or ketal) ring form, and only the open form with the exposed aldehyde can participate in a reductive

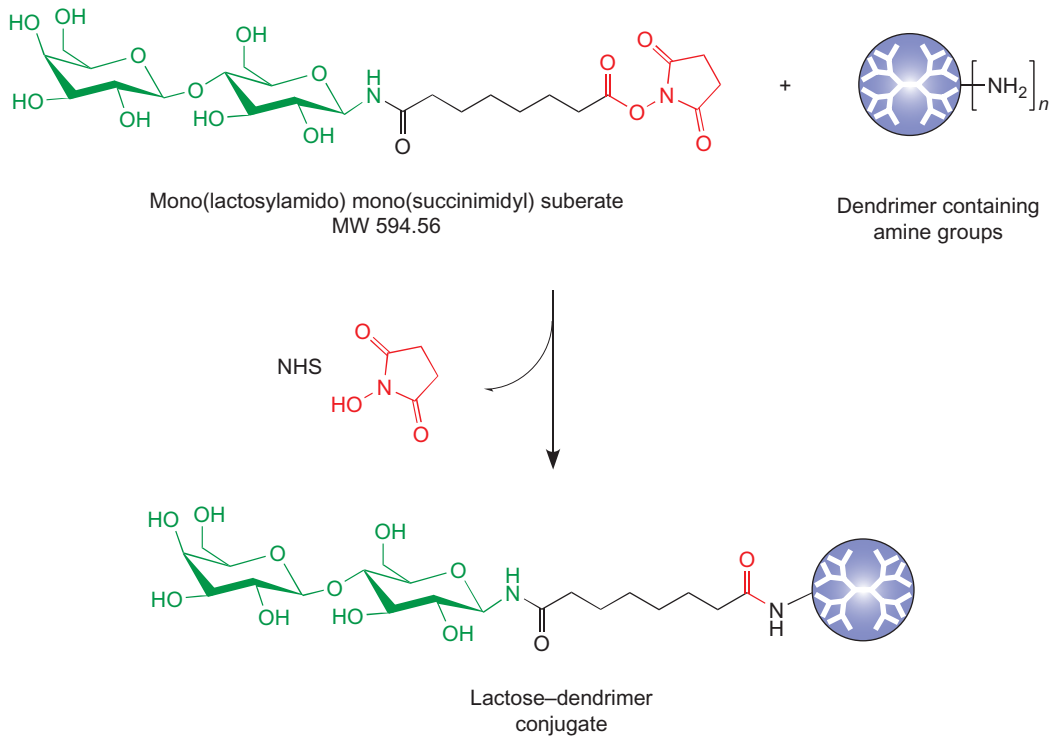

FIGURE 8.14 The reaction of an amine-containing dendrimer with mono(lactosylamido) mono(succinimidyl) suberate results in the attachment of a lactose unit *via* an amide bond.

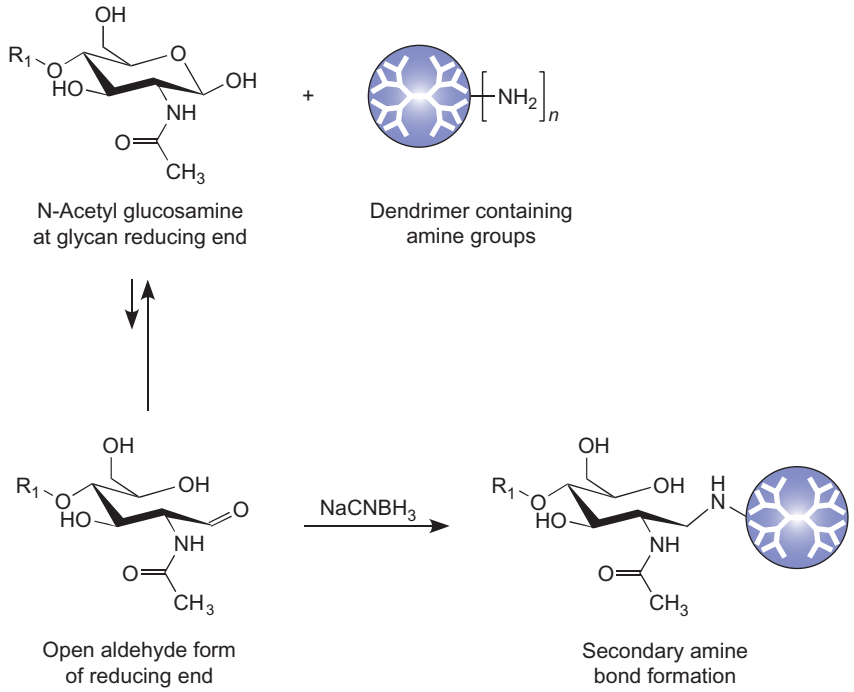

FIGURE 8.15 The reducing end of a glycan or a carbohydrate can be used to conjugate to an amine-containing dendrimer by reductive amination, which results in the formation of a secondary amine linkage.

amination reaction, the rate of modification by this process can be slow. The open form of a reducing sugar is available at any given time in only a small percentage of the total saccharide present, usually far less than 1%. For this reason, reactions carried out with primary amines at room temperature may take days to reach acceptable coupling yields. Typically, such reactions are done at elevated temperatures and over the course of at least several days, or sometimes weeks, to reach completion.

The following method for carbohydrate conjugation to dendrimers may be used to couple a variety of reducing sugars to amine-containing dendrimer, including saccharides, longer-chain carbohydrates, and even complex glycans after release from a protein (see Chapter 2, Section 4.6).

Protocol

1. Dissolve a carbohydrate, saccharide, or glycan sample having a free reducing end in 0.1-*M* sodium acetate, pH 5.0. Alternative coupling conditions that can be used for the modification reaction include 30% glacial acetic acid in DMSO (v/v) or acetic acid/pyridine (1:2, v/v), if the dendrimer is soluble in these solutions. The use of DMSO or pyridine often facilitates solubilization of a greater range of carbohydrates or glycans than aqueous buffers. The presence of acetic acid has been found to accelerate the reductive amination reaction when the organic solvent conditions are used (Bigge *et al.*, 1995). A well-ventilated fume hood should be used for all organic reactions. The concentration of the carbohydrate should be 5 to 100 µ*M* for glycans, but for the modification of dendrimers with other more abundant carbohydrates higher concentrations should be used. For modification of amine-containing dendrimer that are not soluble in the recommended organic solvents, the glycan or carbohydrate initially may be solubilized in DMSO and then an aliquot added to the aqueous reaction buffer.
2. Add to the glycan solution the amine-containing dendrimer to be labeled. Dendrimer concentrations of at least 10 mg/ml will help to increase the reaction kinetics, although the reaction proceeds slowly, mainly due to the limited quantity of open-form reducing sugar available for coupling at any given time.
3. In a fume hood, add to the reaction mixture a quantity of reducing agent (e.g., sodium cyanoborohydride or borane dimethylamine [BDA]) to give a final concentration of 1.0 *M*. The high concentration of reductant will aid in accelerating the reaction to completion. Cyanoborohydride is extremely toxic and should not be handled outside of a fume hood. Use proper protective clothing when handling such compounds.
4. When using nonaqueous reaction conditions, incubate for 1 to 2 h at 60 to 80°C. For reactions in an aqueous environment, the reaction may be carried out at room temperature or 37°C. In this case, the reaction time should be extended to

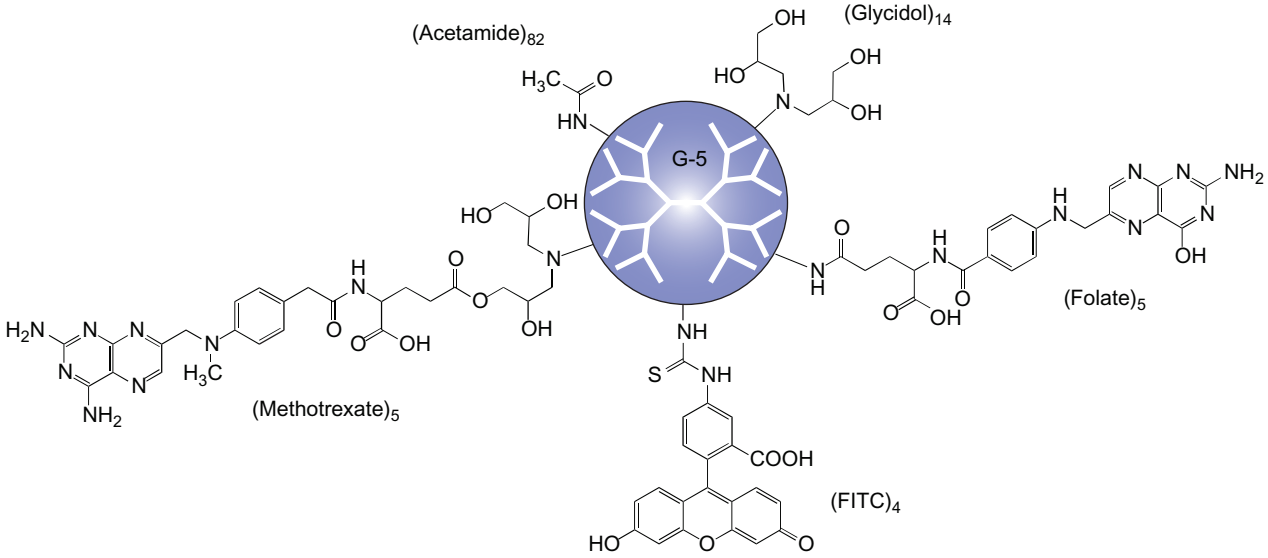

FIGURE 8.16 The creation of a tumor-targeting dendrimer conjugate can take advantage of the multivalent character of the dendrimer polymer. This figure illustrates the attachment of five different groups to an amine-containing dendrimer to produce a chemotherapeutic construct.

at least 24 h. Longer reaction times are not unusual when modifying carbohydrates by reductive amination at ambient temperature.

5. Purify the modified dendrimer from reactants and reaction by-products by dialysis, gel filtration, or ion-exchange chromatography.

Synthesis of other reactive groups on sugars for conjugation with amine-containing dendrimer also has been done with success. For example, André *et al.* (1999) used the *p*-isothiocyanato derivative of *p*-aminophenyl-β-D-lactoside to couple with the amine groups on a G-3 PAMAM dendrimer, forming isothiourea linkages between the sugar and dendrimer. Davis *et al.* (2005) used glycosyl derivatives containing the thiol-reactive group methanethiosulfonate to couple with dendrons modified with thioacetic acid to contain terminal thiol groups. This reactive functionality was again used to conjugate to thiol-containing proteins to create glyco-dendrimer-protein reagents. Woller and Cloninger (2001) used another isothiocyanate derivative of mannose to couple with amine-containing dendrimer of several different generations. Finally, Kensinger *et al.* (2004a) synthesized a thiopropionic acid derivative of galactose and coupled it to amine-containing dendrimer using the amide bond-forming agent HATU (Aldrich) in acetonitrile. The galactose functionalized dendrimers were used to study their binding to HIV-1 gp120 protein (Kensinger *et al.*, 2004b).

Conjugation of Carboxylate Organic Molecules to Amine-Containing Dendrimers

Amine-containing dendrimer molecules of various generations have been used as carriers for small organic molecules, such as chemotherapeutic agents or small-ligand, cell-targeting compounds, such as folic acid (Quintana *et al.*, 2002 Shukla *et al.*, 2003; Islam *et al.*, 2005; Arima *et al.*, 2012; Choi *et al.*, 2012). The presence of folic acid on the dendrimer surface allows the drug complex to bind with over-expressed folate receptors on certain tumor cells (Ross *et al.*, 1994). Adding a chemotherapeutic drug to the folate–dendrimer conjugate creates a toxic payload deliverable directly to the cancer cells *in vivo*.

Majoros *et al.* (2005) synthesized such dendrimer conjugates using the carbodiimide EDC to activate the carboxylate group of folic acid or methotrexate for reaction with the amines on the PAMAM dendrimer surface. A G-5 amine-containing dendrimer first was partially blocked by acetylation according to the previously described procedure. The result was that about 82 of the available amines were capped, leaving about 28 amines still free for coupling with other molecules. In some derivatives, a fluorescent probe (FITC) also was conjugated to the partially blocked dendrimers to provide a detectable tag for following binding to cells. Then both folic acid and methotrexate were conjugated to the labeled dendrimer in separate reactions to yield the final conjugate. Careful tuning of the molar ratios used during each reaction resulted in a modification level per dendrimer of four FITC labels, four folic acids, and five methotrexate groups. In some cases, glycidol also was used to block about 14 of the amine groups and form hydrophilic hydroxylated regions on the dendrimer surface to promote water solubility. Figure 8.16 illustrates the final conjugate composition with a G-5 dendrimer. Although the conjugate structure indicates a single glycidol monomer at each coupling site on the dendrimer, it is likely that some polymerization of glycidol

also occurs during the derivatization step (see Chapter 15, Section 2.1). These conjugates were extensively studied by HPLC to determine properties and modification levels (Islam *et al.*, 2005).

Hong *et al.* (2007) investigated the binding affinity of such folate-dendrimer derivatives toward the folate binding protein (FBP), typically over-expressed on cancer cells. Using SPR analysis, they were able to measure the binding constants of a series of folate–dendrimer conjugates containing different levels of folate modification (from 2 to 14 folates/dendrimer). The results indicate that the combined avidity of multiple folates on a single dendrimer enhanced the binding to FBP by up to 5 orders of magnitude (2500 to 170,000-fold enhancement). This is the first definitive study on the benefits of multivalent dendrimer drugs as compared to the same drug interactions individually in solution. Using this approach to drug targeting, Kukowska-Latallo *et al.* (2005) found that a dendrimer conjugate improved the therapeutic response toward tumor cells in animal models of human epithelial cancer.

Similar dendrimer conjugates for therapeutic application also have been designed for boron neutron capture therapy in the treatment of cancer (Barth *et al.*, 1994; Newkome *et al.*, 1994; Qualmann *et al.*, 1996). In one design, a G-3 PAMAM dendrimer was modified with folate and 12 to 15 polyhedral decaborate clusters (Alam *et al.*, 1989) along with an average of 1 to 1.5 PEG_{2000} units to make the therapeutic conjugate (Shukla *et al.*, 2003). The folate targeting component was not attached to the surface amines, but to the end of an additional amino–PEG_{800} unit. The PEG groups also facilitated increased *in vivo* half-life and prevented immediate uptake of the complex into the liver.

Most of these conjugation reactions involve amide bond formation between a small, organic molecule containing a carboxylate and the amines on the dendrimer surface. There are two potential reaction strategies for creating such conjugates: aqueous or nonaqueous reactions. For the coupling of folic acid to PAMAM dendrimers, Majoros *et al.* (2005) used an organic solvent environment according to the following protocol.

Protocol

1. Dissolve 33 mg of folic acid in a mixture of 24 ml DMF and 8 ml DMSO at room temperature.
2. Add a 14-fold molar excess of EDC (200 mg) with mixing.
3. React for 1 h at room temperature. The product of this reaction forms an amine-reactive ester on folate for coupling to the dendrimer.
4. Dissolve an amine-containing dendrimer in water at a concentration of at least 4.5 mg/ml. Majoros *et al.* (2005) used 403 mg of a partially acetylated G-5 dendrimer that contained 82 blocked amines and 28 available amines for coupling, dissolved in 90 ml of water.
5. Slowly add with mixing, the activated folic acid from step 3 to the amine-containing dendrimer solution to give a final molar ratio of folate-to-dendrimer of 5.5:1.
6. React for 1 h at room temperature with mixing.
7. Purify the modified dendrimer from excess reactants and reaction byproducts by dialysis against water or buffer.

The same type of modification with carboxylate molecules can be done in aqueous solution using EDC. If the ligand to be coupled only has a single carboxylate with no amines or other nucleophiles present, then the dendrimer and ligand may be dissolved at a similar molar ratio in aqueous buffer and EDC added to facilitate the coupling reaction.

Amine-containing dendrimers also have been used to quantify phosphorylated peptides for phosphoproteome analysis by mass spec (Tao *et al.*, 2005; for a review, see Nita-Lazar, 2011). In this novel application, proteins undergoing analysis are reduced and alkylated with iodoacetamide to block sulfhydryls, then trypsin digested. The peptides are then desalted and lyophilized. The dried peptides are methylated in methanolic HCl to eliminate interference by carboxylate groups and then the solvent is removed under vacuum. The mixture of blocked peptides next is reacted with a G-5 PAMAM dendrimer using 50-m*M* EDC and 100-m*M* imidazole in 0.2-*M* MES buffer, pH 6.0 (see the method described in Chapter 23, Section 2.1). The reaction activates the phosphoryl groups on the phosphorylated peptides, which in turn react with the amines on the dendrimers to create phosphoramidate linkages (Figure 8.17). The conjugated phosphopeptides can be separated from non-phosphorylated peptides by simple filtration and washing. Finally, the isolated phosphopeptides can be cleaved from the dendrimer using 10% TFA treatment and analyzed by mass spec.

Epoxy Activation of Amine-Containing Dendrimers

Epoxy groups can be formed on the surface of amine-containing dendrimers by reaction with either *bis*-epoxide compounds or epibromohydrin (or epichlorohydrin). Modification with these compounds forms terminal epoxide groups that can be used for subsequent conjugation with amine-, thiol-, or hydroxyl-containing ligands. Singh (1998) described a simple procedure using epibromohydrin to form an epoxy-activated PAMAM dendrimer for conjugation with thiol-modified alkaline phosphatase enzymes (Figure 8.18).

The following protocol is based on the method of Singh (1998). Other amine-containing dendrimers besides the PAMAM type, such as the PrioStar dendrimers from Starpharma may be used as well.

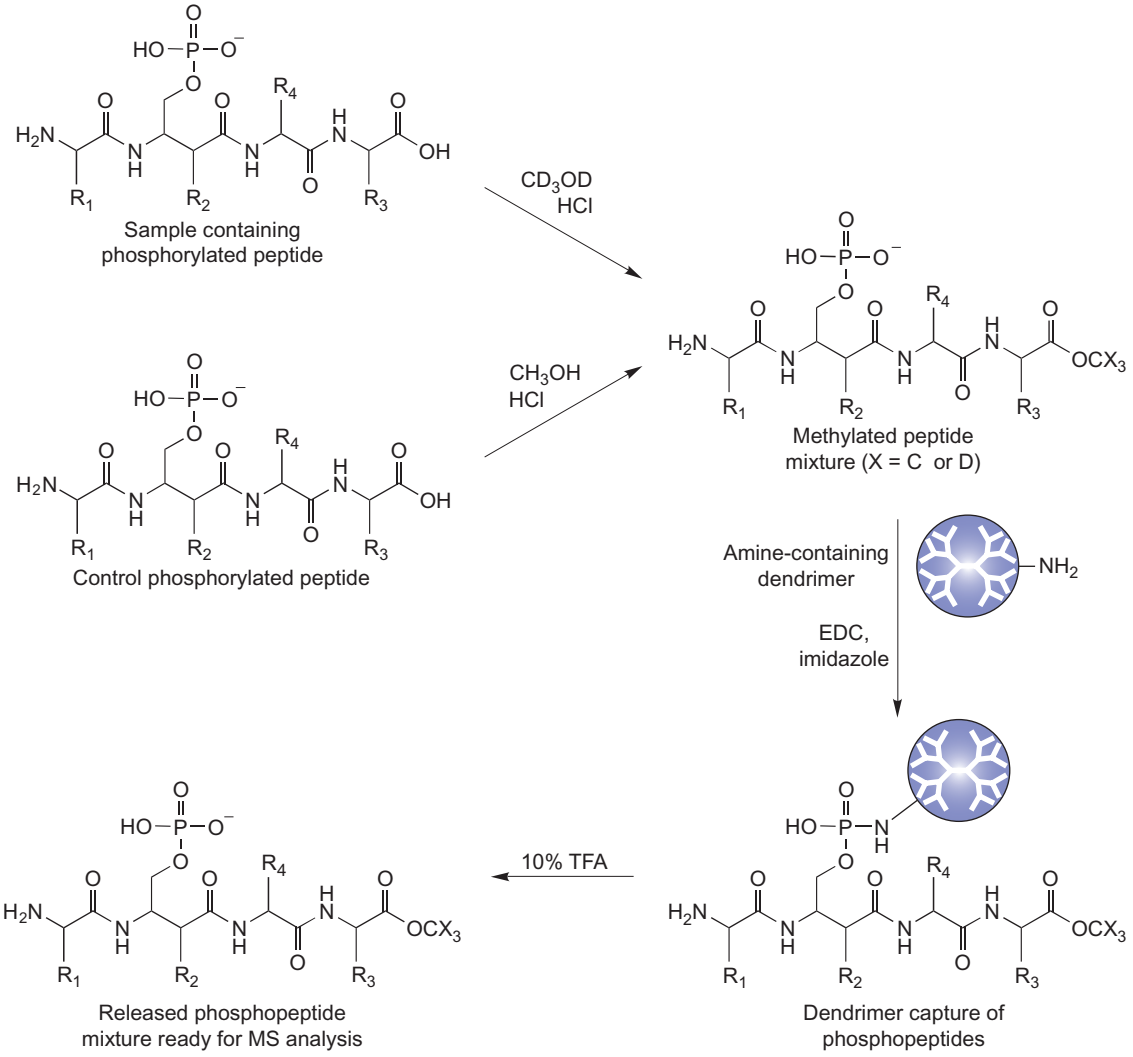

FIGURE 8.17 Phosphopeptides can be separated for mass spec analysis using an amine-containing dendrimer. A control sample and a test sample first are methylated to block their carboxylate groups and then mixed together in equal amounts. An amine-containing dendrimer then is used to capture the phosphorylated peptides by conjugation with the phospho groups using EDC and imidazole to form phosphoramidate bonds. After separation of the phosphopeptide–dendrimer conjugates using size exclusion chromatography, the phosphopeptides are cleaved off using TFA and analyzed by mass spec.

Protocol

1. Dissolve a dendrimer in 50% methanol/water at a concentration of at least 10 mg/ml. Singh (1998) used about 165 mg of a G-5 PAMAM dendrimer dissolved in 1 ml of the alcohol/water mixture. Use a fume hood for all operations.
2. Add 200 mg of sodium carbonate per ml of the dendrimer solution prepared in step 1 and a quantity of epibromohydrin equal to a 285-fold molar excess over the amount of dendrimer present. The large excess of reagent ensures that the amines get fully blocked during the reaction and will prevent any amines from crosslinking by reaction with the epoxy ends of the modified dendrimer.
3. React for 4 h with mixing in a fume hood.
4. Dilute the reaction mixture 10-fold with 50% methanol/water and purify the epoxy-activated dendrimer by repeated ultrafiltration using a membrane with a molecular weight cutoff able to retain the size of dendrimer being activated. Repeat the dilution and concentration steps until the filtrate is neutral in pH.
5. The epoxy-activated dendrimer may be conjugated to thiol-containing proteins by reaction in 50-m*M* sodium phosphate, pH 7.2. The reaction can be done at 4°C or at room temperature for 8 to 16 h to form thioether linkages.
6. Purify the conjugate by gel filtration to separate protein–dendrimer complexes from excess protein or dendrimer.

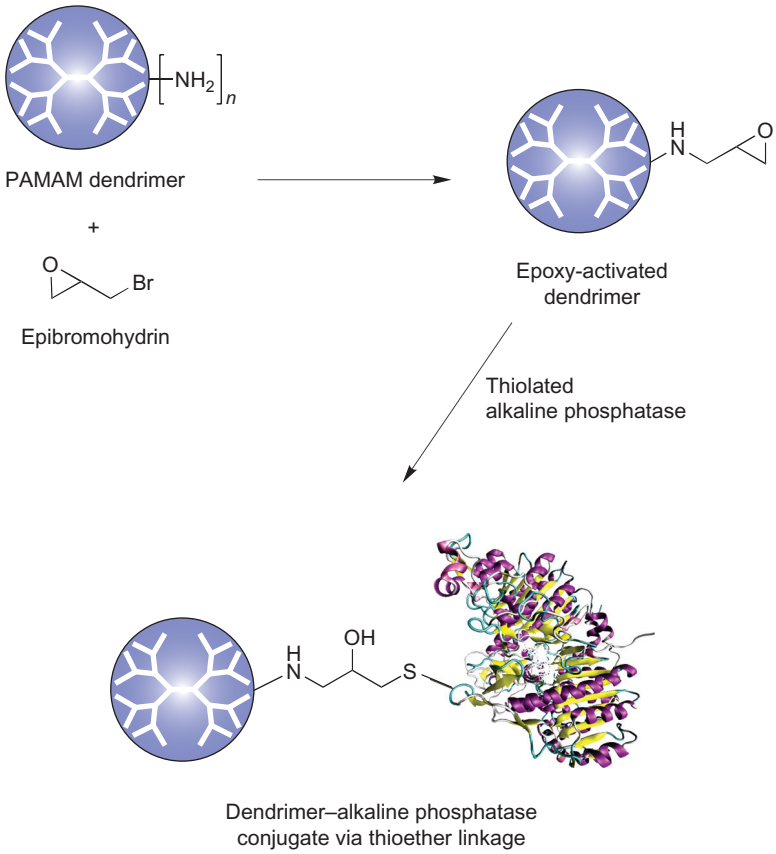

FIGURE 8.18 Amine-containing dendrimers can be activated with epibromohydrin to result in the formation of reactive epoxy groups on the dendrimer surface. This reactive intermediate then can be used to conjugate with thiol-containing proteins, such as thiolated alkaline phosphatase. The reaction results in the formation of a thioether bond.

Biotinylation of Amine-Containing Dendrimers

Amine-containing dendrimers can be modified to contain one or more biotin groups for interaction with avidin or streptavidin reagents. The polyvalent nature of a dendrimer permits the formation of a biotin multimeric structure for potential enhancement of detection in avidin–biotin assays. Since a biotin–dendrimer scaffold allows many biotin-binding proteins to dock simultaneously and form larger complexes, these conjugates can recruit more detection molecules to bind at the site of an analyte. This can have direct effect on the sensitivity of immunoassays, such as fluorescence detection, enzyme linked immunoadsorbent assays (ELISAs), and western blotting procedures.

This type of biotinylated dendrimer-based signal amplification technique has been done to increase the detection of genomic DNA in suspension arrays (Borucki *et al.*, 2005), wherein a DNA dendrimer was biotinylated multiple times and also modified to contain a targeting oligo sequence. The DNA dendrimer, which in that case was a construct consisting of partially hybridized oligonucleotide sequences branching out from a central core, was modified to contain as many as 850 to 900 biotin molecules on its surface along with at least one targeting oligonucleotide sequence. After genomic DNA was allowed to bind to a capture oligo on a fluorescence microparticle, the biotinylated dendrimer was added and it bound to the genomic DNA via hybridization with the targeting oligo. Finally, streptavidin–phycoerythrin detection conjugate was added and it then was bound to the biotin groups on the dendrimer (Figure 8.19). The resultant fluorescent signal was amplified beyond that possible using a simple biotinylated oligo directly.

A similar type of biotin-dendritic multimer also was used to boost sensitivity in DNA microarray detection by 100-fold over that obtainable using traditional avidin–biotin reagent systems (Stears, 2000; Striebel *et al.*, 2004). With this system, a polyvalent biotin dendrimer is able to bind many labeled avidin or streptavidin molecules that may carry enzymes or fluorescent probes for assay detection. In addition, if the biotinylated dendrimer and the streptavidin detection agent are added at the same time, then at the site of a captured analyte, the biotin–dendrimer conjugates can form huge multidendrimer complexes wherein avidin or streptavidin

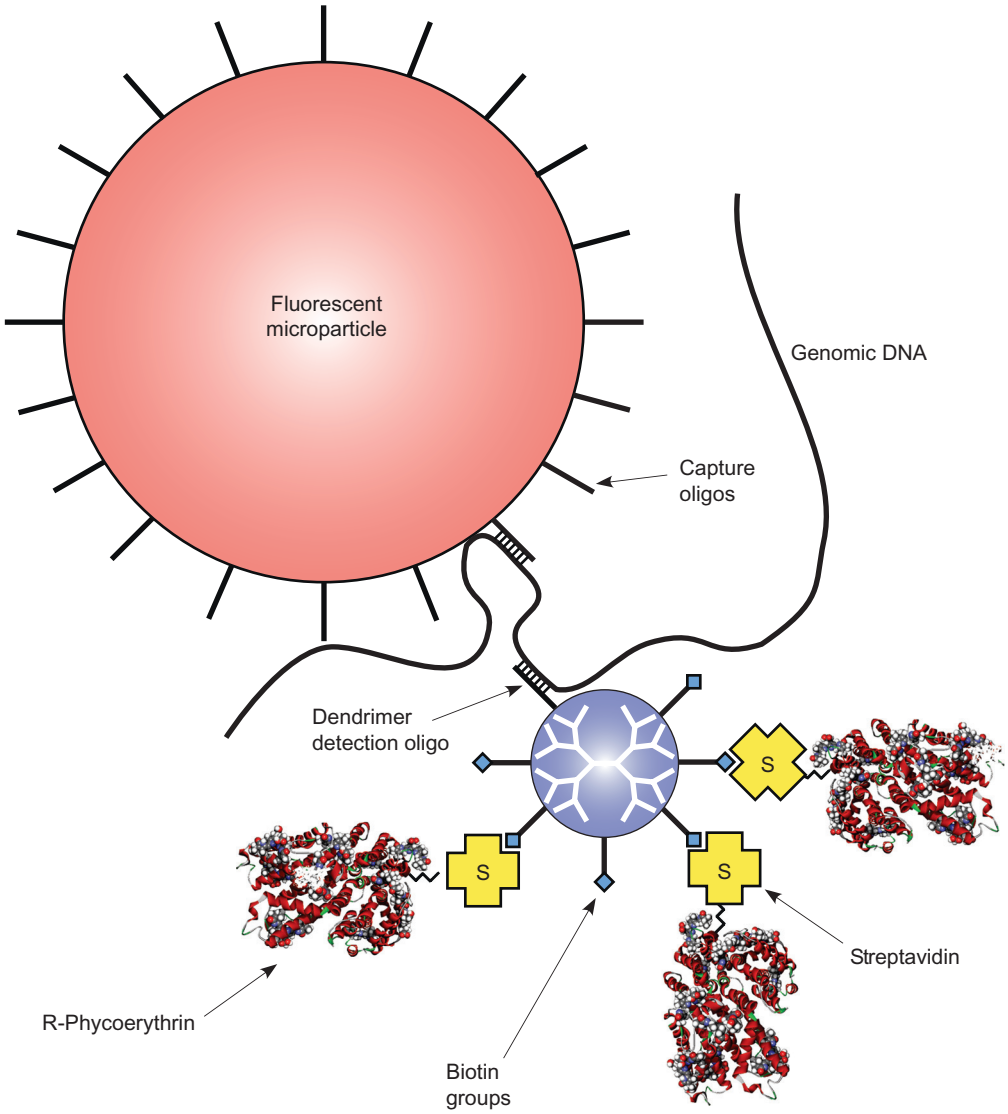

FIGURE 8.19 Biotinylated dendrimers can be used to enhance signals in assay procedures using the (strept)avidin–biotin interaction. In this example, a fluorescent microsphere containing capture oligos is able to interact with target DNA while a biotinylated dendrimer also containing detection oligo sequences binds to the genomic DNA target. The interaction of the dendrimer is detected using streptavidin–phycoerythrin conjugates, which are intensely fluorescent.

detection reagents bridge between more than one dendrimer. Thus, the use of multivalent biotin–dendrimers can become universal enhancers of DNA hybridization assays or immunoassay procedures.

Another example of an immunoassay enhancement using biotinylated dendrimers involves a novel detection technique called carbonylmetallo-immunoassay (CMIA). This technology involves the use of an NHS-4-pentynoate-(dicobalt hexacarbonyl) transition metal chelate labeling reagent or (n^5-cyclopentadienyl) iron dicarbonyl (n^1-*N*-maleimidato) group, which can be detected using Fourier transform infrared spectroscopy (Salmain *et al.*, 1991, 1992; Philomin *et al.*, 1994; Varenne *et al.*, 1992, 1995; Vessières *et al.*, 1999). These compounds can be coupled to amine groups on PAMAM dendrimers to yield amide linkages. Salmain *et al.* (2002) developed a dendrimer-based signal enhancement method to increase the sensitivity of the IR detection chelate. A G-4 PAMAM dendrimer containing 64 primary amine groups was labeled with NHS-biotin and the iron chelate to yield a complex containing 45 chelate groups and 4 biotins (Figure 8.20). The ratios in the final dendrimer conjugate were of course dependent on the molar ratios in the initial reaction mixture and could be controlled through careful planning of the conjugation process.

Biotinylated dendrimers also have been used to develop targeting conjugates for therapeutic use in

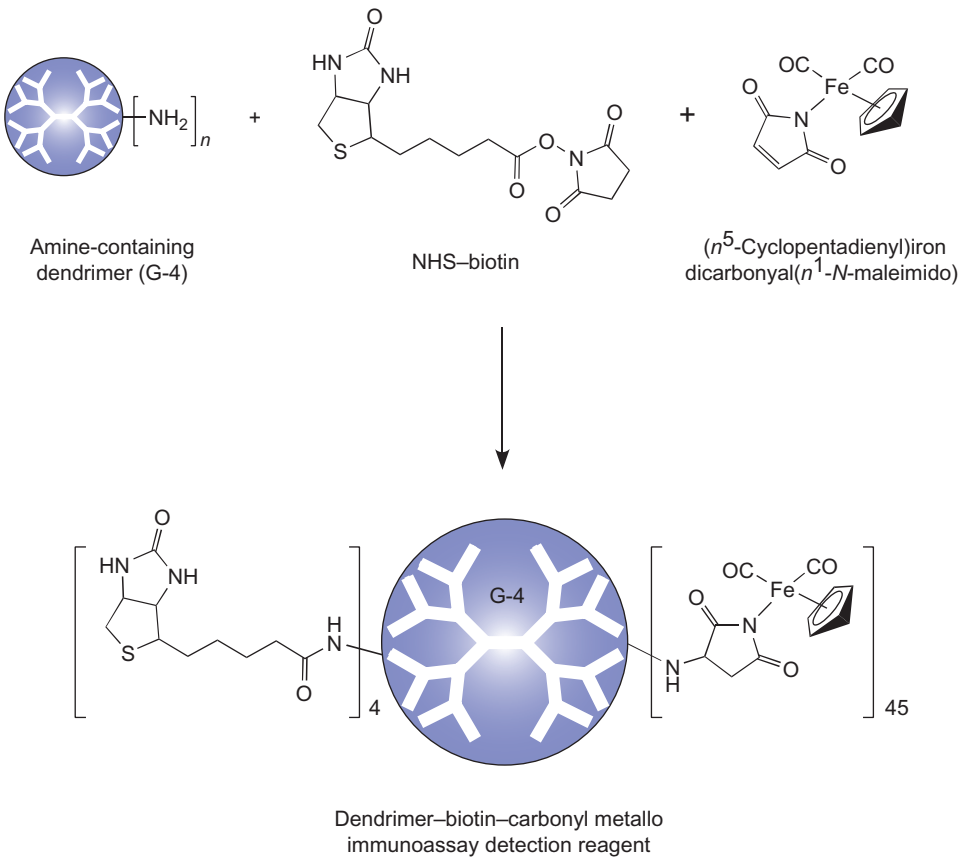

FIGURE 8.20 The multivalent surface of dendrimers can be used to couple biotin groups and labels for detection in immunoassays. One such conjugate was made by coupling NHS–biotin and a maleimido–iron chelate to an amine-containing dendrimer for use in an unique carbonyl metallo assay method.

targeting cancer cells. Wilbur *et al.* (1998) studied several different PAMAM generations in the coupling of a water soluble biotin analog with unique biotinidase insensitivity. The biotin–dendrimer conjugates were compared with biotin trimers or biotin tetramers in their ability to recruit radionuclide-labeled streptavidin complexes after binding to a streptavidin–antibody conjugate already bound to antigen on a tumor cell surface. It was found that the biotinylated dendrimer increased the number of radionuclide-streptavidin binding events by a factor of 4.

The efficiency of biotinylation also was determined relative to the size of the amine-containing dendrimer (Wilbur *et al.*, 1998). The reactions were performed in DMF with triethylamine added as a proton acceptor, so competing hydrolysis of the NHS ester on the biotin compound was not an issue. In reacting each generation of dendrimer with a large excess of biotinylation agent, it was found that G-0, G-1, G-2, and G-3 PAMAM dendrimers could all be completely biotinylated by modification of all of the pendent amine groups. Only when reaching the size of a G-4 dendrimer was the biotinylation yield less than the number of total amine groups present (51 of 64 possible amines modified). This indicates that, unlike with protein labeling, the reactivity and accessibility of available amines on dendrimers remain high even when working with mid-sized molecules.

Mamede *et al.* (2003) developed a biotinylated G-4 PAMAM dendrimer containing multiple DTPA chelating groups for use in radiotherapy of intraperitoneally disseminated tumors. The G-4 dendrimer was reacted with sulfo-NHS–LC-biotin at a molar ratio that resulted in approximately 2.5 biotin molecules per dendrimer. This conjugate then was conjugated with 2-(*p*-isothiocyanatobenzyl)-6-methyldiethylenetriaminepentaacetic acid to give about 52 DTPA chelating groups per dendrimer. Finally, the complex was loaded with radioactive ^{111}In and also incubated with avidin to result in two to three avidin molecules per dendrimer binding to the biotin groups on the surface. The positive charge of the avidin protein molecules facilitated entry into the tumor cells, while the radioactive cargo killed the cells. The use of dendrimers in cancer therapeutics, including biotinylated ones, has been recently reviewed (Guo and Shi, 2012).

The biotinylation of amine-containing dendrimer may be accomplished using either an organic reaction

environment or an aqueous medium. For modification of PAMAM dendrimers with a biotinidase-resistant biotin compound, Wilbur *et al.* (1998) performed the reaction in DMF with triethylamine as catalyst (proton acceptor). The following protocol illustrates this type of procedure using the biotinylation reagent NHS–PEG_4–biotin, which closely compares to the biotinidase insensitive compound used in the published procedure (also see Chapter 18, Section 1.3).

Protocol

1. In a fume hood, dissolve an amine-containing dendrimer in DMF at a concentration of at least 10 mg/ml with mixing. For the modification of a G-3 dendrimer, Wilbur *et al.* (1998) used approximately 240 mg of dendrimer dissolved in 10 ml of DMF. Other concentrations will work well in this procedure.
2. Add 15.7 µl of triethylamine (0.12 m*M*) to the dendrimer solution with mixing.
3. Dissolve a quantity of NHS–PEG_4–biotin (MW 588.67) in the dendrimer solution with mixing to bring the final reagent-to-dendrimer ratio in the reaction medium to at least 1.25 times greater than the molar amount of amines to be modified. To saturate completely a G-3 dendrimer initially containing 32 primary amine groups, add at least 8 mg of biotinylation reagent for each mg of dendrimer being modified. Using this molar ratio of biotin-to-dendrimer in the reaction will result in a high modification yield of all the amine groups on the dendrimer, especially for G-1 through G-3 size dendrimers. If a lower modification level is desired, then scale back the amount of biotinylation reagent added accordingly. Note: The most important consideration is optimizing the molar ratio of biotinylation reagent to dendrimer to obtain the desired modification level in the final conjugate. This entirely depends on the intended application of the biotinylated dendrimer, and a series of reactions containing different biotinylation ratios may have to be done to determine the best ratio to use.
4. React for a minimum of 1 h at room temperature with mixing. Longer reaction times may be used, particularly if a maximal modification level of biotin is desired.
5. Purify the biotinylated dendrimer by diluting it with an equal volume of water and then using dialysis, ultrafiltration, or size exclusion chromatography.

Another method that can be used to biotinylate an amine-containing dendrimer is to perform a similar reaction in aqueous buffer conditions. The following protocol is based on the methods of Tomalia *et al.* (1998) and Mamede *et al.* (2003).

Protocol

1. Dissolve 10 mg (0.7 µmol) of a G-4 PAMAM dendrimer in 1 ml of 0.1-*M* sodium phosphate, pH 9.0.
2. Add a 3-fold molar excess of biotinylation reagent over the molar quantity of dendrimer present. For the use of sulfo-NHS–LC-biotin (MW 556), this represents the addition of 2.1 µmol or 1.16 mg. This reaction ratio will result in a modification level of about 2.5 biotin groups per dendrimer. Other molar ratios also may be used, depending on the desired level of modification and the intended use for the conjugate.
3. React for 30 to 60 min at room temperature with mixing.
4. Purify the biotin-dendrimer using size exclusion chromatography on a desalting matrix or by use of ultrafiltration (e.g., centrifugal concentrators).

Fluorescent Labeling of Amine Dendrimers

The multivalent nature of dendrimers can be used to advantage for signal enhancement in numerous fluorescence detection schemes. A broad selection of hydrophilic organic fluorescent probes is available as amine-reactive derivatives (Chapter 10), many of which may be used to form conjugates with amine-containing dendrimers. Coupling multiple fluorescent labels to each dendrimer molecule creates a complex with increased luminescence or brightness for use in fluorescence assays (Tomalia *et al.*, 1998). Even fluorescent environmental probes have been found to have enhanced activity if conjugated to dendrimer core structures (Albertazzi *et al.*, 2011). In addition, combining a fluorescently labeled dendrimer with the ability to link it to targeting molecules, such as antibodies or streptavidin, provides a reagent system having superior detection capability compared to the use of fluorescently labeled proteins. Manduchi *et al.* (2002) demonstrated that a fluorescent dendrimer could be a more sensitive detection reagent than the use of directly labeled primary antibodies or indirect immunoassay methods using labeled secondary antibodies for microarray assay methods.

For instance, a dendrimer easily can be coupled with a large number of fluorescent dyes and still provide additional coupling sites for biotinylation. The only limitation to the number of fluorescent modifications is if fluorescence quenching starts to take place, in which case no further modifications will result in increased signal. A series of such conjugates using different levels of fluorophore modification should be done to determine the optimal level of dye-to-dendrimer before quenching occurs.

A fluorescent, biotinylated dendrimer of this type then can be used in a (strept)avidin–biotin assay to

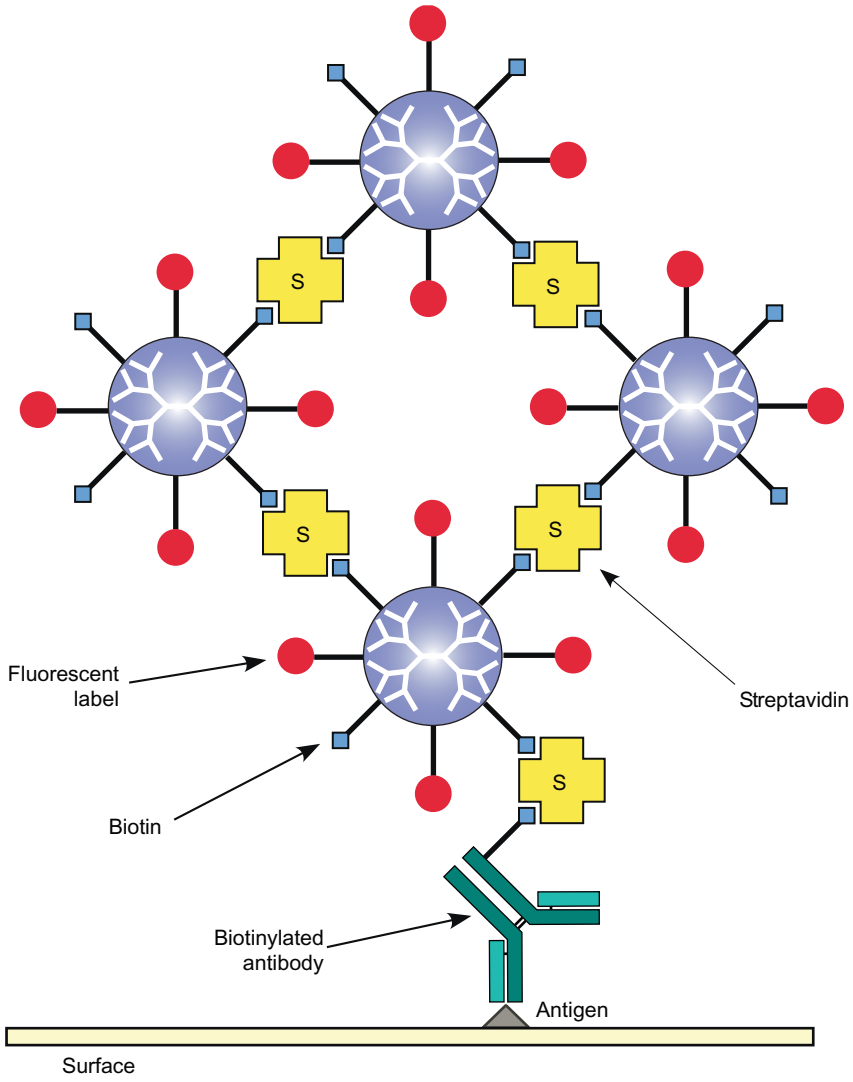

FIGURE 8.21 Dendrimers that are fluorescently labeled as well as biotinylated create enhanced detection reagents for use in (strept)avidin–biotin-based assays. Large complexes containing multiple fluorescent dendrimers can bind to antigens and form a highly sensitive detection system that exceeds the detection capability of fluorescently labeled antibodies.

detect analytes. Having more than one biotin group on such a conjugate allows it to interact with multiple streptavidin molecules, thus forming a megameric complex with a biotinylated primary antibody bound at the site of an analyte. In this way, many more fluorescent molecules are recruited to the point of detection than is possible using directly labeled proteins (Figure 8.21). In fact, for detection of DNA targets, dendrimer-based fluorescence enhancement methods have been identified as an important route to increasing signal and avoiding polymerase chain reaction (PCR) or other amplification methods (Nilsen *et al.*, 1997; Vogelbacker *et al.*, 1997; Kricka, 1999).

Fluorescent labels on dendrimers also are convenient to track the interaction of functionalized dendrimers for cell targeting. After the conjugation of targeting groups such as antibodies or folic acid on a dendrimer along with radiolabels or toxic components, there are still amine groups available to add fluorescent labels for detection purposes (Minard-Basquin *et al.*, 2003; Patri *et al.*, 2004; Thomas *et al.*, 2005). Such complexes may be assessed as to their specificity by monitoring the fluorescent signal as the dendrimers bind to target cells.

Dendrimers bearing certain fluorescent molecules attached on their periphery have been shown to be environmentally sensitive probes for the presence of certain metal ions or to changes in pH (Balzani *et al.*, 2000; Paola *et al.*, 2005). In addition, PAMAM dendrimers modified with the relatively hydrophobic dye Oregon Green 488 were shown to be a more effective transfection agent for anti-sense oligonucleotides than the dendrimer alone—plus the complex could be tracked within the cell due to the fluorescence of the dye (Yoo and Juliano, 2000).

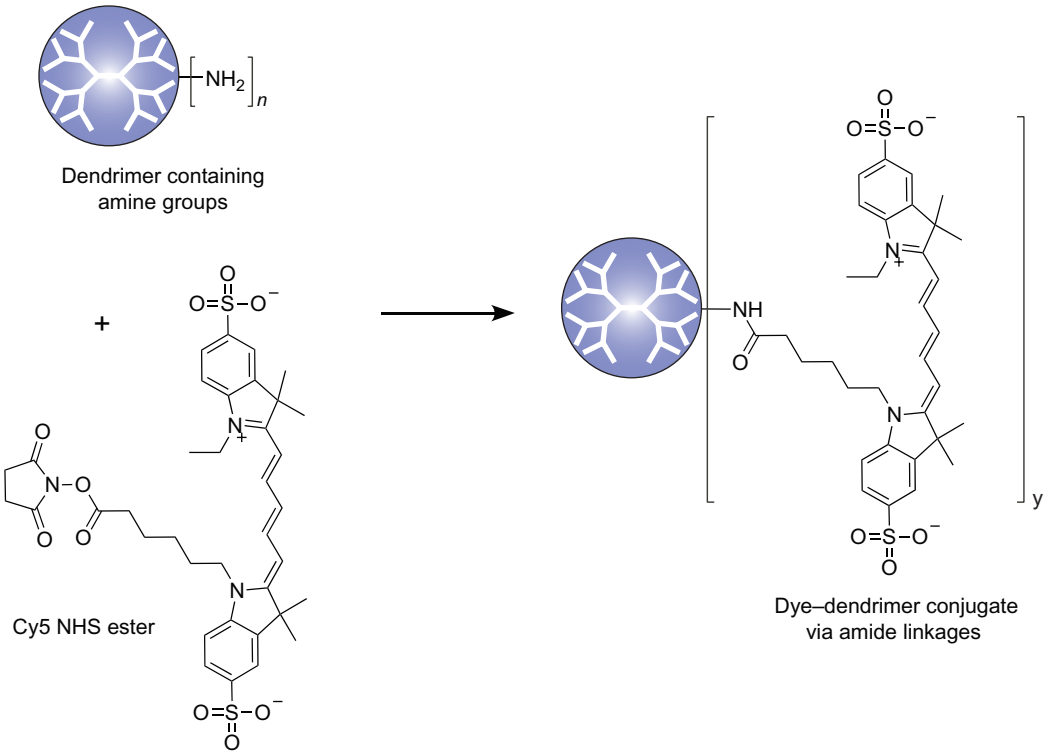

FIGURE 8.22 Fluorescent dyes such as an amine-reactive Cy5 derivative can be coupled to amine-containing dendrimer at relatively high substitution levels to create intensely fluorescent detection agents. If the dendrimer also is derivatized to contain an affinity group or a targeting group then specific fluorescent detection at high sensitivity can be realized.

Specific procedures for the conjugation of fluorescent labels to amine-containing molecules can be found in Chapter 10. The following protocol describes one such reaction for an amine-containing dendrimer with the fluorescent cyanine reactive probe, DyLight 650 NHS ester. This dye has spectral properties that are nearly identical to the original Cy5-type dye, but the DyLight one has negatively charged sulfonate groups, which makes the resultant compound extremely water soluble. Coupling reactions with other fluorescent dyes may be performed similarly, but in each case optimization of the molar ratio of dye-to-dendrimer should be performed to produce the best conjugate for its intended application. Note that higher levels of dye incorporation do not necessarily correlate to brighter fluorescent conjugates, because fluorescence energy transfer and quenching may occur between dye molecules as the density of dyes increases on the dendrimer surface. However, it appears that fluorescent dye substitution on dendrimers can be done at a higher density than on proteins before such quenching effects occurs. Figure 8.22 illustrates the reaction between an amine-containing dendrimer and a disulfonated Cy5 NHS ester derivative. Although the exact structure of the DyLight 650 NHS ester is not published, it is similar to the known Cy5 structure but contains additional sulfonate groups to increase water solubility.

Protocol

1. In a fume hood, dissolve the DyLight 650 NHS ester at a concentration of 10 mg/ml in dry DMF.
2. Dissolve the amine-containing dendrimer to be modified in DMF or buffer (50-m*M* sodium borate, pH 8.5) at a concentration of at least 10 mg/ml. Avoid the use of amine-containing buffers for an aqueous reaction, such as Tris or imidazole, as these will react with the NHS ester on the dye and prevent conjugation to the dendrimer. For reactions done in organic solvent, add triethylamine to a final concentration of 1.25-times greater than the amount of reactive dye to be added to the solution.
3. Add a quantity of the DyLight 650 dye to the dendrimer solution to provide at least a 1.25-fold molar excess of dye over the amount of dendrimer present (for nonaqueous reactions) or a 6- to 15-fold molar excess for aqueous reactions. Mix well to dissolve. The optimal amount of dye added should be determined experimentally by preparing a series of conjugates using different molar ratios of dye-to-dendrimer.
4. React for 1 h at room temperature with mixing.
5. Remove unreacted dye and reaction byproducts from the modified dendrimer by gel filtration or dialysis, using a molecular weight cutoff suitable for the size of the dendrimer.

3. DENDRIMER–CHELATE DERIVATIVES FOR IMAGING APPLICATIONS

Imaging agents consisting of metal chelating compounds have been used extensively for the modification of targeting agents for the *in vivo* detection of specific cells, organs, or vascular systems. The proper chelating group can coordinate securely a radioactive element or a contrast-enhancing agent, which can be imaged using radio-imaging techniques or magnetic resonance imaging (MRI), respectively. Many such polydentate chelating agents are described in Chapter 12, Section 1. These compounds are designed to have bifunctional characteristics in that one end is reactive for coupling to another molecule and the other end contains the chelating group.

The polyvalent nature of dendrimers has been investigated as vehicles for carrying multiple chelator groups to enhance signals in various imaging applications (Barthand Soloway, 1994; Yoo *et al.*, 1999; Kobayashi *et al.*, 2000, 2001; Sato *et al.*, 2001; Klemm *et al.*, 2012). In addition, in certain chelate–dendrimer constructs, excess amines on the dendrimer surface can aid in the cellular uptake process through charge-mediated endocytosis.

Roberts *et al.* (1990) conjugated porphyrins to PAMAM dendrimers as carriers to link them to antibody molecules for *in vivo* targeting. The porphyrin derivative was a *N*-(4-nitrobenzyl)-5-(4-carboxylphenyl)-10,15,20-tris (4-sulfophenyl)porphine containing one carboxylate group, which could be coupled to the amine groups on the dendrimer using the EDC/NHS method to form an amide bond. This porphyrin compound was effective at chelating copper ions, especially ^{67}Cu, which has nuclear decay properties ideal for potential use as a chemotherapeutic agent.

One of the more common chelating groups used for imaging applications is diethylenetriamine pentaacetic acid (DTPA). This compound is available in amine-reactive form as the anhydride or as a isothiocyanatobenzyl derivative, such as 2-(*p*-isothiocyanatobenzyl)-6-methyldiethylenetriaminepentaacetic acid chelate (1B4M; MW 555) (Kobayashi *et al.*, 1999). There are various isothiocyanatobenzyl-DTPA derivatives available that avoid conjugation of one of the chelator's carboxylate groups, which would be necessary using the anhydride form (Mirzadeh *et al.*, 1990; Brechbiel and Gansow, 1991; Behr *et al.*, 1999; Michel *et al.*, 2002; Brouwers *et al.*, 2003; Macrocyclics, Inc.). Any of these derivatives can be used to modify an amine-containing dendrimer to contain multiple chelating groups on its surface (Figure 8.23). Mamede *et al.* (2003) used the SCN-Bzl-DTPA compound 1B4M to modify a biotinylated G-4 PAMAM dendrimer to contain approximately 52 chelating group substitutions. The conjugate then was loaded with ^{111}In and complexed with avidin for investigation of its use for radiotherapy applications.

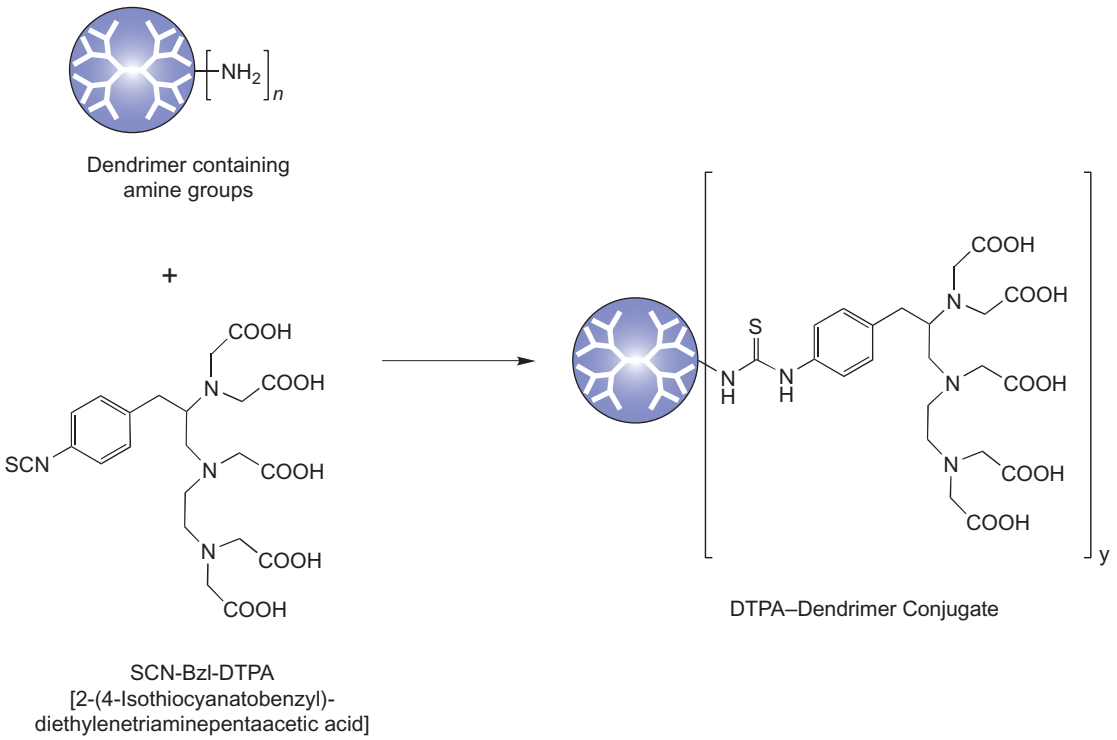

FIGURE 8.23 Chelating groups such as the isothiocyanate derivative of DTPA can be used to create multivalent chelating complexes with amine-containing dendrimer. Such complexes are able to coordinate multiple metal ions for detection, imaging, or radioimmunotherapy purposes.

Kobayashi *et al.* (2003) similarly prepared a DTPA-modified PAMAM dendrimer using the same isothiocyanate derivative for use in MRI imaging. A G-8 amine-dendrimer was reacted with a 1024-fold excess of chelating compound, resulting in a heavily loaded complex. In this case, the resultant conjugate was charged with ^{153}Gd to create a high-intensity contrast agent for *in vivo* imaging use in animals.

The following protocol for the modification of an amine-containing dendrimer with an SCN-Bzl-DTPA chelator is based on the literature references previously cited. Dendrimers of other generations will work well in this procedure provided that the molar ratios of reactants are adjusted for the size of dendrimer being used and the substitution level desired.

Protocol

1. Dissolve 10 mg of a G-4 amine-containing dendrimer in 1 ml of 0.1-*M* sodium carbonate buffer, pH 9.0.
2. Add a quantity of the SCN-Bzl-DTPA bifunctional chelating agent to obtain the desired molar excess of label over the amount of dendrimer present. The optimal ratio may be determined experimentally by preparing a series of dendrimer–chelate conjugates using different molar ratios and choosing the one that works the best in the intended application.
3. React for at least 1 h at room temperature with mixing. Some reactions have been done for up to 24 h at elevated temperatures (e.g., 40°C).
4. Purify the DTPA–dendrimer using dialysis, size exclusion chromatography, or spin-tube concentrators having a molecular weight cutoff of 5000 Daltons.

Other chelate–dendrimer constructs may be prepared using alternative bifunctional chelating agents according to Chapter 12, Section 1.

4. DENDRIMER DERIVATIVES AS SURFACE MODIFICATION AGENTS

The extremely branched nature of dendrimers provides multiple functionalities for creating high-capacity surfaces for coupling affinity molecules. The presence of numerous pendent groups on dendrimers can be used to advantage both in facilitating attachment to the surface and in providing a biocompatible coating for protein coupling. For instance, dendrimer modification of gold surfaces, both planer and nanoparticle, have the potential to create a matrix for high-density ligand coupling and low nonspecificity in assays. However, the dendrimer type and the characteristics of the pendent functionalities come into play in forming the optimal surface environment. PAMAM or amine-containing dendrimers of other types could result in relatively high nonspecific binding, particularly if unmasked terminal amines provide sites for charge interactions with other proteins (Yoon *et al.*, 2002; Hong *et al.*, 2003a, 2004).

Amine-containing dendrimers also can be used to pattern biological molecules on gold surfaces (Hong *et al.*, 2003b). In this application, PAMAM dendrimers were printed onto a SAM surface prepared using 11-mercaptoundecanoic acid to create sites for linking biomolecules. The carboxylate groups on the termini of the decanoic acid groups were activated with carbodiimide (EDC) and petafluorophenol to create reactive PFP esters (Chapter 3, Section 1.14). A PAMAM dendrimer solution in methanol (0.7 n*M*) was printed onto this activated SAM surface by contact printing. Reaction between the PFP esters on the SAM molecules and the amines on the PAMAM molecules covalently coupled the dendrimers to the surface via amide bond linkages. The dendrimers then were biotinylated with sulfo-NHS–biotin, washed, and allowed to interact with fluorescently labeled avidin, which was bound to the surface through interaction with the biotin groups. The fluorescent label was used to detect the bound protein and assess the efficiency of dendrimer surface functionalization.

Alternatively, PAMAM dendrimers can be linked to glass surfaces containing aldehyde functionalities through Schiff base formation and reductive amination using sodium cyanoborohydride. Hong *et al.* (2003b) patterned dendrimers on aldehyde slides and then blocked excess aldehyde groups using a 2-h incubation with 1-*M* 2-(2-aminoethoxy)ethanol. The result was covalently linked dendrimers on the slides containing an abundance of dendritic amines for further conjugation.

Hong *et al.* (2004) also found that modification of PAMAM dendrimers with a short PEG linker arm could act to reduce nonspecificity caused by the amines on the dendrimer modified surface. An azido-PEG_3-amine spacer was activated with nitrophenyl carbamate to yield an activated intermediate that could be used to modify the amines on the dendrimer (Figure 8.24). Reaction at high molar ratio resulted in about 61 PEG–azido spacers on the dendrimer. Reduction of the azido group to an amine using triphenylphosphine in THF provided the dendrimer–PEG–amine derivative for surface modification. The added presence of the PEG spacer arm reduced nonspecific binding to the dendrimer surface despite the fact that both the PAMAM and PEG-modified dendrimer both had terminal amino groups present. Another bioconjugation route to using this azido–PEG–dendrimer is to make an alkyne-containing protein or ligand and couple it to the modified dendrimer using click chemistry. The reaction of an azide with an alkyne in the presence of Cu(I) results in a cycloaddition reaction, which forms a triazole ring. See Chapter 17, Section 5, for more details on the click reaction.

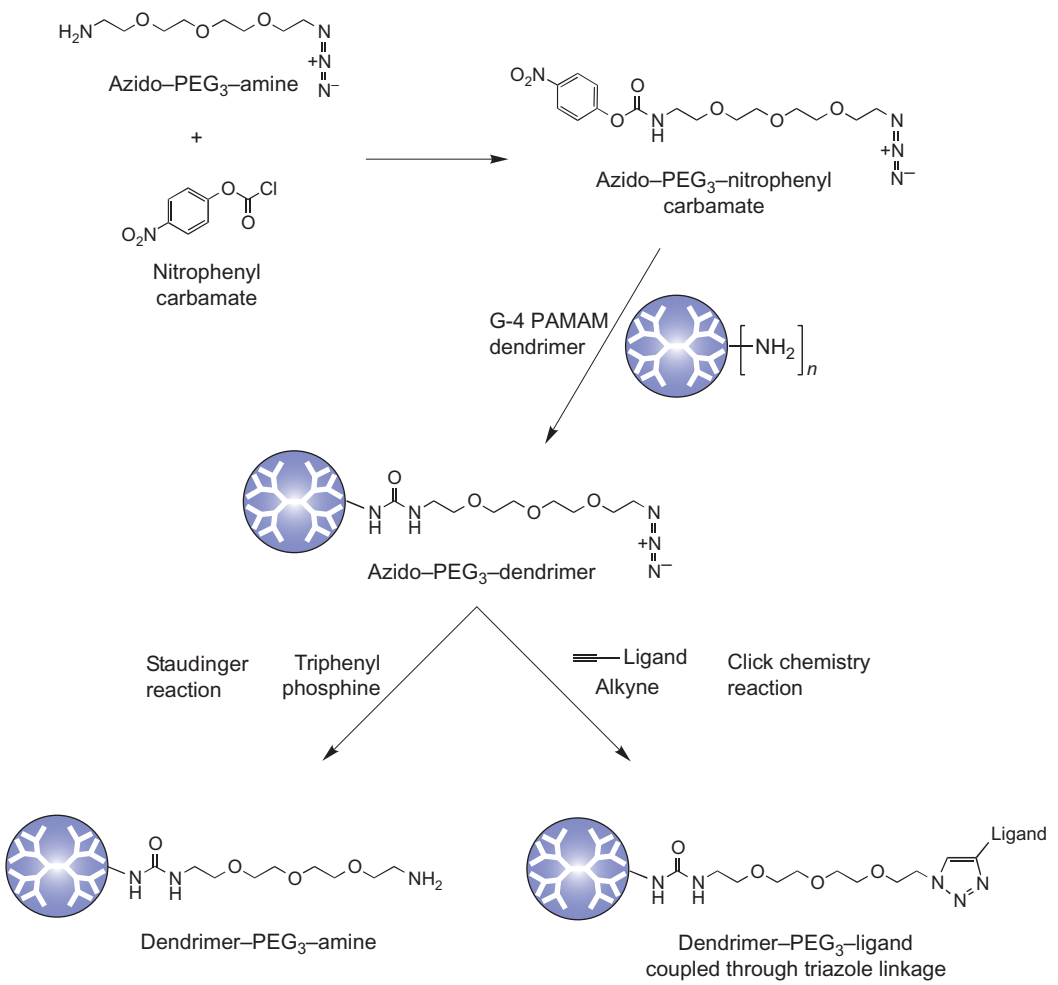

FIGURE 8.24 Azido–PEG–amine linkers can be coupled to amine-containing dendrimers by formation of an intermediate reactive nitrophenyl carbamate group. This compound then can be reacted with the amines on a dendrimer to form an azido–dendrimer derivative that can be used in chemoselective ligation strategies. The azide groups can be reacted with alkyne derivatives in a click chemistry reaction to couple ligands through a triazole linkage. Alternatively, the azido groups can undergo a Staudinger reaction with a phosphine compound to give the amino–PEG–dendrimer derivative. In addition, a Staudinger ligation reaction can be done using a phosphine derivative that would result in a covalent amide bond linkage (see Chapter 17, Section 4).

In another interesting route to creating dendrimer-functionalized surfaces, Pathak *et al.* (2004) activated the silanol groups on glass slides using CDI (Chapter 4, Section 3). The resultant reactive imidazole carbamate groups could be coupled to amine-containing dendrimers to form covalent carbamate linkages directly to the surface. Studying the effect of surface modification with generations 1 to 5 of a series of poly(propyleneimine) dendrimers resulted in the conclusion that dendrimers of G-3 size and above created surfaces of very high binding activity for coupling affinity ligands, with a G-4 dendrimer giving the greatest binding potential. This method may provide an excellent modification strategy for immobilizing affinity ligands onto planer and spherical silica surfaces. Once the amine-containing dendrimer surface was created, coupling proteins to it was done using the heterobifunctional crosslinker, sulfo-GMBS, which formed a thiol-reactive surface.

Benters *et al.* (2002) used three different coupling strategies to coat glass slides with amine-containing dendrimers for subsequent immobilization of oligonucleotides for preparing DNA microarrays. Cleaned slides were initially modified with 3-aminopropyltriethoxysilane (APTS) or glycidyloxypropyltrimethoxysilane (GOPTS) to create functional groups for further modification. The APTS-modified slides subsequently were reacted either with glutaric anhydride to form terminal carboxylate groups or with 1,4-phenylenediisothiocyanate (PDITC) to create reactive isothiocyanate groups on the surface. The carboxylate-containing slides were activated using the carbodiimide DCC along with NHS in DMF to form reactive NHS ester groups for coupling the amine-containing dendrimer.

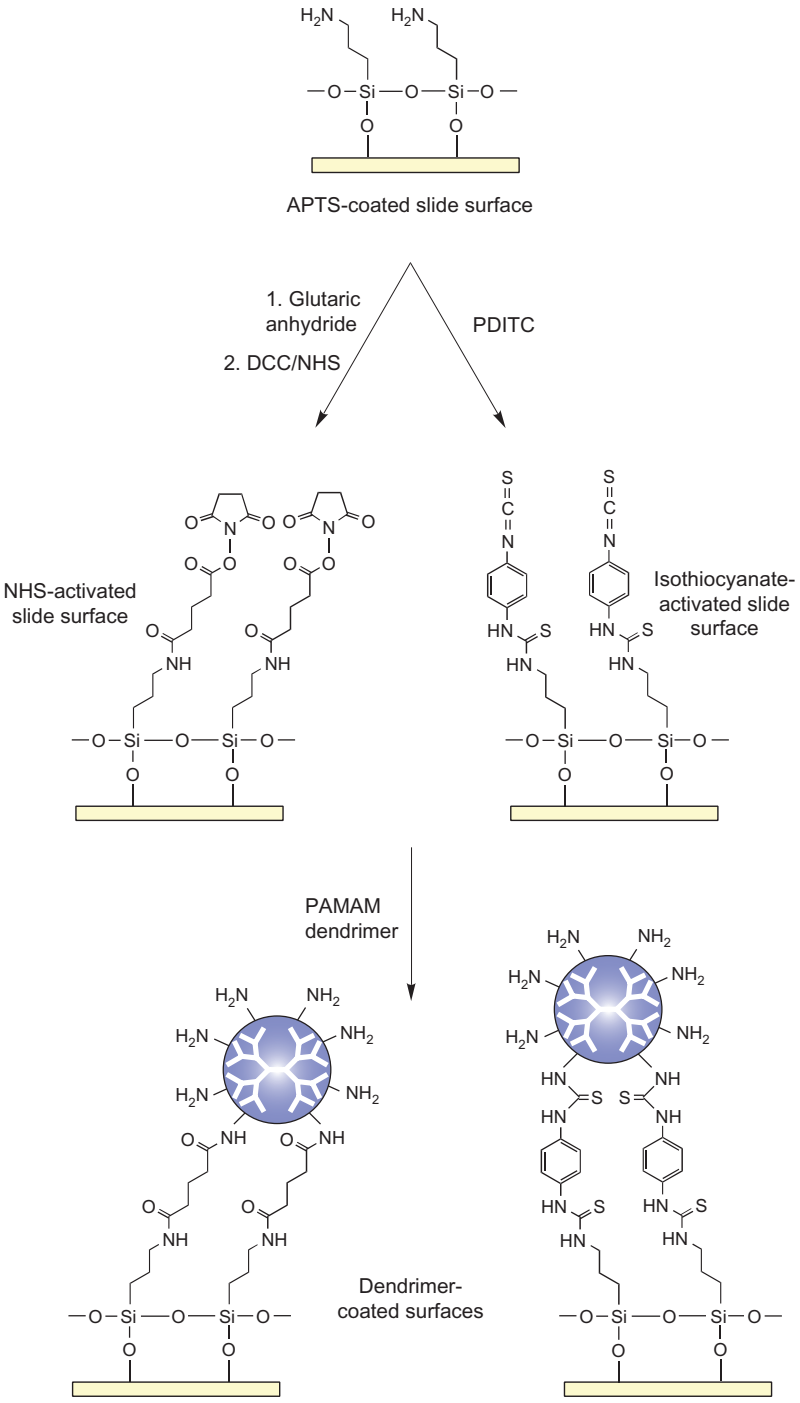

FIGURE 8.25 The multivalent nature of dendrimers can be used to add increased functionality to surfaces. Aminopropyl silane surfaces can be activated with either PDITC or through use of a cyclic anhydride plus DCC/NHS to give amine-reactive surfaces. These reactive surfaces can be used to couple amine-containing dendrimer to provide a high density of amine groups on the surface for further bioconjugation.

G-4 PAMAM dendrimers were attached to each of the three activated slides using a 100-mg/ml solution in methanol. The result formed covalently attached dendrimer layers on the slide surfaces, which then were again activated for the coupling of oligonucleotides. The dendrimer activation process was similar to that of the APTS surface to form reactive NHS esters. The dendrimers first were modified with glutaric anhydride and then activated using DCC and NHS in DMF. This process formed amine reactive NHS esters on the dendrimers, which then could be used to immobilize directly 5′-amine modified oligos (Figure 8.25).

Dendrimer-coated slides prepared using the methods of Benters *et al.* (2002) were found to provide significantly greater signal in fluorescent DNA hybridization assays than conventional slides prepared by coupling DNA directly to silane-or poly-L-lysine-modified surfaces. Clearly, dendrimers provide a 3D surface with greater functionality and biocompatibility for producing high-activity arrays.

Le Berre *et al.* (2003) also investigated the use of dendrimers to provide enhanced coupling capability and increased signal for DNA microarrays. In this application, the dendrimers consisted of a core of hexachlorocyclo-triphosphazene ($N_3P_3Cl_6$), which terminated in aryl aldehyde groups on the surface (Launay *et al.*, 1994, 1997; Slomkowski *et al.*, 1999). A G-4 aldehyde dendrimer containing 96 pendent aldehydes was coupled to a slide surface after modification with APTS to contain amines. Multiple Schiff base interactions with the amine groups on the derivatized slide effectively immobilized the dendrimers. Next, the spotting of amine-modified DNA to the aldehyde-dendrimer surface with overnight incubation followed by reduction with sodium cyanoborohydride resulted in covalently linking both the dendrimers to the surface and the oligos to the aldehyde groups through secondary amine bonds. A comparison of the dendrimer-coupled DNA slides to 11 commercially available activated glass slides indicated that the dendrimer slide provided among the highest fluorescence intensities in hybridization assays and 10- to 100-fold higher detection sensitivity than conventional slides.

Dendrimers also can provide increased capacity to immobilize capture antibodies for use in ELISA assays. Bosnjakovic *et al.* (2012) coupled PAMAM dendrimers to microplate wells using a PEG-based spacer arm and then used the amino groups on the dendrimer to couple the antibodies. The dendrimer-based immunoassay platform provided enhanced capture and detection for tumor necrosis factor-alpha cytokine as compared to normal ELISA capture plates prepared by simple adsorption of the antibody onto the surface.

5. DENDRIMER FLUORESCENT QUANTUM DOTS

Dendrimers can be used to effectively coat and passivate fluorescent quantum dots to make biocompatible surfaces for coupling proteins or other biomolecules. In addition, the ability of dendrimers to contain guest molecules within their 3D structure also has led to the creation of dendrimer–metal nanoclusters having fluorescent properties. In both applications, dendrimers are used to envelop metal or semiconductor nanoparticles that possess fluorescent properties useful for biological detection.

Huang and Tomalia (2005) used PAMAM dendrimers to coat gold nanoparticles or CdSe/CdS core/shell fluorescent quantum dots by preparing a disulfide-core dendrimer (using cystamine). The dendrimer was then succinylated to create terminal carboxylate groups, its core reduced with DTT, and the thiol dendron used to modify quantum dots by dative bonding to the particle surface. The result was an organized polymeric coating on the gold particles or quantum dots that terminated in multiple carboxylate groups for conjugation of biomolecules (Figure 8.26). The negative charges on the dendron terminals provided charge repulsion to maintain the colloidal stability of the small nanoparticles in solution, while the polyvalent nature of the dendrons made available an abundance of coupling sites for conjugation.

Testing of G-1, G-2, and G-3 dendrimers in this application provided insight into the density of surface modification needed to passivate completely the particles and prevent aggregation. The G-1 dendron was insufficient in this regard, but both the G-2 and G-3 dendrons were big enough to create a surface barrier, which resulted in excellent colloidal stability of the particles in solution.

Zheng and Dickson (2002) created a new type of fluorescent dendrimer construct by sequestering small nanoclusters of silver within hydroxyl-terminated G-2 or G-4 PAMAM dendrimers (16 hydroxyls on G-2 and 64 hydroxyls on G-4). The internal structure of a dendrimer is known to interact with charged silver ions in solution (Varnavski *et al.*, 2001). Without adding a reducing agent, such as sodium borohydride, which is typically used to form silver nanoparticles, it was discovered that the silver ion dendrimer complex could be photoactivated to cause silver reduction to elemental silver within the internal structure of the dendrimers. The resulting very small dendrimer/silver nanoclusters displayed strong fluorescence with absorption bands at 345 nm and 430 nm and a broad emission curve extending from slightly less than 500 nm to nearly 700 nm. By contrast, if borohydride reduction was used, larger silver nanoparticles were formed (3–7 nm) within the dendrimers which displayed no fluorescence characteristics but only strong plasmon absorption at 398 nm. Thus, small fluorescent nanoclusters containing only up to about 8 atoms of silver were formed by photoactivation and stably sequestered within the G-2 or G-4 interior. These properties were in agreement with studies on silver clusters of 2 to 8 atoms, which have been shown to have size-dependent fluorescence characteristics (Tani and Murofushi, 1994).

The broad emission band displayed by these silver/dendrimer constructs actually was found to consist of five overlapping fluorescent peaks caused by individual silver/dendrimer complexes. Each of these complexes

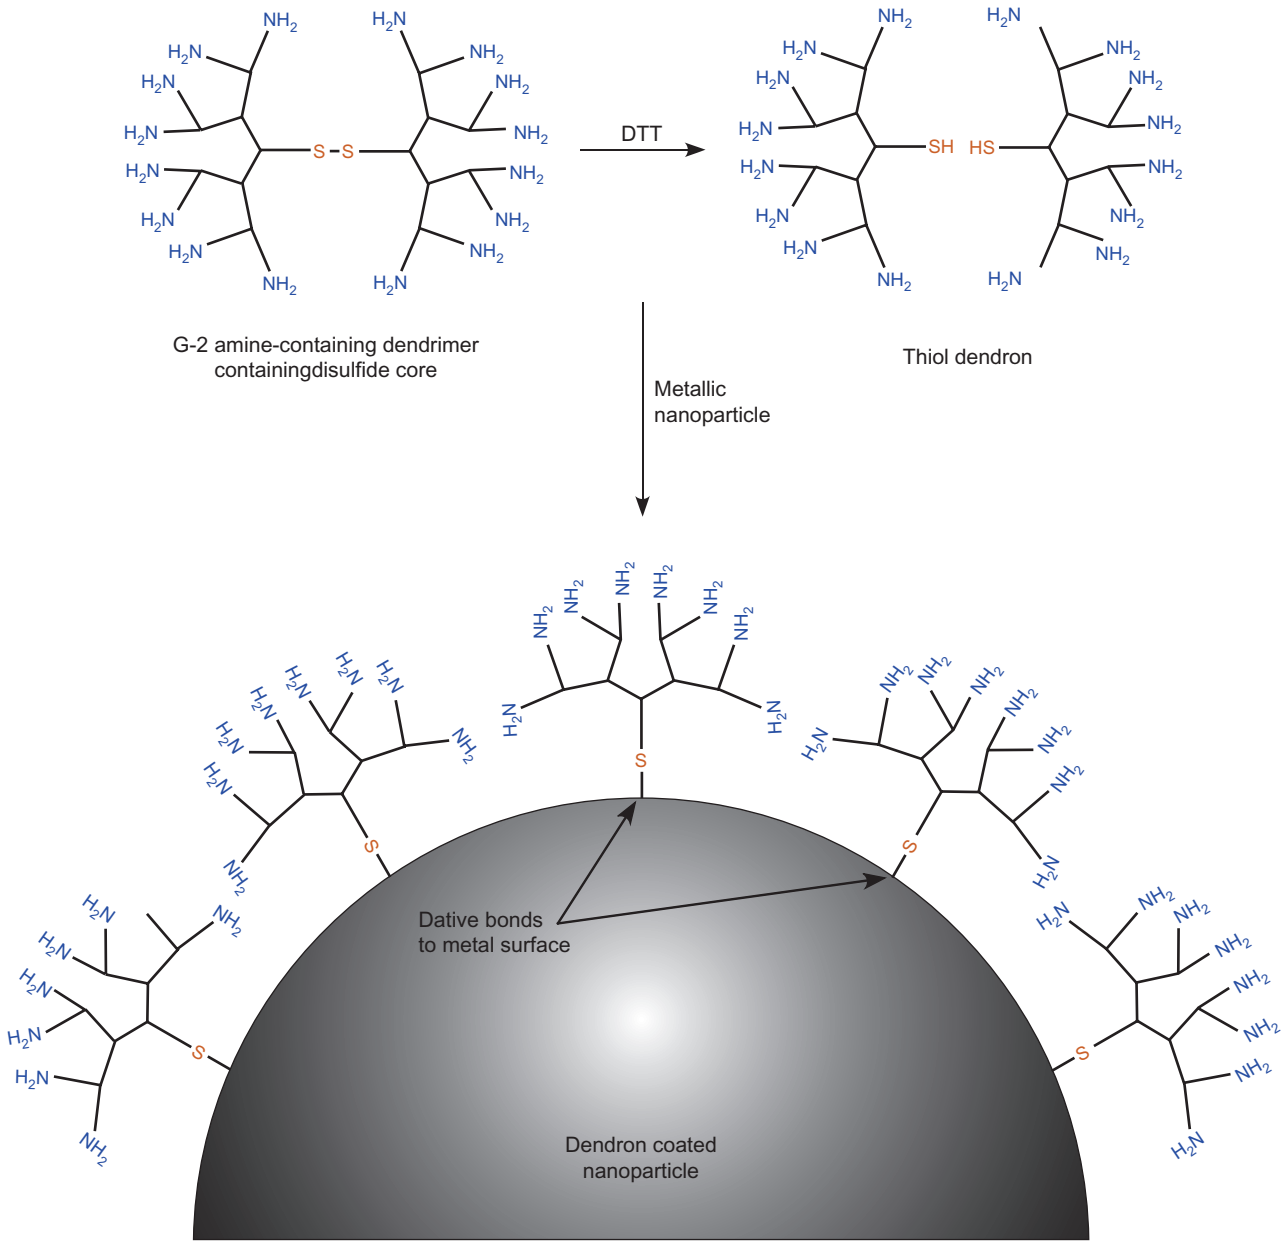

FIGURE 8.26 Dendrimers made with a disulfide-containing core can be reduced to produce dendrons having free thiol groups for surface modification. Dative binding of these thiol dendrons to gold or metallic surfaces can provide a high density of amine groups for coupling proteins or other molecules.

evidently contained a uniquely sized silver nanocluster, which resulted in an individual emission peak. Therefore, all the silver/dendrimer complexes together in solution presented a combined average of these five discrete emission peaks, and thus displayed the broad emission band covering nearly 200 nm in width across the spectrum.

Lesniak *et al.* (2005) also describe the preparation and use of similar dendrimer/silver nanoclusters using G-5 PAMAM dendrimers terminated with amino, hydroxyl, or carboxyl functionalities. In this method, 25 Ag (I) ions were entrapped within each dendrimer and photoactivated by irradiation with UV light. This reduced the silver ions to Ag (0) metal nanoclusters totalling 25 atoms per dendrimer. The resultant silver/dendrimer nanocomposites were fluorescent with excitation in the range of 300 to 400 nm and emission in the range of 400 to 500 nm. Investigations into the use of the complexes as fluorescent detection reagents for cell-based imaging

proved positive, with the properties closely matching the expected characteristics of the parent dendrimer for cell uptake and cytotoxicity.

The polyvalent nature of dendrimer molecules also has been used to modify semiconductor quantum dot surfaces to provide increased bioconjugation capacity or to use a PAMAM dendrimer's surface positive charge to enhance the entry of the nanoparticle into cells (Higuchi *et al.*, 2011). In addition, dendrimer-functionalized quantum dots have been used to develop fluorescent imaging agents for tumor targeting *in vivo* (Akin *et al.*, 2012). The conjugation methods that can be used for quantum dots are discussed in greater detail in Chapter 10, Section 10.

CHAPTER

9

Cross-Bridges and Cleavable Reagent Systems

Crosslinking and modification reagents may possess functionality other than their reactivity toward certain chemical groups. In particular, the cross-bridge of the molecule can be designed to contain constituents that allow cleavage of the reagent after use. Occasionally, the coupling reaction itself provides linkages susceptible to subsequent cleavage. Why would you want to break a conjugate apart after having formed it? The ability can be very important in studies involving the biospecific interactions between two molecules, especially if only one of the molecules is known or characterized. Cleavability allows the conjugation reaction to be verified through identification of the crosslinked molecules after conjugation and purification of the complex. Precise points of modification can be determined by mass spec analysis after cleavage. In some cases, purification of unknown target molecules is facilitated by the ability to cleave the crosslinking bonds after isolation of the complex. For instance, a protein modified near its binding site with a photoreactive heterobifunctional crosslinker can be incubated with its receptor or specific binding molecule, a covalent linkage then can be formed by exposure to UV light, and the complex analyzed by subsequent cleavage of the crosslink.

In another example, ligands can be biotinylated with a cleavable biotinylation reagent and then incubated with receptor molecules. The resulting complex can be isolated by affinity chromatography on immobilized (strept)avidin. Final purification of the ligand–receptor can be accomplished by cleaving the biotin modification sites while the complex is still bound to the support. The receptor complex thus can be eluted from the column without the usual harsh conditions required to break the avidin–biotin interaction.

The ability to cleave a crosslink can also provide a means of transferring a label from one protein to another. For instance, a photoreactive heterobifunctional crosslinker that is iodinatable and cleavable can be used to tag an unknown receptor molecule after conjugation. For example, the crosslinker SASD (Chapter 6, Section 3.2) can be iodinated before it is employed in a crosslinking reaction. It is then used to modify a protein through its amine-reactive NHS ester end and purified from excess crosslinker. After incubation of the modified protein with specific binding molecules (e.g., other proteins) and photoreactive crosslinking, the conjugate can be broken by reduction of the disulfide group within the cross-bridge of the reagent. Since the radiolabeled part of the crosslinker is now attached to the unknown interacting molecule, the tracer is effectively transferred from the initially modified molecule. Thus, unknown interacting molecules can be tracked after their binding to an SASD-labeled substance.

Another crosslinker, SAED (Chapter 6, Section 3.9), can be used in a similar fashion, but instead of transferring a radioactive label, it contains a fluorescent portion that is transferred to a binding molecule after cleavage. Similarly, sulfo-SBED routinely is used to study protein interaction. Cleavage of a disulfide bridge after capture of interacting proteins results in transfer of a biotin label to the unknown prey protein (Chapter 24, Section 3.1). The biotin modification can then be used to detect or isolate the unknown interactor for subsequent identification.

The ability to break a crosslink can be an important feature of a modification or conjugation reagent. This chemistry typically is built into the cross-bridge or reactive ends of a reagent using disulfides, glycol groups, diazo bonds, esters, sulfone groups, acylhydrazones, nitrophenyl groups, or acetal linkages. The following sections describe these chemical characteristics and their respective cleavage conditions.

1. CLEAVAGE OF DISULFIDES BY REDUCTION

The formation of a disulfide linkage between crosslinked molecules is an important option for many conjugation chemistries. Examples of reagents that have

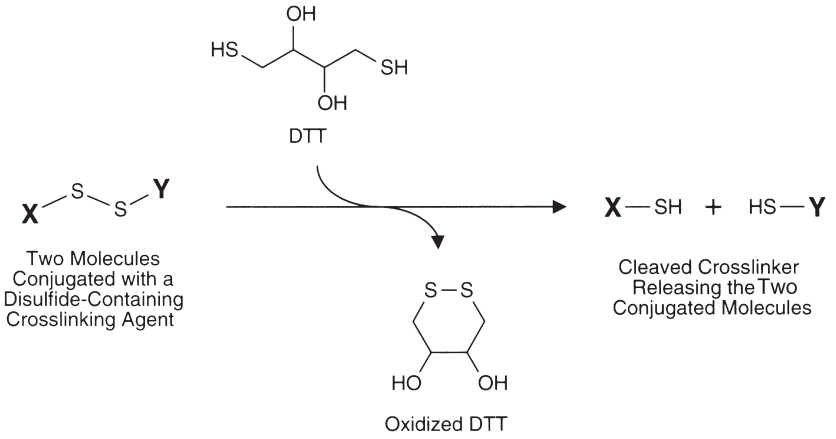

FIGURE 9.1 Cleavage of disulfide-containing crosslinking compounds can be achieved using a reducing agent such as DTT. Reduction causes the conjugates to break apart into their original components with each component containing a portion of the crosslinker that terminates in a thiol group.

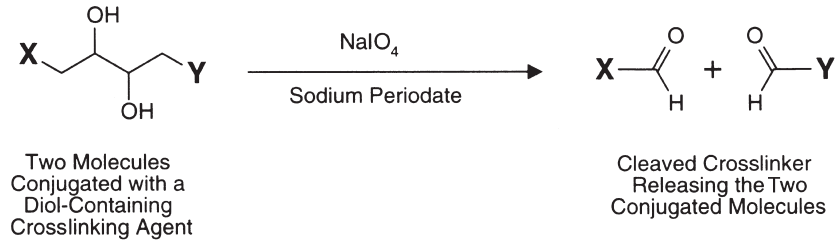

FIGURE 9.2 Crosslinkers containing a diol group in their cross-bridge design may be cleaved by oxidation with sodium periodate.

this capability include the pyridyl disulfide-containing heterobifunctionals like SPDP (Chapter 6, Section 1.1) and SMPT (Chapter 6, Section 1.2). Other non-sulfhydryl-reactive crosslinkers still may possess a disulfide group within their cross-bridge construction. The presence of such disulfide groups, whether designed in the crosslinker or created as a product of their reactions, allows for specific cleavage of the complex or modified molecule after conjugation. Disulfide bonds can be broken by a number of methods (Chapter 2, Section 4.1), utilizing either direct hydrogenolysis by a strong reductant such as sodium borohydride or through a disulfide interchange process with a compound containing one or more free sulfhydryls (Figure 9.1).

Cleavage of disulfide bonds is easily achieved by incubation with a reducing agent at a level of 10- to 100-m*M* concentration. If the disulfides in the crosslinks are the only ones present in the complexed molecules, then reduction will yield unconjugated molecules—one or both of which will contain a portion of the crosslinker, and on both molecules a free sulfhydryl will be created. Caution should be used with this method of cleavage, however, if other disulfides are present in the conjugated molecules. Some protein disulfides, for instance, may also be affected by the reduction step. Complete cleavage of all disulfides in crosslinked proteins by inclusion of unfolding agents (e.g., guanidine) may yield additional protein fragments of lower molecular weight due to subunit disassociation.

2. PERIODATE-CLEAVABLE GLYCOLS

Crosslinking agents can be designed to contain adjacent carbon atoms possessing hydroxyl groups. Cross-bridges containing such diols or glycol residues can be constructed from the inclusion of an internal tartaric acid spacer or similar compound in their synthesis (e.g., DST, Chapter 5, Section 1.3). These groups can easily be cleaved by oxidation with sodium periodate (Chapter 2, Section 4.4). Treatment with 15-m*M* periodate at physiological pH will break the carbon–carbon bond between the glycol portion, oxidizing each hydroxyl to an aldehyde, and cleaving the associated crosslinked molecules (Figure 9.2). Under these conditions, glycosylated portions of glycoproteins or other carbohydrate-containing molecules will also be affected, forming additional aldehyde groups. In some cases, the production of aldehyde residues may cause secondary reactions to occur, especially Schiff base formation with available amine groups. To avoid unexpected crosslinks that may form through such intermolecular Schiff base formation, after oxidation and removal of excess periodate, Tris or ethanolamine may be included to tie up the aldehydes and stabilize the cleaved products.

Sodium periodate may also affect tryptophan residues in some proteins. The oxidation of tryptophan can result in activity losses if the amino acid is an essential component of the active site. For instance, avidin and streptavidin may be severely inactivated by treatment

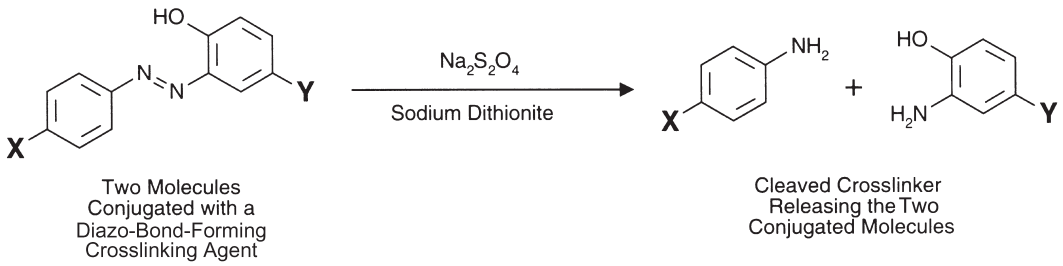

FIGURE 9.3 Crosslinking agents that form diazo bonds may be cleaved using sodium dithionite.

with periodate, since tryptophan is important in forming the biotin-binding pocket. In addition, many other amino acid residues are susceptible to oxidation by periodate (Chapter 2, Section 1.1). Limiting the time of oxidation is important to restricting oxidation to diol groups while not affecting other protein structures.

The use of periodate as a cleavage agent does have advantages, however. Unlike the use of cleavable crosslinkers that contain disulfide bonds which require a reductant to break the conjugate, cleavage of diol-containing crosslinks with periodate typically preserves the indigenous disulfide bonds and tertiary structure of proteins and other molecules. As a result, with most proteins bioactivity usually remains unaffected after mild periodate treatment.

3. DITHIONITE-CLEAVABLE BONDS

Crosslinking compounds containing diazo bonds within their structures can be specifically cleaved with dithionite (Jaffe *et al.*, 1980). In addition, crosslinks formed by the reaction of a diazonium compound (Chapter 3, Section 6.1) with a tyrosine residue can be broken using this reagent. Sodium dithionite (also called sodium hydrosulfite) reduces the diazo linkage, breaking the bond between the nitrogens and leaving a primary amine on both fragments of the crosslinker (Figure 9.3). The reaction is usually carried out in alkaline conditions; a 25-min incubation with 0.1-*M* dithionite in 0.2-*M* sodium borate, pH 9, works well. As the diazo bonds are broken, any color associated with the reagent will disappear.

Dithionite is also capable of cleaving oxime linkages that are formed as the result of the reaction of an aldehyde and aminoxy group (Pojer, 1979). Thus, crosslinks formed between two proteins or other molecules using this reaction strategy can be specifically broken using sodium dithionite.

In a novel application, Fonović *et al.* (2007) designed dithionite-cleavable, activity-based probes for the covalent modification of thiol or serine proteases. In many cell extracts DTT is added to maintain a reducing environment; therefore, cleavable probes containing disulfides would be incompatible with the extract buffer system. One probe design contains an active site binding region with an epoxide warhead group, which can link to the thiol within the binding pocket of a cysteine protease through a thioether bond. The other end of the probe contains a biotin tag to allow purification of labeled enzymes on a streptavidin affinity chromatography support. The crossbridge of this probe contains a diazo group, which can be cleaved using dithionite (Figure 9.4). The design facilitates mild elution of isolated enzymes from the streptavidin column without the typical severe denaturing conditions required to break the biotin–streptavidin interaction.

4. HYDROXYLAMINE-CLEAVABLE ESTERS

Hydroxylamine is a powerful nucleophile which, under alkaline conditions, is effective in breaking ester bonds. Crosslinking agents containing esterified spacer components can be cleaved after undergoing a conjugation reaction by incubation with 0.1-*M* hydroxylamine, pH 8.5, for 3 to 6 h at 37°C (Abdella *et al.*, 1979). The reaction results in the formation of an amide derivative on one fragment of the cleaved crosslinker and a hydroxyl group on the other fragment (Figure 9.5). Thioester bonds are also susceptible to cleavage under these conditions. Thioesters may be broken with the production of an amide and a sulfhydryl group on either side of the crosslinker fragments.

An example of a hydroxylamine–cleavable reagent is EGS (Chapter 5, Section 1.5) which contains two ester bonds made by the esterification of ethylene glycol with succinic acid. Cleavage with hydroxylamine yields two fragments terminating with an amide bond and concomitant release of ethylene glycol. Mass spec evidence of the cleavage products from an EGS crosslink indicates that the cleaved parts can undergo cyclization to form a succinimide group on both fragments (Petrotchenko *et al.*, 2005).

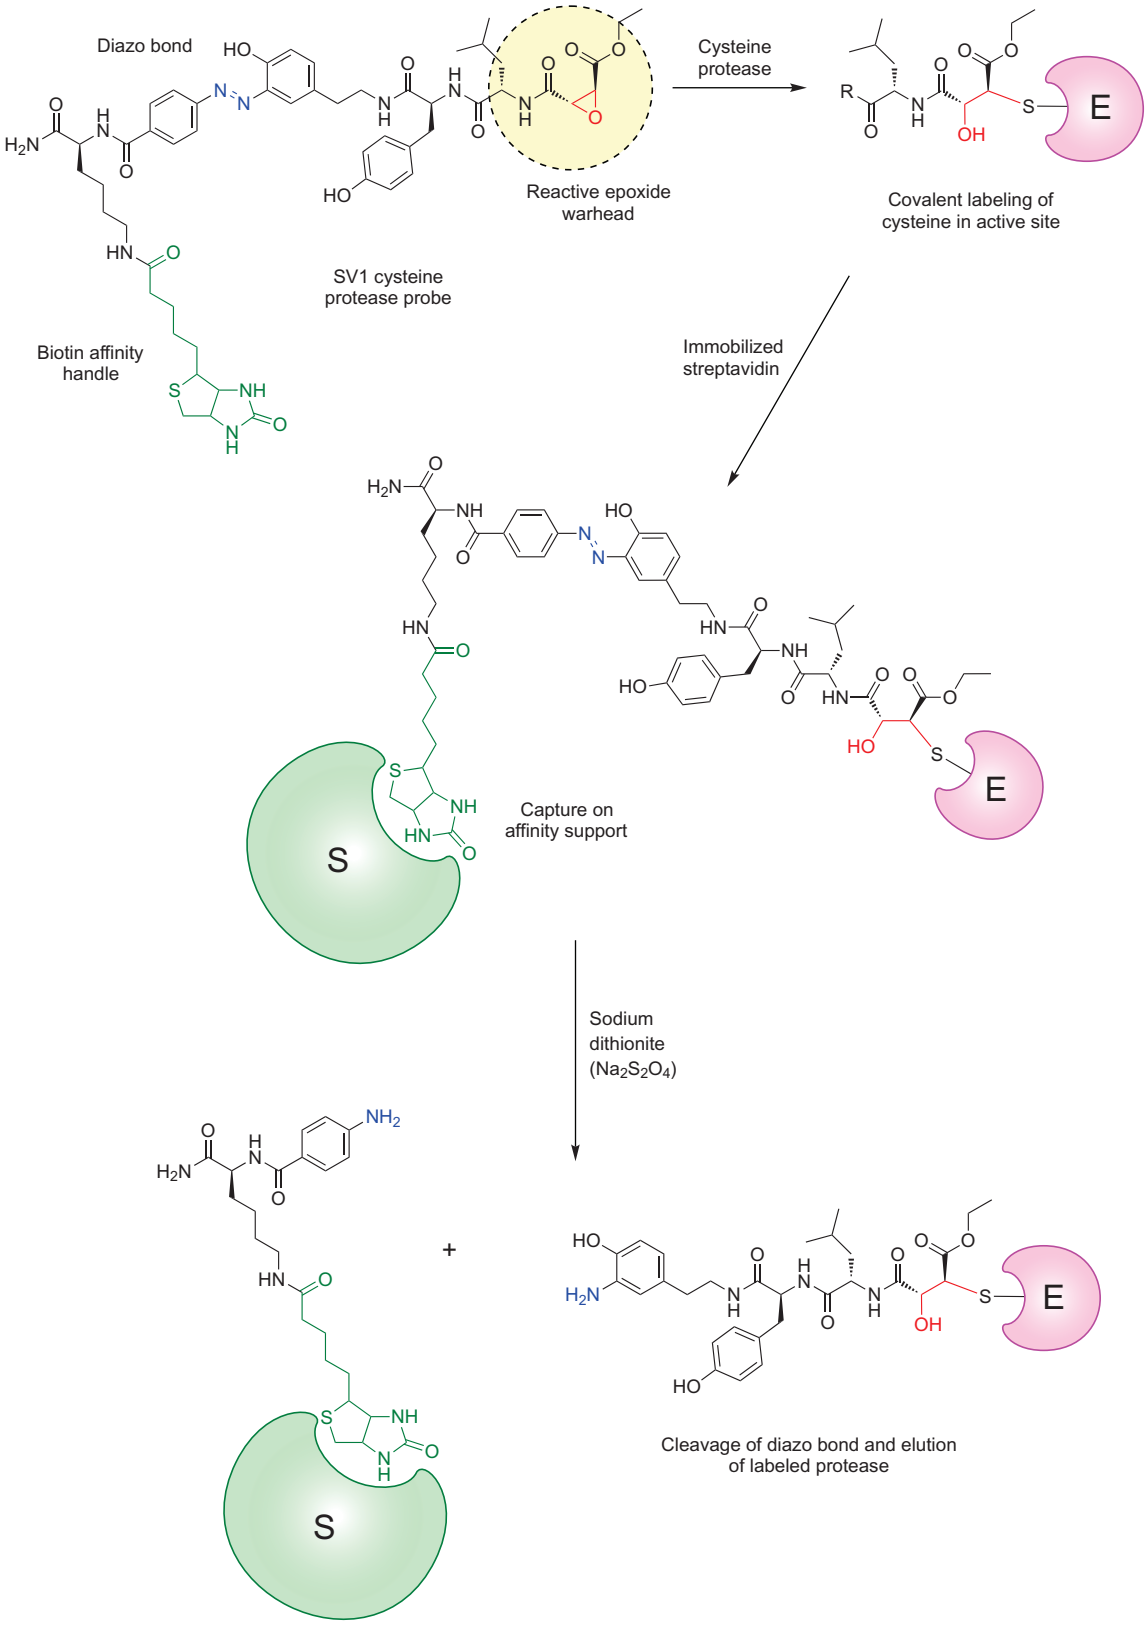

FIGURE 9.4 Use of an active site warhead probe containing a dithionite-cleavable diazo bond.

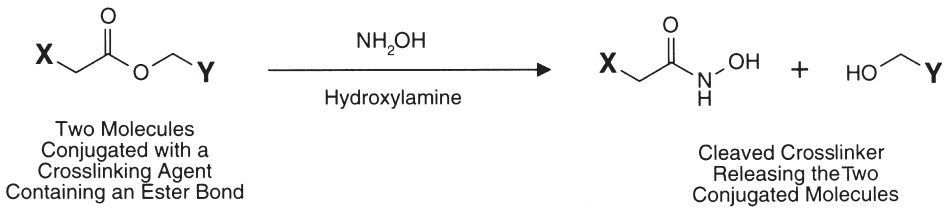

FIGURE 9.5 Crosslinkers containing an ester group in their cross-bridge are susceptible to cleavage under alkaline conditions using hydroxylamine.

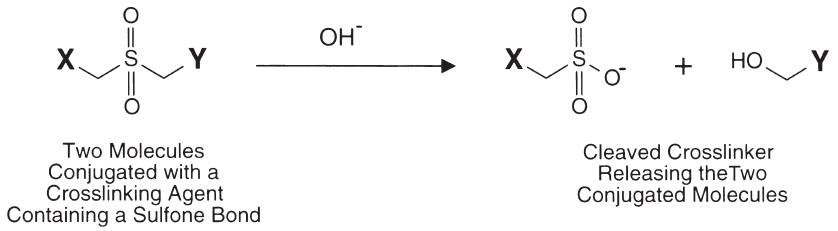

FIGURE 9.6 Crosslinkers that have an internal sulfone group in their cross-bridge may be cleaved using base.

5. BASE LABILE SULFONES

The presence of a sulfone group in a crosslinking reagent can allow for cleavage of a conjugate through hydrolysis of the linkage under basic conditions. In 0.1-*M* sodium phosphate, adjusted to pH 11.6 by addition of Tris base, containing 6-*M* urea, 0.1% SDS, and 2-m*M* DTT, sulfone groups were successfully cleaved after incubation at 37°C for 2 h (Zarling *et al.*, 1980). In that study, peptide antigens on the surface of lymphocyte receptors were crosslinked with the homobifunctional, amine-reactive reagent BSOCOES (Chapter 5, Section 1.4), purified, and cleaved for analysis. The presence of urea, SDS, and DTT was not absolutely necessary for breaking the sulfone bond; rather, they served to disrupt completely protein/peptide structure for complete dissociation of the complex.

In addition to BSOCOES, the amine-reactive, bisfluorobenzene reagent DFDNPS (Chapter 5, Section 4.2) also contains an internal sulfone group that is easily cleaved under basic conditions (Wold, 1961, 1972). Hydrolysis of the sulfone yields two crosslinker fragments, one terminating in a sulfonic acid group and the other containing a hydroxyl group (Figure 9.6).

6. ACYL HYDRAZONE-CLEAVABLE LINKERS

A common method of targeting active sites within proteins is to use a biotin-containing probe that can covalently link to a functional group within or near the active center of an enzyme or receptor protein. Once active proteins are labeled in a complex sample such as a cell extract, the biotin handle is used as an affinity tag that can interact with immobilized streptavidin to facilitate purification (Chapter 1, Section 3.3, and Chapter 15, Section 2.5). This is an efficient capture method to isolate the modified proteins, but subsequent elution from the streptavidin support often results in severe denaturation of bound proteins. To overcome this problem, various cleavable biotin tags have been designed which contain, for instance, disulfides or esters that can be cleaved using reducing agents or hydroxylamine under alkaline conditions, respectively. Recently, Park *et al.* (2009) introduced an acylhydrazone-containing biotin probe that can be cleaved under very mild conditions. A single acylhydrazone linkage in the cross-bridge between the biotin tag and the active site probe allows cleavage and elution from a streptavidin affinity support in the presence of an excess of a hydrazide-containing reagent (Figure 9.7).

Hydrazone bonds have been used extensively in the design of bioconjugates for use as drug delivery agents (Kale and Torchilin, 2007), for chemoselective ligation reactions (Chapter 17, Section 2), and to immobilize affinity ligands on particles or chromatography supports (Chapter 14, Section 4.2, and Chapter 15, Section 2.4). A hydrazone bond is reasonably stable at neutral or slightly alkaline pH values, but at slightly acidic pH (4–5) it is labile to hydrazide exchange reactions. Under these conditions, the addition of a hydrazide derivative will cleave the hydrazone bond in the cross-bridge of an enzyme probe, resulting in hydrazide exchange and covalent modification of the labeled enzyme with the cleavage reagent. Thus, the active site probe cannot

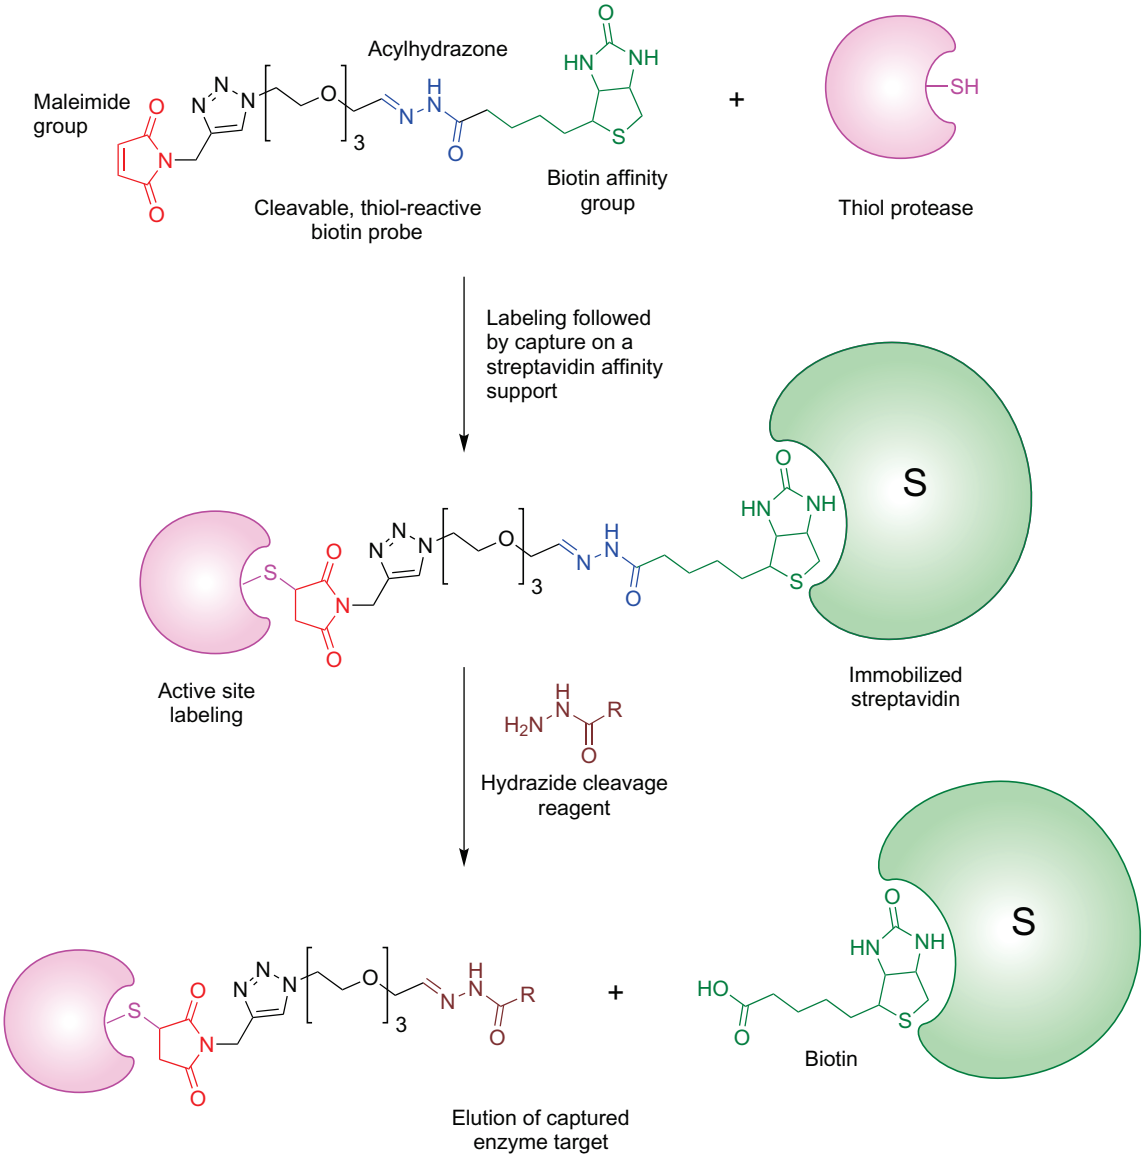

FIGURE 9.7 Cleavage of biotin–acylhydrazone active site probe using a labeled hydrazide reagent.

only facilitate labeling of active enzymes and isolation from complex proteomic mixtures, but further labeling with detection components, if desired, during the cleavage reaction. Capture of a biotin probe–enzyme complex on an immobilized streptavidin support can be followed by release and labeling of the enzyme with, for instance, a fluorescent tag containing a hydrazide group. The fluorescently labeled enzyme can then be used in detection experiments to image or track the enzyme.

7. PHOTOCLEAVABLE LINKERS

The ability to cleave cross-bridges through the use of light is an important option that allows for controlled release of protecting groups or for rapid, timed release of part of a conjugate component from a covalent complex. Photolabile groups can be incorporated into the design of standard bioconjugate reagents and used in normal fashion to create crosslinked, modified, or immobilized molecules. Photocleavable groups have been used in the study of protein–protein interactions and in drug discovery and development, especially as the trigger for the release of "caged" ligands or prodrugs that have therapeutic activity only upon photocleavage (Gorman and Prestwich, 2000).

Reagents containing a photocleavage site can be of many types, including crosslinkers or modification agents, which can have reactive groups at either end or contain an affinity group on one end. The cross-bridge

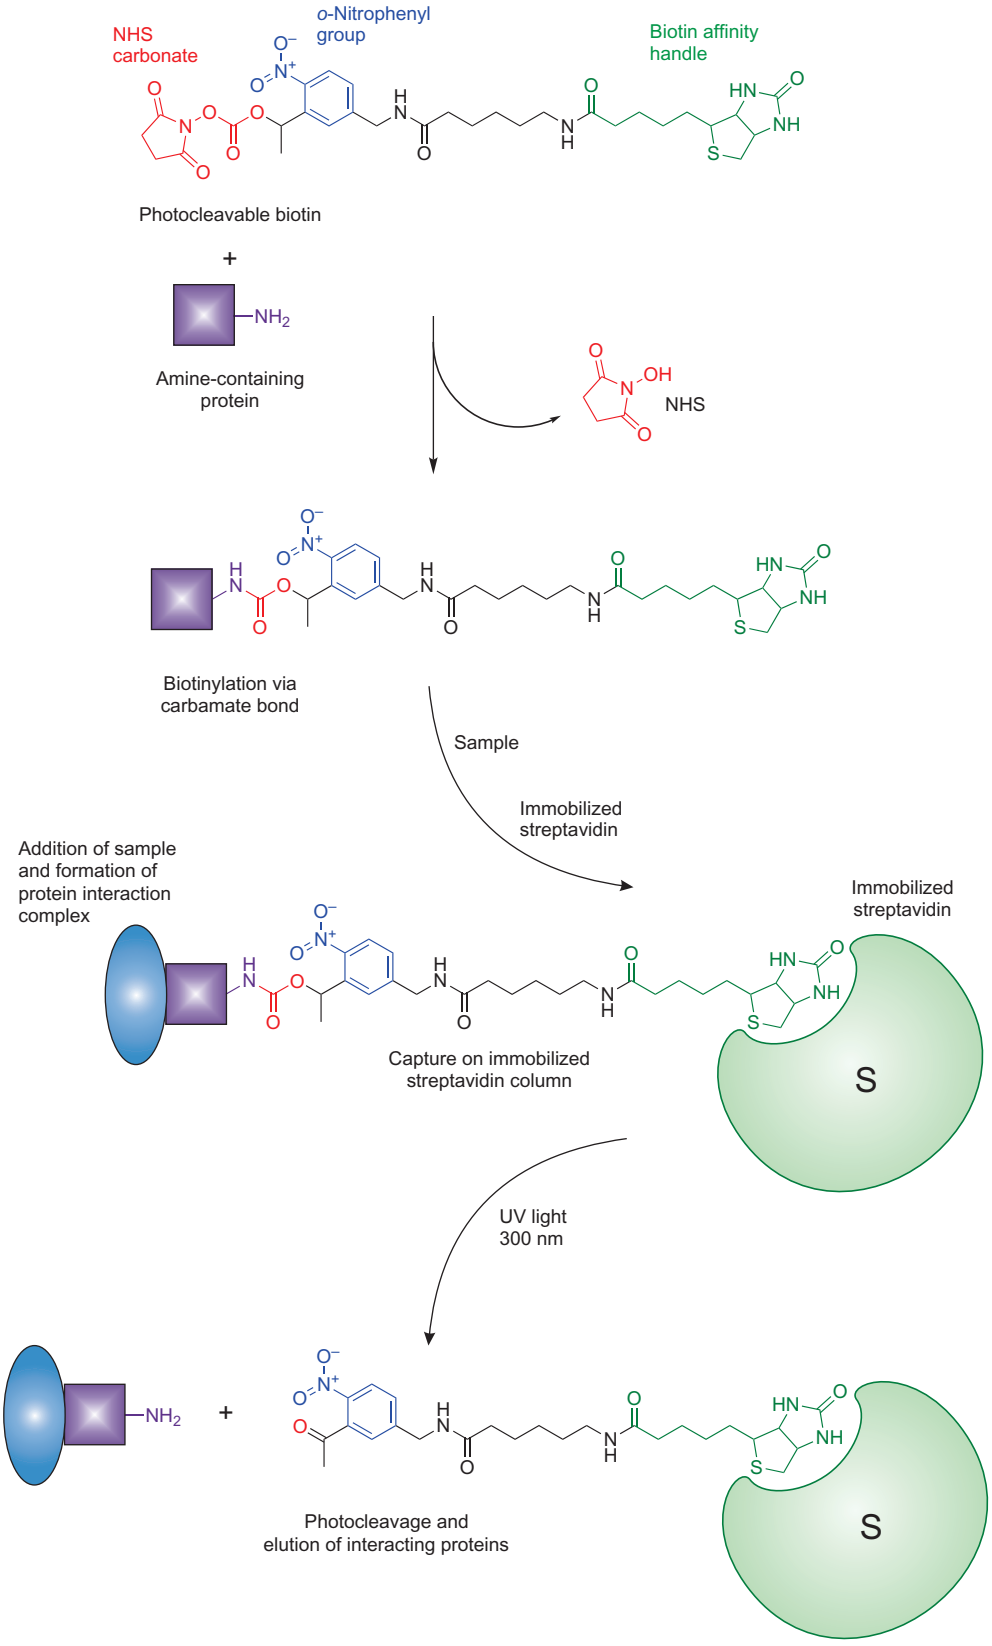

FIGURE 9.8 Photocleavable biotin reactions with an amine-containing protein or molecule and subsequent photocleavage of the cross-bridge to release the biotinylated molecule.

of such compounds remains stable so long as it is not exposed to light strong enough and at the right wavelength to cause cleavage (normal room light poses no problems for brief exposures). Olenjnik *et al.* (1995) designed biotin derivatives containing an internal *ortho*-nitrophenyl group within the spacer arm, which also contains a thermoreactive aryl carbonate ester (before coupling) or an aryl carbamate bond (after coupling). Upon exposure of this cross-bridge with UV light at 300 nm, this group undergoes a photoreaction leading to bond breakage at the aryl carbamate linkage with concomitant cleavage of the biotin group from the rest of the molecule (Rothschild *et al.*, 1999) (Figure 9.8). The photocleavage reaction is rapid and complete within about 5 min of exposure to UV light.

The advantage of incorporating photocleavable sites into a biotinylation agent (or an active site probe containing biotin) is that the resultant biotin conjugate can be captured on an immobilized streptavidin support and subsequently eluted by exposure to light. This process can facilitate the isolation of a group of interacting proteins that can be studied in their native form, because elution can be carried out without the use of strongly denaturing conditions typically associated with the use of the biotin–streptavidin interaction.

CHAPTER

10

Fluorescent Probes

Labels, tags, and probes are relatively small modifying agents that can be used to modify proteins, nucleic acids, and other molecules. These compounds often contain groups that provide, either directly or indirectly, sensitive detectability by virtue of some intrinsic chemical or atomic property such as fluorescence, chemiluminescence, absorptivity, radioactivity, or affinity toward another biomolecule. Most probes can be designed to contain a reactive group capable of coupling to the functional groups of biomolecules, thus making conjugation possible. After modification of a protein, for instance, the probe becomes covalently attached, thus permanently tagging it with a unique detectable property, which can be used to assay or track the conjugate as it interacts with other biomolecules.

Fluorescent labels used in this manner can provide tremendous sensitivity due to their property of repeated light emission upon excitation. Proteins, nucleic acids, and other molecules can be labeled with fluorescent probes to provide highly sensitive reagents for numerous *in vitro* assay procedures. For instance, fluorescently tagged antibodies can be used to probe cells and tissues for the presence of particular antigens and then be detected through the use of fluorescence microscopy techniques. Since each probe has its own fluorescence emission character, more than one labeled molecule—each tagged with a different fluorophore—can be used at the same time to detect two or more target molecules.

A fluorescent molecule has the ability to absorb photons of energy at one wavelength and subsequently emit energy at another wavelength. The absorption process is also called excitation, since the quantum energy levels of some of the compound's electrons increase with photon uptake. The absorption band usually is not isolated at a discrete photon energy level but is spread out over a range of wavelengths with at least one peak of maximal absorbance within this excitation region. The extinction coefficient (ε, expressed as $M^{-1}cm^{-1}$) at the absorbance peak maximum is a unique characteristic of each fluorophore under a given environmental condition (such as the solvent it is dissolved in).

The excess energy of an excited fluorophore can be lost as heat or through collisions with adjacent molecules or released as photons of light as the electrons return to the lower, ground-state energy level (Figure 10.1). This process of light emission occurs in less than 10^{-4}s after excitation and is known as fluorescence. Fluorescence takes place from the lowest excited singlet state as the electron collapses back down to the ground state and releases a photon. According to Stokes' law, the emission wavelength is always longer and thus of lower energy than the wavelength of excitation (Kawamura, Jr., 1977). The ratio of total photon emission over the entire range of fluorescence to the total photon absorption is called the quantum yield (QY). Quantum yield values range from 0 to 1. The larger the QY value the more efficient the photon emission or luminescence. For a particular fluorophore under fixed environmental conditions, both its extinction coefficient and its quantum yield are fundamental characteristics of its photochemical behavior.

Not only should a fluorescent compound suitable for analytical studies have a high QY, but also its fluorescence emission spectrum should be separated sufficiently from its excitation spectrum to ensure good signal isolation. A fluorophore's Stokes shift is a measure of the separation of its maximal absorbance wavelength from its emission wavelength maxima (Figure 10.2). The greater the Stokes shift, the better the signal isolation and therefore less interference from Rayleigh-scattered excitation light.

The majority of reported fluorophores of practical use in labeling biomolecules contain an aromatic ring system as the generator of luminescence. In general, as the conjugated electron system gets larger, the emission wavelength is shifted to the red or longer wavelengths. Also, the extinction coefficient and QY of larger conjugated systems typically are greater than those of small aromatic compounds. Fluorescent compounds emitting in the far red or near infrared (NIR) region typically have extinction coefficients greater than $100{,}000\,M^{-1}cm^{-1}$ and sometimes greater than $200{,}000\,M^{-1}cm^{-1}$, whereas dyes that emit in the blue region of the spectrum usually have extinction coefficients of less than $25{,}000\,M^{-1}cm^{-1}$.

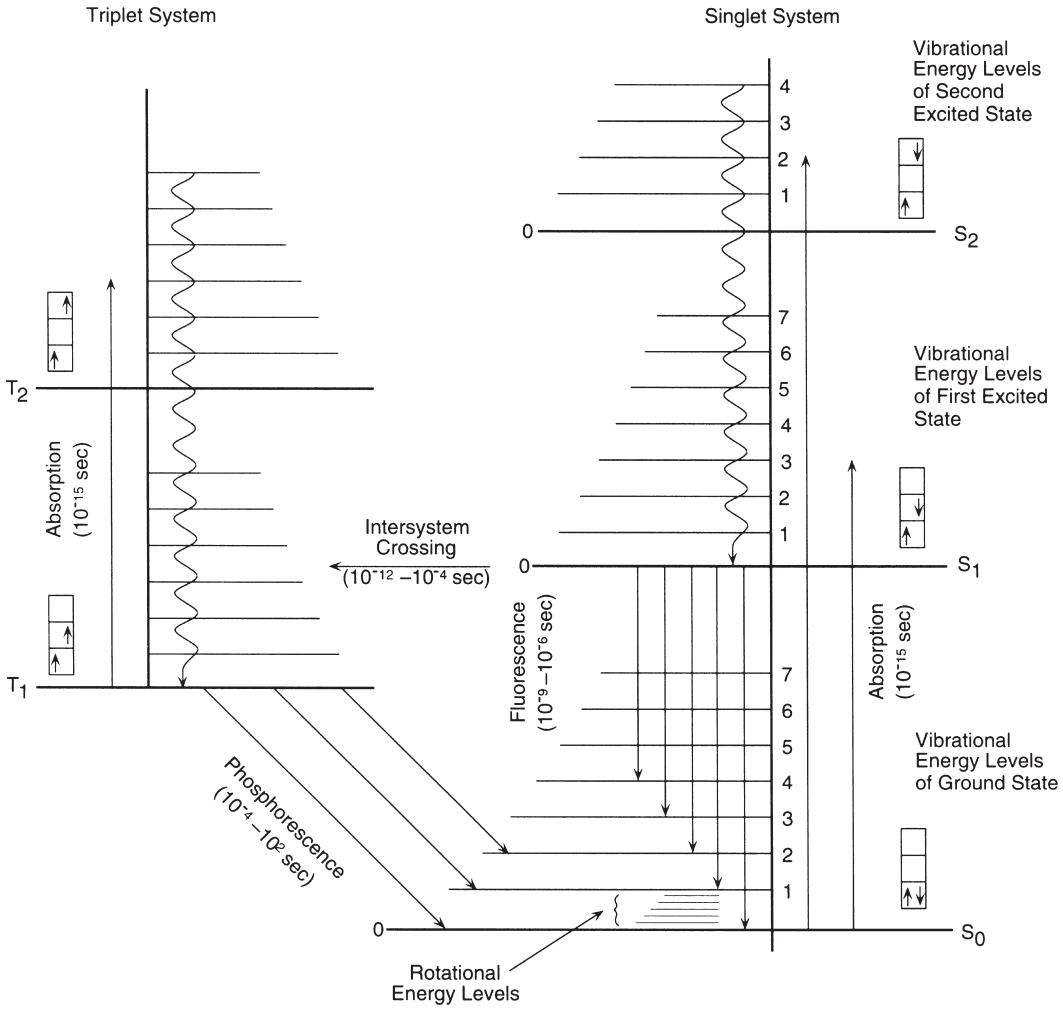

FIGURE 10.1 Energy diagram showing the transition states involved in the absorption and decay of electromagnetic energy. Energy may be released through heat or internal collisions, transferred to other molecules, or emitted as photons of light. Fluorescence occurs from within the singlet system as light energy is released, returning the electrons to the ground state. Phosphorescence occurs from the triplet system and involves a longer emission process at lower energies than that of fluorescence.

Aromatic ring constituents can have a pronounced affect on fluorescence. The presence of ring activators or electron donating groups (e.g., *ortho* and *para* directors) generally can increase QY, while the presence of electron-withdrawing groups generally reduces QY. An example of this effect can be found in the photoreactive heterobifunctional crosslinker SAED (Chapter 6, Section 3.9). Before photoactivation, SAED possesses a photoreactive phenyl azide group on its AMCA-derived end. This electron-withdrawing group quenches the fluorescence of the compound so that the AMCA dye does not behave as it characteristically does in the underivatized state. Upon photolysis, however, the phenyl azide either gets coupled to a target molecule or breaks down to an amine. In either case, the presence of an amine (or its derivative) eliminates the fluorescence-quenching effects of the azide and restores the coumarin group's fluorescent character.

Another potential ring constituent having a dramatic effect on fluorescence is the presence of heavy atoms. Aromatic rings possessing heavy atoms typically diminish QY by enhancing the probability of the excited singlet state going on to triplet transition. Energy decay from a triplet excited state causes phosphorescence instead of fluorescence. The phosphorescent band is located at longer wavelengths (and thus lower energies) relative to the fluorescent spectrum. The energy transition to the triplet state is therefore in direct contention with fluorescence, and has the effect of decreasing overall luminescence. Halogen substitution on aromatic-ring-containing fluorophores also can have a quenching effect, which generally follows the size of the atom: I > Br > Cl > F. Depending on the dye type and other constituents on the aromatic system, the presence of heavier halogen atoms on a fluorescent aromatic ring typically may cause a decrease

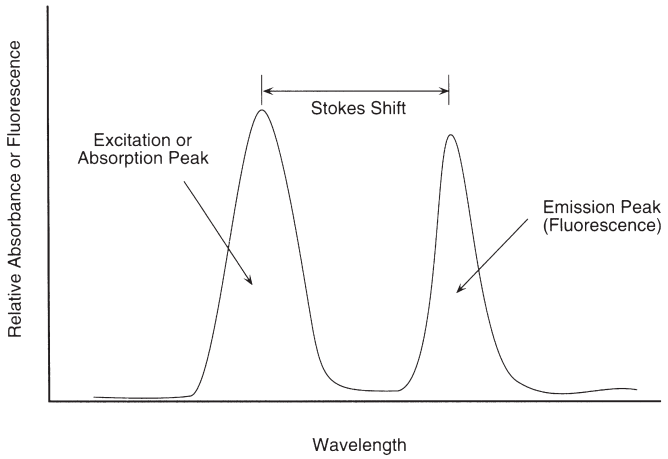

FIGURE 10.2 Typical spectral scan of a fluorescent compound showing its absorbance peak or wavelengths of most efficient excitation and its emission peak or wavelengths where light emission occurs. The Stokes shift is the distance in nanometers between the absorbance peak and the emission peak. The larger the Stokes shift, the less interference that will occur from excitation light when measuring fluorescence emission.

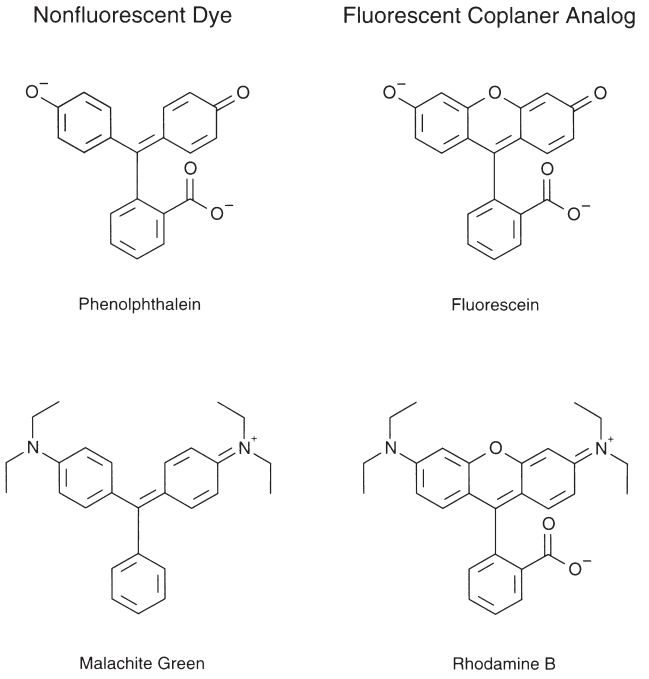

FIGURE 10.3 Fluorescent character in organic compounds is often determined by the presence of a planar aromatic ring system. The fluorescent compounds differ from the nonfluorescent ones only in the closure of their central ring system, which produces a conjugated system having the required constraints to create a planar triple-ring configuration.

in fluorescence or eliminate it altogether. However, the carbocyanine dye Alexa 680 has a bromine atom on its outer pyridinium ring and it still retains intense fluorescence character. However the presence of an iodine atom nearly guarantees complete elimination of fluorescence (Turro *et al.*, 2009). Thus, radioiodination of a fluorescent ring structure likely is not possible without dramatically decreasing (or eliminating) its QY.

The aromatic ring systems of most of the following fluorophores consist of polycyclic structures that may also contain a conjugated bridge between ring systems. To maintain fluorescence in such compounds, it is important that the entire system be coplanar or the rings be in the same dimensional plane. In fact, the differences between some non-fluorescent chromogenic dyes and their corresponding, structurally similar fluorophores are minor, but the planer nature of the fluorophores gives them their luminescent properties. For instance, Figure 10.3 illustrates the similarity of the dyes phenolphthalein and malachite green to the nearly identical fluorescent molecules fluorescein and rhodamine, respectively. The only difference among these dyes and fluorophores is the presence of the oxygen bridge between the upper phenyl rings which creates the rigid aromatic system that constricts the molecule to a planer shape, thus conferring luminescent qualities.

Fluorescent compounds are sensitive to changes in their chemical environment. Alterations in media pH, buffer components, solvent polarity, or dissolved oxygen can affect and quench the QY of a fluorescent probe (Bright, 1988). The presence of absorbing components in solution which absorb light at or near the excitation wavelength of the fluorophore will also have the effect of decreasing luminescence. In addition, noncovalent interactions of the probe with other components in solution can inhibit rotational freedom and quench fluorescence. In this regard, the binding of an anti-fluorescein antibody to the fluorescent dye completely abolishes its fluorescence. Also, environmental ozone levels have been shown to affect the fluorescence of some dye molecules, particularly cyanine-type dyes used in microarray gene measurements (Branham *et al.*, 2007) (Section 8).

Over-labeling a macromolecule with a fluorescent probe also causes decreases in QY due to dye–dye interactions. Quenching caused by energy transfer interactions between fluorescent molecules often occurs as the level of probe substitution reaches about 8 to 10 fluorophores per protein. Not only can the emission intensity decrease severely at high substitution levels, but the degree of nonspecific binding caused by the number of aromatic groups attached to the biomolecule can increase severely. Fluorophore self-quenching at high substitution or concentration levels can be due to energy transfer from excited-state molecules to ground-state dimers (Chen and Knutson, 1988). Hydrophobic dyes are particularly prone to such aggregation and quenching effects in aqueous buffers.

One method of reducing dye–dye interactions is to add negative charge character to the fluorescent

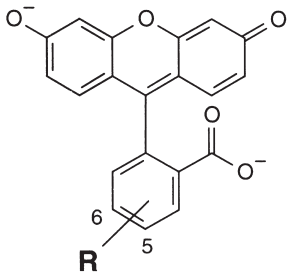
molecule. This is typically performed by the addition of sulfonate groups on aromatic rings or on alkyl tethers built off the central dye structure. The high negative charge character of the sulfonate groups creates like-charge repulsion between dye molecules, thus dramatically reducing their tendency to interact. The presence of three to four sulfonate groups on a probe usually creates a very hydrophilic molecule with lower nonspecific binding character than in biological solutions and greater QY than the corresponding dye without sulfonates.

Another approach to creating hydrophilic dyes is to add discrete PEG tethers to selected regions of the dye structure. The excellent water-solubilizing properties of PEG modifications can mask the core hydrophobicity of polycyclic aromatic fluorescent molecules, thus limiting dye–dye interactions and dramatically decreasing nonspecific binding toward biomolecules in a sample. The combination of PEG and sulfonate modifications on certain dye structures can create an optimum dye with maximal QY and excellent hydrophilicity. Many modern carbocyanine and xanthene type dyes incorporate water-solubilizing groups to avoid insolubility of dye conjugates and reduce background signals in fluorescent staining procedures. See Chapter 18 for a discussion of discrete PEG compounds that can be used for this purpose.

The following sections describe some of the most popular fluorescent probes for use in labeling biomolecules. These fluorophores are available from a number of manufacturers in several different forms, with a variety of reactive groups able to couple to specific functional groups on target molecules or with different substituents added to increase QY or hydrophilicity. By far, the most often used fluorescent core structures are water-soluble derivatives of cyanine, fluorescein, rhodamine, and coumarin—probably in that order. However, new fluorescent molecules are being developed and reported continually. For instance, there is growing interest in the use of lanthanide chelates for time-resolved fluorescence (Section 9) or quantum dot nanocrystals (Section 10) for highly stable fluorescence in multiplex detection schemes. Careful study of each dye's individual properties can lead to the successful labeling of a biomolecule for any anticipated application.

Suggested references on fluorescent spectroscopy and the use of fluorescent probes include Pansare *et al.* (2012), Lakowicz (1991, 1999, 2006), Bright (1988), Dewey (1991), McGown and Warner (1990), Ploem and Tanke (1987), Darzynkiewicz and Crissman (1990), Haugland (1991), and Waggoner (1990).

1. FLUORESCEIN DERIVATIVES



Fluorescein and its derivatives represent one of the most popular of all fluorescent labeling agents. Its fluorescent character is created by the presence of a multi-ring aromatic xanthene core structure, which creates the rigid planar nature of its upper, fused three-ring system (Figure 10.4). In its most elementary form, the molecule has a molecular weight of about 332 Da, but most modification reagents based on fluorescein are derivatives of this basic structure prepared through substitutions off the No. 5 or 6 carbons of its lower ring. The derivatives provide reactivity toward particular functional groups in biomolecules, allowing rapid labeling of proteins and nucleic acids.

Fluorescein has an effective excitation wavelength range of about 488 to 495 nm, closely matching the photon emission for an argon laser (488 nm). Some fluorescein derivatives are sold using the 488 reference in their name to reflect this excitation characteristic (e.g., DyLight 488 from Thermo Fisher and Alexa 488 from Invitrogen). The dye's emission spectrum occurs between 518 and 525 nm, depending on the derivative chosen. Under ideal conditions, its QY can be as high as 0.75; however, its fluorescent intensity fades when it is dissolved in aqueous buffers, exposed to light, or stored for extended periods (Kawamura, Jr., 1977). In environments below pH 7.0, fluorescein's QY is significantly quenched. In addition, when derivatives of fluorescein are conjugated to proteins, the degree of fluorescent quenching can be as high as 50%, especially for relatively hydrophobic forms of the dye. Fluorescein derivatives having multiple sulfonates on them helps to alleviate the quenching problem when labeling at higher density but does not completely eliminate it. Even so, the fluorophore usually maintains excellent detectability in assay systems.

The following sections describe the most important fluorescein derivatives having reactive groups commonly used to label biomolecules.

1.1. Amine-Reactive Fluorescein Derivatives

Two general forms of amine-reactive fluorescein probes are available. Both of them react under alkaline

Reactive Fluorescein Derivatives

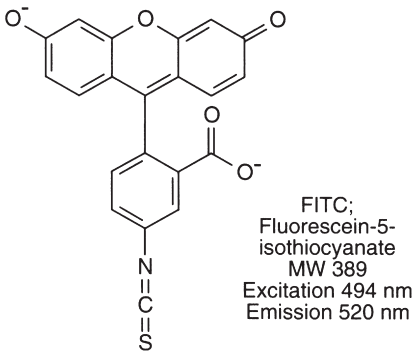


FIGURE 10.4 Fluorescein derivatives often are produced through modification at the C-5 or C-6 positions on the lower aromatic ring.

conditions with primary amines in proteins and other molecules to form stable, highly fluorescent derivatives.

1.2. Fluorescein Isothiocyanate (FITC)

FITC is one of the most popular fluorescent probes ever created. An isothiocyanate derivative of fluorescein is synthesized by modification of its lower ring at the 5- or 6-carbon positions. The two resulting isomers are nearly identical in their reactivity and spectral properties, including excitation and emission wavelengths and intensities. Their chemical differences, however, may affect the separation of modified proteins from excess reagent or the analysis of tagged molecules by electrophoresis. For this reason, most manufacturers purify the carbon-5 derivative as the FITC reagent of choice.

Isothiocyanates react with nucleophiles such as amines, sulfhydryls, and the phenolate ion of tyrosine side chains (Podhradsky *et al.*, 1979). The only stable product, however, is with primary amine groups, and so FITC is almost entirely selective for modifying ε- and N-terminal amines in proteins (Jobbagy and Kiraly, 1966). The reaction involves attack of the nucleophile on the central, electrophilic carbon of the isothiocyanate group (Figure 10.5). The resulting electron shift creates a thiourea linkage between FITC and the protein with no leaving group.

FITC can be dissolved in DMF as a concentrated stock solution prior to its addition to an aqueous reaction mixture. This may make aliquoting small quantities of the compound easier. The reagent is water soluble above pH 6. The isothiocyanate group is reasonably stable in aqueous solution for short periods, but will degrade. FITC also can break down and lose activity upon storage. It is best, therefore, to use fresh reagent for modification purposes. Storage should be under desiccated conditions, protected from light, and at −20°C.

The fluorescent properties of FITC include an absorbance maximum at about 495 nm and an emission wavelength of 520 nm. Fluorescent quenching of the molecule is possible. Under concentrated conditions, fluorescein-to-fluorescein interactions result in energy transfer and self-quenching, which reduce the luminescence yield. This phenomenon can occur with fluorescein-tagged molecules as well. If derivatization of a protein is carried out at too high a level, the resultant quantum yield of the conjugate will be depressed. Typically, modifications of proteins involve adding no more than eight to ten fluorescein molecules per protein molecule, with a four to five substitution level considered optimal.

FITC has been used in numerous applications involving fluorescence detection. Antibodies or their fragments can be labeled to detect antigens in cells, tissue sections, blots, or on surfaces (Clausen, 1988). Tagging molecules with FITC is also useful in detecting proteins after electrophoretic separations (Strottmann *et al.*, 1983), for microsequencing analysis of proteins and peptides (Muramoto *et al.*, 1984), in analysis of molecules using capillary zone electrophoresis (Cheng and Dovichi, 1988), and in tracking and detecting molecules involved in various bio-interactions (Friedman and Ball, 1989; Burtnick, 1984).

The level of fluorescein modification in a macromolecule can be determined by measuring its absorbance at or near its characteristic excitation maximum (~498 nm). The number of fluorochrome molecules per molecule of protein is known as the F/P ratio. This value should be measured for all derivatives prepared with fluorescent tags. The ratio is important in predicting the behavior

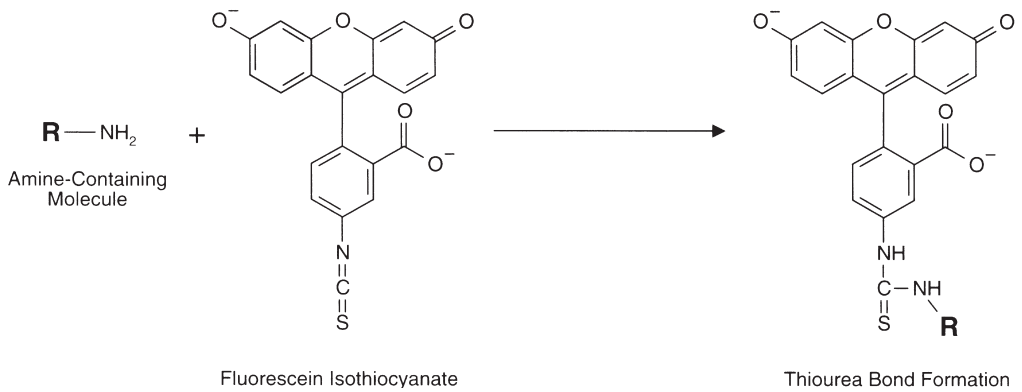

FIGURE 10.5 FITC reacts with amine-containing compounds to produce an isothiourea linkage.

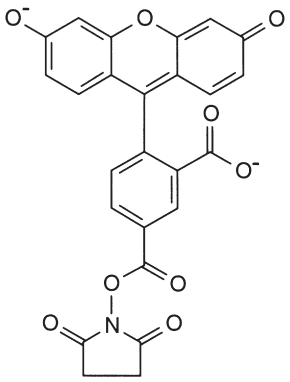
of antibodies labeled with FITC (Hebert *et al.*, 1967; Beutner, 1971). Using the known extinction coefficient of FITC in solution at pH 13 ($\varepsilon_{498\,nm} = 8.1–8.5 \times 10^4$) (McKinney *et al.*, 1964; Jobbagy and Jobbagy, 1972) a determination of derivatization level can be made after excess FITC is removed. At pH 7.8, the absorbance of protein-coupled FITC decreases by 8% (Dalen and Haaijman, 1974).

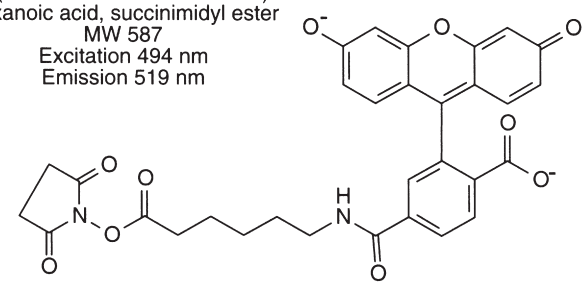
Despite the fact that FITC is one of the oldest reactive dyes used for labeling biomolecules, it still is being used extensively for detection purposes (Lui *et al.*, 2011; Segal *et al.*, 2011; Pushpanathan *et al.*, 2012).

A general protocol for the modification of proteins, particularly immunoglobulins, with FITC is given below. Slight modifications to the amount of reagent added to the reaction may be made to optimize the F/P ratio.



Protocol

1. Prepare a protein solution in 0.1-*M* sodium carbonate, pH 9.0, at a concentration of at least 2 mg/ml.
2. In a darkened lab, dissolve FITC (Thermo Fisher) in dry DMSO at a concentration of 1 mg/ml. Do not use old FITC, as breakdown of the isothiocyanate group over time may decrease coupling efficiency. Protect from light by wrapping in aluminum foil or using amber vials.
3. In a darkened lab, slowly add 50 to 100 µl of FITC solution to each milliliter of protein solution (at 2-mg/ml concentration). Gently mix the protein solution as the FITC is added.
4. React for at least 8 h at 4°C in the dark.
5. The reaction may be quenched by the addition of ammonium chloride to a final concentration of 50-m*M*. Some protocols also include at this point the addition of 0.1% xylene cylanol and 5% glycerol as a photon absorber and fluorescence stabilizer, respectively (Petrou *et al.*, 2002). React for a further 2 h to stop the reaction by blocking remaining isothiocyanate groups.
6. Purify the derivative by gel filtration using a PBS buffer or another suitable buffer for the particular protein being modified. The use of a desalting resin with low exclusion limits works well. To obtain complete separation, the column size should be 15 to 20 times the size of the applied sample. Fluorescent molecules often nonspecifically stick to the gel filtration support, so reuse of the column is not recommended.



1.3. NHS–Fluorescein and NHS–LC-Fluorescein

NHS–fluorescein is another amine-reactive fluorescent probe that contains a carboxy-succinimidyl ester group off the No. 5 or 6 carbons on fluorescein's lower ring structure (Khanna and Ullman, 1980; Vigers *et al.*, 1988; Brinkley, 1992). The 5- and 6-isomers are virtually identical in their reactivity and fluorescent characteristics. Similar to FITC (above), NHS–fluorescein can be used to label proteins and other macromolecules that contain primary amine groups. This reagent is more stable than FITC, especially in storage. The NHS ester reaction proceeds rapidly at slightly alkaline pH values, resulting in a stable, amide-linked derivative (Chapter 3, Section 1.4; Figure 10.6).

NHS-Fluorescein;
5-Carboxyfluorescein,
succinimidyl ester
MW 457
Excitation 491 nm
Emission 518 nm

NHS-LC-Fluorescein;
6-(Fluorescein-5-carboxamido)
hexanoic acid, succinimidyl ester
MW 587
Excitation 494 nm
Emission 519 nm

The fluorescent properties of NHS–fluorescein are similar to FITC. The wavelength of maximal absorbance or excitation for the reagent is 491 nm and its emission maximum is 518 nm, exhibiting a visual color of green (Sheehan and Hrapchak, 1980). Its molar extinction coefficient at 491 nm in a pH 8.0 buffer environment is 66,000 $M^{-1}\,cm^{-1}$. Other components in solution as well as the pH can change this value.

NHS–fluorescein is insoluble directly in aqueous solution and should be dissolved in organic solvent prior to addition of a small aliquot to a buffered reaction medium. Concentrated stock solutions may be prepared in DMSO or DMF. Such solutions are relatively stable if protected from light. Reaction conditions should be maintained at the optimal reactivity for NHS esters—pH 7 to 9.

NHS–LC-fluorescein (Invitrogen) is an analog of NHS–fluorescein that contains a 6-aminocaproic acid spacer group, extending the NHS ester group away from the fluorescein portion. The longer length of the coupling arm may decrease steric hindrance around the fluorescent head of the molecule, thus reducing any

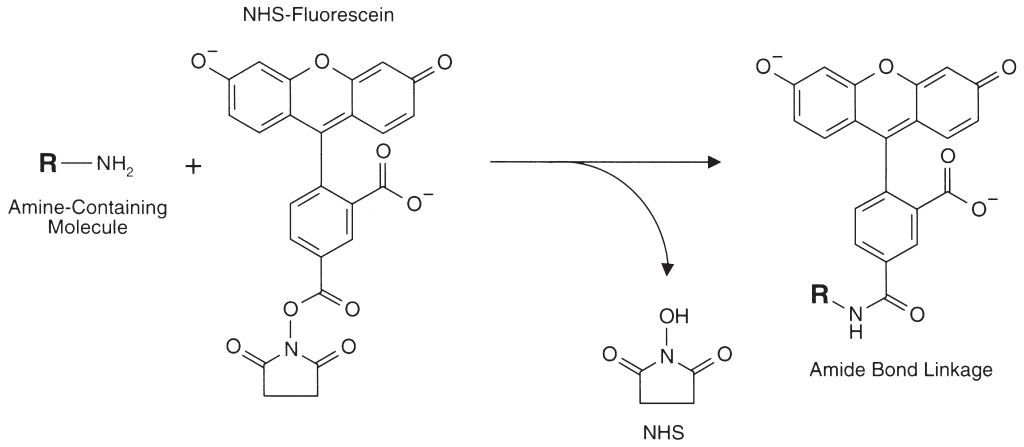


FIGURE 10.6 NHS–fluorescein reacts with amine-containing compounds via its NHS ester group to form amide bonds.

fluorescence quenching due to its attachment to a macromolecule. All other properties of the long-chain version are virtually identical to that described above for NHS–fluorescein.

Sulfonated versions of NHS–fluorescein dyes also are available that contain negative charges to make the molecule more water soluble and avoid nonspecific interactions with biomolecules (Thermo Fisher and Invitrogen). These 488-type dyes are a better choice than the original fluorescein dyes, because of their advantages when working with proteins and other biological samples, including greater brightness, lower nonspecific binding, and less tendency to quench. The NHS ester reactions of the sulfonated dyes are identical to those of the non-sulfonated types, but the sulfonated ones can be labeled on proteins at higher densities without fluorescence quenching or protein precipitation.

NHS–fluorescein has been used to label proteins for fluorescence detection (Domashevskiy *et al.*, 2012), to modify dendrimers (Biswas *et al.*, 2012), for labeling peptides to monitor their interaction with surfaces (Jeong *et al.*, 2011), and to develop assays based on fluorescence polarization (Novitsky and Sloyer, 2012).

The following procedure is a suggested method for using NHS-fluorescein to label immunoglobulins.

Protocol

1. Dissolve the IgG to be labeled in 50-m*M* sodium bicarbonate buffer, pH 8.5, at a concentration of 10 mg/ml.
2. Dissolve 0.5 mg of NHS-fluorescein (Thermo Fisher) in 0.5 ml DMSO. Protect from light.
3. In a darkened lab, slowly add 50 to 100 µl of the NHS–fluorescein solution to the antibody solution, while mixing. Protect from light by wrapping the reaction vessel in aluminum foil.
4. React for 2 h on ice.
5. Remove unreacted NHS–fluorescein and reaction by-products by gel filtration or dialysis. Continue to protect all labeled protein solutions from light.

A spectrophotometric assessment of the F/P ratio should be carried out after purification of the tagged antibody. The measurement of absorbance at 495 nm (for fluorescein) divided by the absorbance at 280 nm should be between 0.3 and 1.0 to obtain a good fluorescent derivative of acceptable activity and low background. This usually translates into a ratio of about four to seven fluorescein molecules per protein molecule.

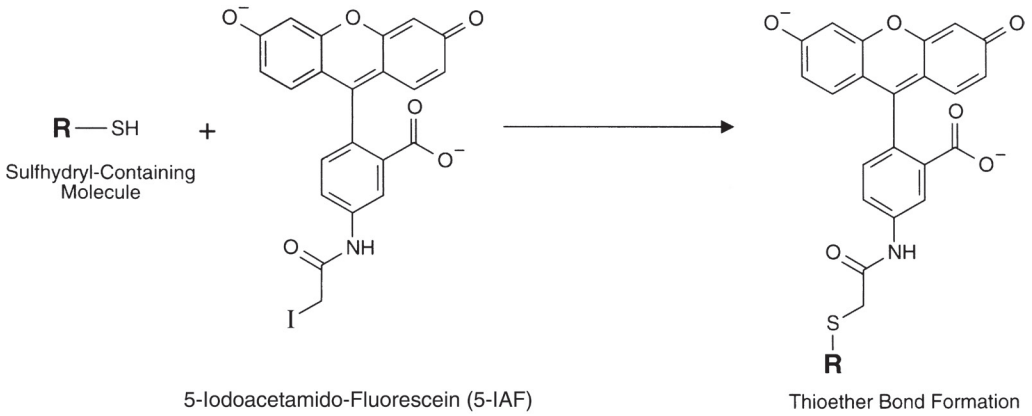
1.4. Sulfhydryl-Reactive Fluorescein Derivatives

Fluorescein derivatives containing a sulfhydryl-reactive group off the lower ring structure are available to direct the modification reaction to more limited sites on target molecules. Coupling through sulfhydryls instead of amines can help to avoid active centers in proteins, thus preserving activity in the fluorescent probe complex. Sulfhydryl reaction sites can be naturally available through free cysteine side chains, generated by reduction of disulfides, or created by the use of thiolation reagents (Chapter 2, Section 4.1).

The first two compounds discussed in this section are truly sulfhydryl reactive, using the common iodoacetyl and maleimide functionalities, respectively. The third derivative, however, is not reactive directly with sulfhydryl groups but contains a protected sulfhydryl which, after deprotection, can be used to react with other sulfhydryl-reactive crosslinkers.

1.5. 5-(and 6)-Iodoacetamido-Fluorescein

The iodoacetamido derivatives of fluorescein possess a sulfhydryl-reactive iodoacetyl group (Chapter 2,



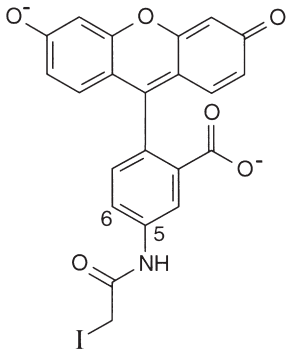


FIGURE 10.7 5-IAF can be used to modify sulfhydryl-containing molecules, creating stable thioether linkages.

Section 4.2, and Chapter 3, Section 2.1) at either the 5- or 6-carbon position on their lower ring. The isomers are commercially available in purified form, since some reactivity and specificity differences between the 5- and 6-derivatives toward various sulfhydryl sites in proteins may be observed. Both iodoacetamido derivatives are among the most intense fluorophores available for labeling biomolecules due to high QY.

The iodoacetyl group of both isomers reacts with sulfhydryls under slightly alkaline conditions to yield stable thioether linkages (Figure 10.7). They do not react with unreduced disulfides in cystine residues or with oxidized glutathione (Gorman *et al.*, 1987). The thioether bonds will be hydrolyzed under conditions necessary for complete protein hydrolysis prior to amino acid analysis.

5- (and 6)-Iodoacetamido-Fluorescein
MW 515.26
Excitation: 490–495 nm
Emission: 515–520 nm
ε at 492 nm = 80,000–85,000 $M^{-1}cm^{-1}$

Care must be taken to protect these reagents from light, not only to maintain the fluorescent yield of the fluorescein probe, but also to protect the iodoacetyl group from light-catalyzed breakdown. Iodoacetamido-fluorescein is soluble in DMF and also in aqueous solutions maintained above pH 6.0. Concentrated stock solutions may be prepared in DMF prior to the addition of a small aliquot to a reaction mixture. Protect solutions from light by wrapping in aluminum foil and working in subdued light.

The spectral properties of these derivatives are similar to native fluorescein. The excitation maximum occurs at about 490 to 495 nm and its emission peak at 515 to 520 nm, producing light in the green region of the spectrum. The extinction coefficient of 5-iodoacetamido-fluorescein at its wavelength of maximum absorbance, 491 nm, is 82,000 $M^{-1}cm^{-1}$ (pH 9), whereas the extinction coefficient of 6-iodoacetamido-fluorescein is 77,000 $M^{-1}cm^{-1}$ at 493 nm (pH 9).

The 5-iodoacetamido derivative of fluorescein (5-IAF) has been used to label numerous proteins and other biomolecules, including actin (Plank and Ware, 1987), myosin (Aguirre *et al.*, 1986), troponin (Greene, 1986), hemoglobin (Hirsch *et al.*, 1986), and sulfhydryl-containing proteins separated by SDS electrophoresis (Gorman, 1984).

The 6-iodoacetamido derivative (6-IAF) has been used to label myosin (Ando, 1984), actin (Konno and Morales, 1985), microtubule-associated proteins (Scherson *et al.*, 1984), and histones (Cocco *et al.*, 1986).

Iodoacetamido-fluorescein continues to be used to tag thiol-containing molecules for fluorescence detection. Abate-Pella *et al.* (2012) used the dye to investigate Ras-mediated signal transduction, Maki (2011) used it to label human p53 to study its import and export from the nucleus, and the dye was also used to analyze alpha-1-acid glycoprotein isoforms (Garrido-Medina *et al.*, 2012).

The following protocol for labeling proteins with 5-IAF is adapted from Gorman (1987). It is a bit unusual

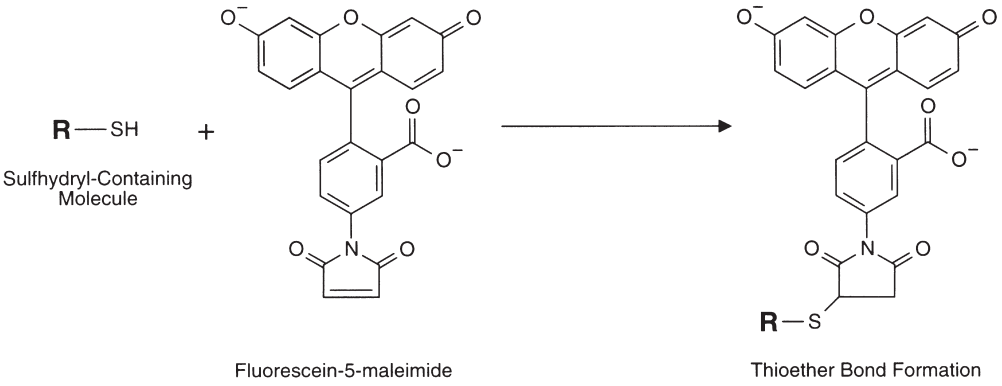

FIGURE 10.8 Fluorescein-5-maleimide can be used to modify sulfhydryl groups in proteins and other molecules, forming thioether bonds.

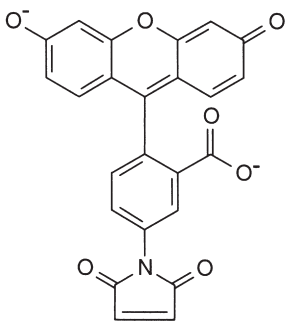
in that it involves reduction of disulfides with DTT and immediate reaction with 5-IAF in excess without removal of excess reductant. The procedure can be changed to include a gel filtration step after disulfide reduction to remove excess DTT, but in any case, it should be optimized for each protein to be modified. An alternative to the use of DTT to produce sulfhydryls is thiolation with a compound that can generate free thiols upon reaction with a protein (Chapter 2, Section 4.1).

Protocol

1. Dissolve a protein containing disulfide residues at a concentration of 5 to 10 mg/ml in 0.1-*M* ammonium carbonate containing 1% SDS and 20-m*M* DTT. Note: The presence of detergent may be eliminated if certain disulfides can be reduced in the protein without completely denaturing it, such as in the reduction of antibodies in the hinge region. If only partial reduction is done, then the amount of DTT should be reduced to about a 3-fold molar excess over the concentration of antibody present (Sun *et al.*, 2005). For this type of labeling the reaction buffer should be 50-m*M* sodium borate, pH 8.5.
2. For complete reduction of all disulfides in the presence of a denaturant, react for 16 h at 0°C and 2 h at room temperature. For partial reduction of disulfides, the reaction time may be reduced to 2 h at 37°C, particularly for antibody thiol reduction, if only partial reduction of thiols in the hinge region is done.
3. Add a 5-fold molar excess of 5-IAF (Thermo Fisher) over the amount of DTT present. The fluorescent probe may be solubilized in DMF prior to addition of a small aliquot to the reaction mixture. Do not exceed 10% DMF in the final aqueous solution.
4. React for 2 h at room temperature in the dark.
5. To recover a protein that has been completely reduced and labeled, precipitate the protein by the addition of 9 volumes of methanol at −20°C. Collect the protein pellet by centrifugation at 8000 *g* for 15 min (4°C). If partial reduction was done followed by labeling with 5-IAF, then purify the labeled protein by gel filtration or dialysis using a molecular weight cutoff of about 5000 Daltons.

An alternative protocol for labeling sulfhydryl-containing proteins that does not require DTT reduction can be found in a method adapted from Ando (1984). When preparing any fluorescently labeled protein, optimization of the dye-to-protein ratio is important to obtain the best performance in the intended application.



Protocol

1. Prepare a 20-m*M* 6-IAF (Thermo Fisher) solution by dissolving 10.3 mg per milliliter of DMF. Prepare freshly and protect from light.
2. Dissolve the protein to be modified at a concentration of 5 to 10 mg/ml in 20-m*M* TES, pH 7.0. TES is 2-[tris(hydroxymethyl)methylamino]-1-ethanesulfonic acid.
3. Slowly add 25 to 50 µl of the 6-IAF solution to each milliliter of the protein solution while mixing.
4. React for 2 h at 4°C in the dark.
5. Remove excess reactant and reaction byproducts by gel filtration using a desalting resin or dialysis.

1.6. Fluorescein-5-Maleimide

Fluorescein-5-maleimide is a fluorescent probe containing a sulfhydryl-reactive maleimide group on it lower ring structure. The modification of sulfhydryl-containing molecules under physiological pH conditions will result in stable thioether bonds (Chapter 3, Section 2.2) (Figure 10.8). The derivative thus possesses fluorescent properties

closely characteristic of fluorescein molecules: excitation wavelength = 490 nm; emission wavelength = 515 nm, in the green spectral region. Conjugates prepared by fluorescein-5-maleimide are among the most intensely fluorescent probes available. The reactivity of the maleimide group is similar to that of the iodoacetyl derivative discussed previously.

Fluorescein-5-maleimide
MW 427
Excitation: 490–495 nm
Emission: 515–520 nm
ε at 490 nm = 83,000 $M^{-1}cm^{-1}$

Thus, this reagent can be used to fluorescently label proteins and other biomolecules containing free sulfhydryl residues. If there are no SH groups available, their creation can be accomplished by reduction of indigenous disulfides or through the use of various thiolation reagents (Chapter 2, Section 4.1).

Fluorescein-5-maleimide is slightly soluble in aqueous solutions above pH 6 (~1-m*M* concentration). It may be dissolved in DMF at higher concentrations and a small addition of this solution made to an aqueous reaction mixture to initiate labeling. Do not exceed 10% DMF in the reaction buffer to avoid protein precipitation. At pH 8, the reagent has an extinction coefficient at 490 nm of about 78,000 $M^{-1}cm^{-1}$.

Fluorescein-5-maleimide has been used in numerous applications, including labeling the transmembrane glycoprotein H-2K^k on both the N- and C-terminal regions to investigate the structure of the molecule (Cardoza *et al.*, 1984), for the determination of two different conformations of the protein actin (Konno and Morales, 1985), in the study of a bacterial sensory receptors (Falke *et al.*, 1988), in the structural mapping of chloroplast coupling factor (Snyder and Hammes, 1984, 1985), for localization of the stilbenedisulfonate receptor on human erythrocytes (Rao *et al.*, 1979), to investigate the calcium-dependent ATPase protein structure of sarcoplasmic reticulum (Bigelow and Inesi, 1991), and to study the movement of tRNA during peptide bond formation on ribosomes (Odom *et al.*, 1990).

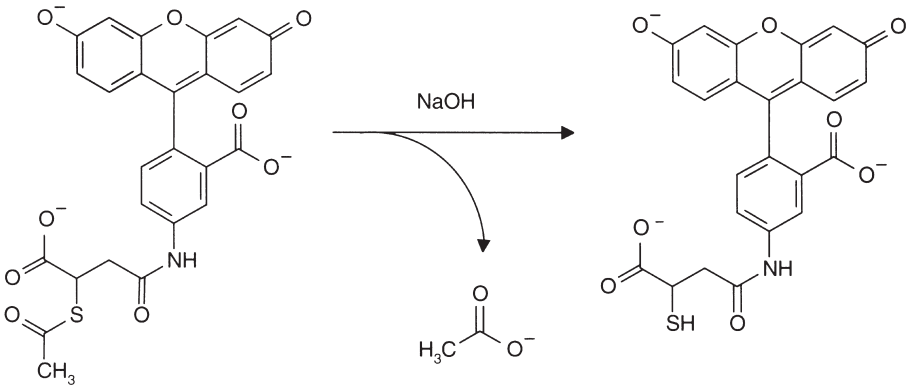
Fluorescein-5-maleimide has also been used to study the assembly dynamics of mycobacterium tuberculosis (Chen *et al.*, 2007), to study monomers and dimers of NhaA Na^+/H^+ antiporter of *E. coli* (Rimon *et al.*, 2007), to investigate the regulation of the protein disulfide proteome by mitochondria (Yang *et al.*, 2007), and to study the folded state of fibronectin type III domains (Lemmon *et al.*, 2011).

Protocol

1. Dissolve a sulfhydryl-containing protein or other macromolecule at a concentration of 1 to 10 mg/ml in 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Other buffers within the range of pH 6.5 to 7.5 may be used as long as they do not contain extraneous sulfhydryls.
2. Dissolve fluorescein-5-maleimide (Thermo Fisher, Invitrogen) in DMF at a concentration of 10-m*M* (4.25 mg/ml). Protect from light.
3. In subdued lighting conditions, add 25 to 50 µl of the fluorescein solution to each milliliter of protein solution while mixing. Alternatively, determine the exact molar quantity of protein present and add a 25-fold molar excess of fluorescein-5-maleimide solution.
4. React for 2 to 4 h at room temperature in the dark. The reaction also may be performed at 0 to 4°C, but allow at least 8 h for completion.
5. Immediately purify the derivative using gel filtration on a desalting resin. Protect the solutions from light during the chromatography.

1.7. SAMSA–Fluorescein

SAMSA–fluorescein, 5-((2-(and 3)-*S*-(acetylmercapto) succinoyl)amino)fluorescein, is a fluorescent probe containing a protected sulfhydryl group. In its protected state, the compound is unreactive. The acetyl protecting group can be removed by treatment with dilute NaOH at pH 10.0 (Figure 10.9). The resulting free sulfhydryl derivative can be used to label thiol-reactive crosslinkers or to couple with sulfhydryl residues on proteins and other molecules. After activating proteins with crosslinkers containing terminal maleimide, pyridyl disulfide, or iodoacetyl groups, SAMSA–fluorescein can be used to assess the level of modification. For instance, a maleimide-activated protein that has been derivatized with succinimidyl-4-(*N*-maleimidomethyl) cyclohexane-1-carboxylate (SMCC) could be reacted with this reagent to yield a fluorescein derivative that can be assayed spectrofluorometrically for its level of fluorescence. Using the molar extinction coefficient for SAMSA–fluorescein (ε at 495 nm = 80,000 $M^{-1}cm^{-1}$), the molar level of incorporation of the label can be calculated. This determination directly correlates to the original level of maleimide groups present on the protein.



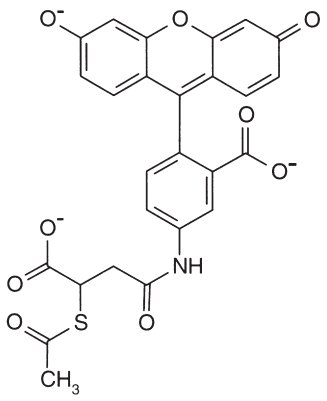


FIGURE 10.9 SAMSA–fluorescein contains a protect thiol that can be deblocked by treatment with hydroxylamine. The reagent then can be used to modify molecules containing sulfhydryl-reactive groups.

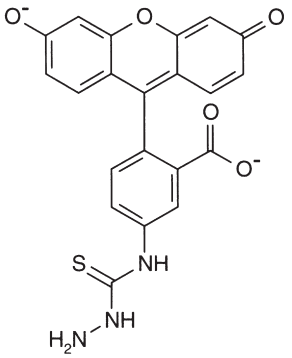
The dye has been used to investigate the uptake mechanisms of a mannan nanogel in macrophages (Ferreira *et al.*, 2012), to optimize the signal-to-noise ratios in making signal-enhanced Raman spectroscopy (SERS) tags (Fabris, 2012), and to tag silver nanoparticles for the development of a therapeutic to treat multidrug resistant cancer (Liu *et al.*, 2012).

SAMSA–fluorescein is an orange solid compound. Dissolved in buffer at pH 9.0, its maximal wavelength of absorption or excitation is at 495 nm, while its emission wavelength maximum is 520 nm. The reagent and all solutions and derivatives made from it are light sensitive and should be stored in the dark. SAMSA–fluorescein is soluble in aqueous solutions above pH 6.0, but it can be dissolved in DMF to prepare a concentrated stock solution prior to adding a small amount to a buffered reaction mixture.

Protocol

1. To deprotect the acetylated sulfhydryl, dissolve the desired amount of SAMSA–fluorescein (Invitrogen) in 100-m*M* NaOH, pH 10.0, at a concentration of 10 mg/ml.
2. React for 15 min at room temperature.
3. Lower the pH to 7 to 8 by the addition of solid sodium phosphate.
4. Add the required amount of deprotected SH-fluorescein to a protein or other macromolecule that had been modified to contain a sulfhydryl-reactive group. Use a 5- to 10-fold molar excess of SH-fluorescein to the expected amount of sulfhydryl reactivity present.
5. React for 2 h at room temperature, protected from light.
6. Remove excess fluorescent probe by gel filtration using a desalting resin.
7. Measure the absorbance of the derivative at 495 nm. Determine the level of fluorophore incorporation by using its molar extinction coefficient.



1.8. Aldehyde-/Ketone- and Cytosine-Reactive Fluorescein Derivatives

Hydrazide groups directly react with aldehyde and ketone groups to form relatively stable hydrazone linkages (Chapter 3, Section 5.1). Two fluorescein derivatives are commonly available that contain hydrazide groups off their No. 5 carbons on the lower ring structure. Both may be used to fluorescently label aldehyde- or ketone-containing molecules. Although most biomolecules do not contain aldehyde or ketone groups in their native state, carbohydrates, glycoproteins, RNA, and other molecules containing sugar residues can be oxidized with sodium periodate to produce reactive formyl groups. The use of modification reagents that generate aldehydes upon coupling to a molecule also can be used to produce a hydrazide-reactive site (Chapter 2, Section 4.4).

DNA and RNA may be modified with hydrazide-reactive probes by reacting their cytosine residues with bisulfite to form reactive sulfone intermediates. These derivatives undergo transamination to couple hydrazide- or amine-containing probes (Draper and Gold, 1980) (Chapter 23, Section 2.3).

1.9. Fluorescein-5-thiosemicarbazide

Fluorescein-5-thiosemicarbazide (Invitrogen) is a hydrazide derivative of fluorescein that can spontaneously react with aldehyde- or ketone-containing molecules to form a covalent, hydrazone linkage (Figure 10.10). It also can be used to label cytosine residues in DNA or RNA by use of the bisulfite activation procedure (Chapter 23, Section 2.1). The resulting fluorescent derivative exhibits an excitation maximum at a wavelength of 492 nm and a maximal emission wavelength of 519 nm when dissolved in buffer at pH 8.6. In the same buffered environment, the compound has an extinction coefficient of approximately 78,000 $M^{-1}cm^{-1}$ at 492 nm.

Fluorescein-5-thiosemicarbazide is soluble in DMF or in buffered aqueous solutions at pH values above 7.0. The reagent may be dissolved in DMF as a concentrated stock solution before adding a small aliquot to an aqueous reaction medium. The compound itself and all solutions made with it should be protected from light to avoid decomposition of its fluorescent properties.

This hydrazide derivative of fluorescein has been used in a number of applications, including site-directed labeling of antibodies through their carbohydrate chains (Duijndam *et al.*, 1988); labeling thrombin and anti-thrombin (Atha *et al.*, 1964), Na^+/K-ATPase glycoprotein (Lee and Fortes, 1985), and periodate-oxidized RNA (Odom *et al.*, 1980, 1984; Ferguson and Yang, 1986; Friedrich *et al.*, 1988); determining carbonyl groups in proteins; and detecting oxidized glycoproteins in gels (Ahn *et al.*, 1987). It also has been used to investigate the molecular basis of RNA recognition (Pagano *et al.*, 2007), in a non-invasive visualization method for assessment of carbonylated protein (Fujita *et al.*, 2007), for the detection of protein carbonyls in aging liver tissue (Chaudhuri *et al.*, 2006), and to label polysaccharides to image as they are transported into cells (Zhang *et al.*, 2011).

The following protocols are generalized for the labeling of cell surface glycoproteins or glycoproteins in solution. Some optimization may be necessary to achieve the best level of fluorescent modification for each particular application.

Protocol for Labeling Cell Surfaces

1. Add 10^6 to 10^8 cells per ml in a PBS solution (10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4) containing 1-m*M* sodium periodate and incubate on ice for 30 min in the dark. This level of periodate addition will target the oxidation only to sialic acid residues (Chapter 2, Section 4.4). If additional sites of glycosylation also are to be labeled, increase the periodate concentration to 10-m*M* and perform the reaction at room temperature in the dark.

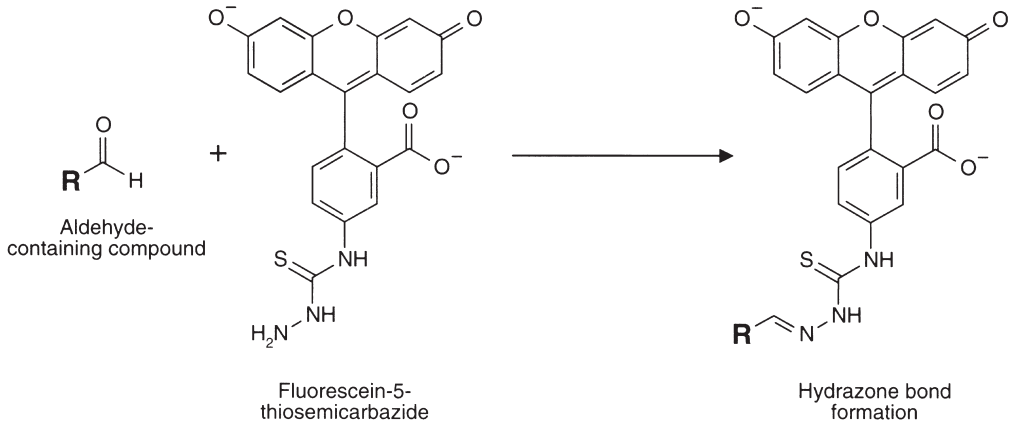


FIGURE 10.10 Fluorescein-5-thiosemicarbazide reacts with aldehyde groups to produce hydrazone linkages.

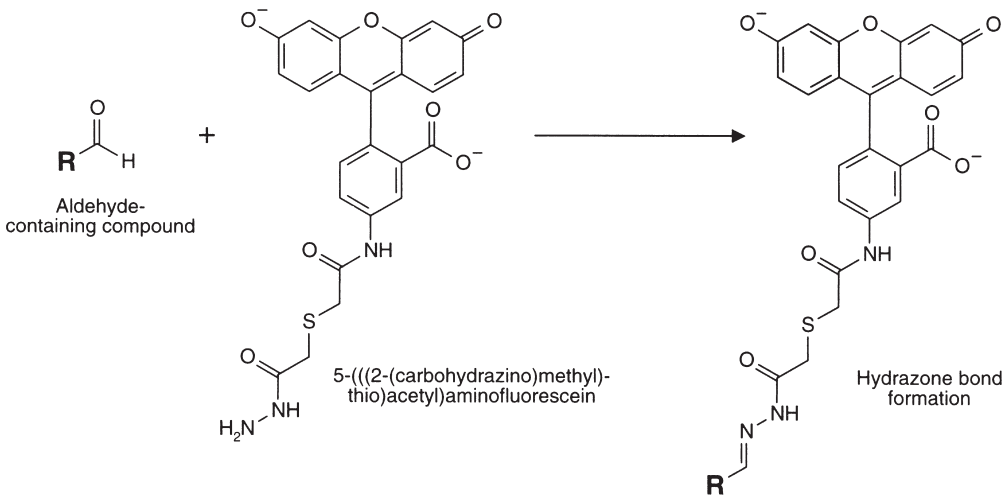
2. Centrifuge and wash cells several times with PBS. Some protocols include a quench step wherein excess sodium periodate is eliminated by addition of glycerol. This can be accomplished by adding 3 volumes of 0.1-*M* glycerol in PBS prior to centrifugation.
3. Resuspend cells in PBS containing 0.5 mg/ml fluorescein-5-thiosemicarbazide.
4. Incubate 30 min in the dark at room temperature.
5. To reduce the hydrazone bonds to more stable linkages, cool the cell suspension to 0°C and add an equal volume of 30-m*M* sodium cyanoborohydride in PBS. Incubate for 40 min. Note: If the presence of a reducing agent is detrimental to protein activity, eliminate the reduction step. In most cases, the hydrazone linkage is stable enough for fluorescent labeling experiments.
6. Centrifuge and wash cells extensively with PBS.

Protocol for Labeling Glycoproteins in Solution

1. Dissolve the glycoprotein(s) to be labeled in ice-cold 1-m*M* sodium periodate, 10-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, for the exclusive oxidation of sialic acid residues. For general carbohydrate oxidation, increase the periodate concentration to 10-m*M* in PBS at room temperature.
2. React for 30 min on ice (for sialic acids) or at room temperature (for other polysaccharide residues).
3. Remove excess reactant by gel filtration using a desalting resin with PBS, pH 7.4. Some protocols use a quenching agent to remove excess periodate prior to gel filtration. This can be done by adding glycerol to a final concentration of 0.1-*M*.
4. To the purified, oxidized glycoprotein(s), add fluorescein-5-thiosemicarbazide to a final concentration of 0.5 mg/ml.
5. React for 30 min at room temperature in the dark.
6. To reduce the hydrazone bonds to more stable linkages, cool the solution to 0°C and add an equal volume of 30-m*M* sodium cyanoborohydride in PBS. Incubate for 40 min. Note: If the presence of a reducing agent is detrimental to protein activity, eliminate the reducing step. In most cases, the hydrazone linkage is stable enough for fluorescent labeling experiments.
7. Purify the fluorescently labeled glycoprotein(s) by gel filtration using a desalting resin.

1.10. 5-(((2-(Carbohydrazino)methyl)thio) acetyl)-aminofluorescein

Another hydrazine derivative of fluorescein, 5-(((2-(carbohydrazino)methyl)thio)acetyl)-aminofluorescein (invitrogen), contains a longer spacer arm off the No. 5 carbon atom of its lower ring than fluorescein-5-thiosemicarbazide, described previously. The reagent can be used to react spontaneously with aldehyde- or ketone-containing molecules and form a hydrazone linkage (Figure 10.11). It also can be used to label cytosine residues in DNA or RNA by use of the bisulfite activation procedure (Chapter 23, Section 2.1). The resulting fluorescent derivative exhibits a maximal excitation at 490 nm and a maximal luminescence emission peak at 516 nm when dissolved in buffer at pH 8.0. In the same buffered environment, the compound has an extinction coefficient of approximately 75,000 $M^{-1}cm^{-1}$ at 490 nm.



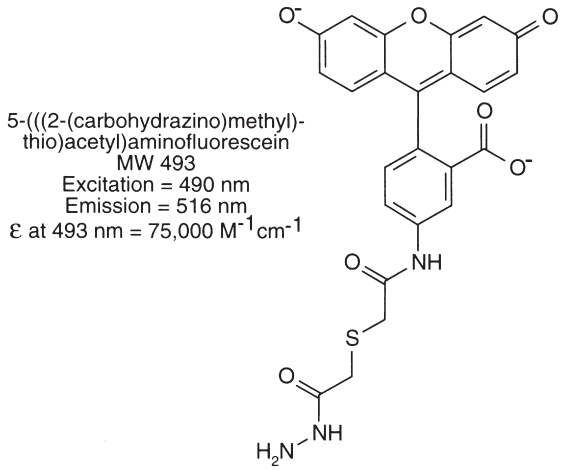


FIGURE 10.11 This carbohydrazide-containing fluorescein derivative can be used to modify aldehyde-containing molecules. Glycoconjugates may be labeled with this reagent after treatment with sodium periodate to produce aldehydes on the carbohydrate portion.

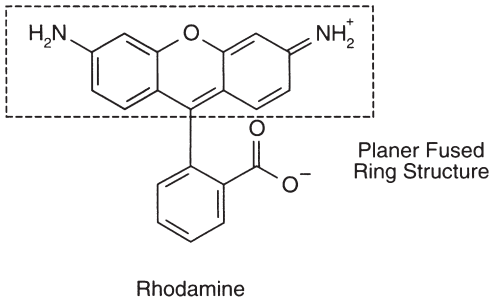

FIGURE 10.12 The basic structure of rhodamine derivatives with the xanthene triple ring system at its core.

The fluorescent probe, 5-(((2-(carbohydrazino)methyl) thio)acetyl)-aminofluorescein, is soluble in DMF or in buffered aqueous solutions at pH values above 7.0. The reagent may be dissolved in DMF as a concentrated stock solution before adding a small aliquot to an aqueous reaction medium. The compound itself and all solutions made with it should be protected from light to avoid decomposition of its fluorescent properties.

The methods for using this reagent in labeling glycoproteins on cell surfaces or in solution are similar to those described for fluorescein-5-thiosemicarbazide, above.

2. RHODAMINE DERIVATIVES

Rhodamine and its derivatives are popular fluorescent probes for labeling all types of biomolecules. Their fluorescent character is created by the presence of a planar, multi-ring aromatic xanthene core structure, similar to the core of fluorescein, but in this case with nitrogen atoms replacing the oxygens on the outer rings (Figure 10.12). Fluorescent modification reagents based on rhodamine are derivatives of this basic structure. Activated rhodamine probes have reactive groups prepared through substitutions off the numbers 5 or 6 carbon atoms of its lower ring. These derivatives provide reactivity toward particular functional groups in biomolecules, allowing rapid labeling of proteins and nucleic acids. Other alterations to the basic rhodamine structure modulate its fluorescent character, creating more intense or stable fluorophores, or changing its wavelength of excitation and emission toward the red region. Many such derivatives are now commercially available.

The tetramethylrhodamine derivative, for instance, has two methyl groups attached to each nitrogen on its outer rings. Activated forms of tetramethylrhodamine are among the most common derivatives of rhodamine used for fluorescent labeling. Another useful derivative is rhodamine B, which contains two ethyl groups on each nitrogen as well as a carboxylate group at the No. 3 position on its lower ring. Rhodamine 6G adds two methyl groups on the outer rings as well as an ethyl ester group off rhodamine B's carboxylate. Rhodamine 110 contains no substituents on the upper nitrogens and only the carboxylate on the lower ring. Sulforhodamine B possesses rhodamine B's two ethyl groups on each nitrogen of the upper rings, but has two sulfonates at the number 3 and 5 positions of its lower ring. This derivative is often called Lissamine™ rhodamine B—Lissamine being a trademark of Imperial Chemical Industries. Another popular derivative of rhodamine, sulforhodamine 101, goes by the name of Texas Red™ (a trademark of Invitrogen). This derivative has intense luminescent properties that take it the farthest into the red region of the spectrum. The basic structures of these rhodamine derivatives are shown in Figure 10.13. The corresponding commercially available rhodamine fluorophores usually contain additional reactive groups, on the No. 5 or 6 carbons of the lower ring, to permit coupling to target molecules (Invitrogen, Thermo Fisher).

Rhodamine derivatives have effective excitation wavelengths within the visible light spectrum from the low- to high-500-nm range, depending on the particular derivative. Their associated emission wavelengths occur from the mid- to high-500-nm range—with Texas Red derivatives typically emitting at over 600 nm—within the orange-to-red visible spectrum. The QY of rhodamine derivatives is generally less than that of fluorescein—only about 25%. However, its fluorescent intensity fades more slowly than fluorescein when it is dissolved in buffers, exposed to light, or stored for extended periods. In addition, its orange-to-red luminescence is in stark contrast to the green of fluorescein. Thus, these two types of probes form an ideal pair for use in double staining techniques, especially in fluorescent microscopy.

The following sections describe the most important rhodamine derivatives commonly used to label biomolecules.

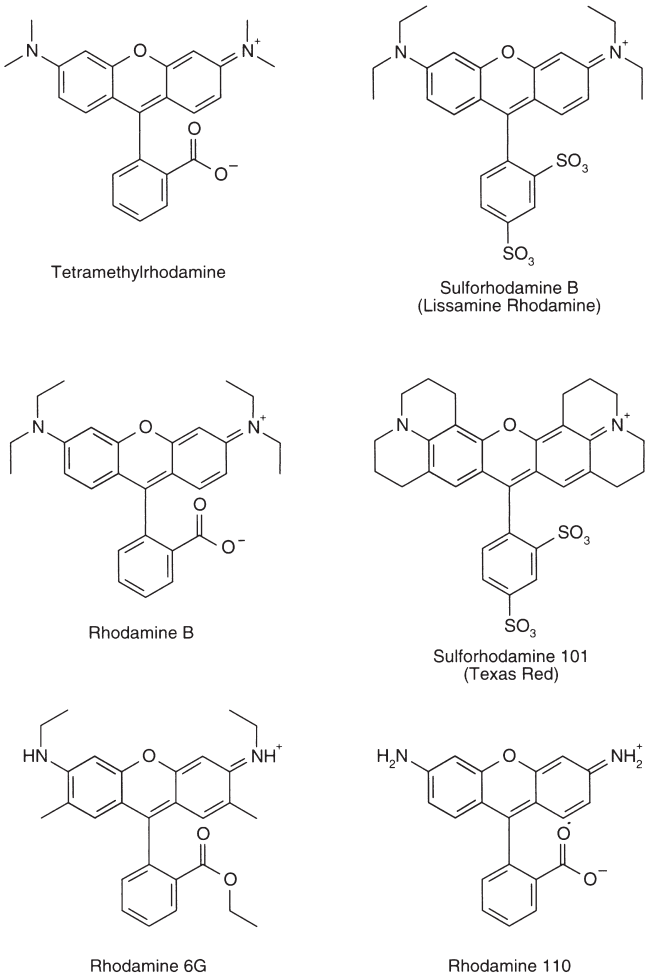

FIGURE 10.13 The primary rhodamine derivatives useful for fluorescent labeling.

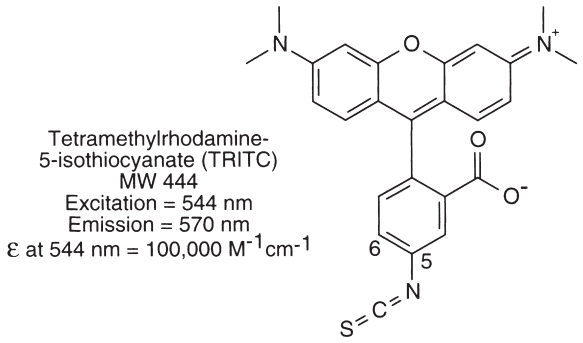

2.1. Amine-Reactive Rhodamine Derivatives

Four forms of amine-reactive rhodamine probes are commonly available. Two of them are based on the tetramethyl derivatives of the fundamental rhodamine structure, one is based on the sulforhodamine B or Lissamine derivative, and the last is the sulforhodamine 101 or Texas Red-type of derivative. All of them react under alkaline conditions with primary amines in proteins and other molecules to form stable, highly fluorescent complexes.

2.2. Tetramethylrhodamine-5-(and 6)-isothiocyanate (TRITC)

TRITC is one of the most popular fluorescent probes available. The isothiocyanate derivative of tetramethylrhodamine is synthesized by modification of its lower ring at the 5- or 6-carbon positions. The two resulting isomers are almost identical in their reactivity but slightly different in their spectral properties, including excitation and emission wavelengths and intensities. The chemical differences in the isomers, however, may affect the separation of modified proteins from excess probe or the analysis of tagged molecules by electrophoresis. For this reason, most manufacturers offer the mixed isomers as well as the purified 5- or 6-isothiocyanate derivatives individually.

Isothiocyanates react with nucleophiles such as amines, sulfhydryls, and the phenolate ion of tyrosine side chains (Podhradsky *et al.*, 1979). The only stable product, however, is with primary amine groups, and so TRITC is almost entirely selective for modifying ε- and N-terminal amines in proteins. The reaction involves attack of the nucleophile on the central, electrophilic carbon of the isothiocyanate group (Figure 10.14). The resulting electron shift creates a thiourea linkage between TRITC and the protein with no leaving group.

TRITC is relatively insoluble in water, but it can be dissolved in DMF or DMSO as a concentrated stock solution prior to its addition to an aqueous reaction mixture. The isothiocyanate group is reasonably stable in aqueous solution for short periods, but will degrade by hydrolysis. TRITC also is more stable to photobleaching than FITC (Section 1), and its absorption and emission spectra are less sensitive to environmental conditions, such as pH. It is best, however, to use only fresh reagent for modification purposes. Storage should be under desiccated conditions, protected from light, and at −20°C.

The fluorescent properties of TRITC (mixed isomers) include an absorbance maximum at about 544 nm and an emission wavelength of 570 nm. Fluorescent quenching of the molecule is possible. Under concentrated conditions, rhodamine-to-rhodamine interactions result in self-quenching which reduces its luminescence yield. This phenomenon can occur with TRITC-tagged molecules, as well. If derivatization of a protein is done at too high a level,

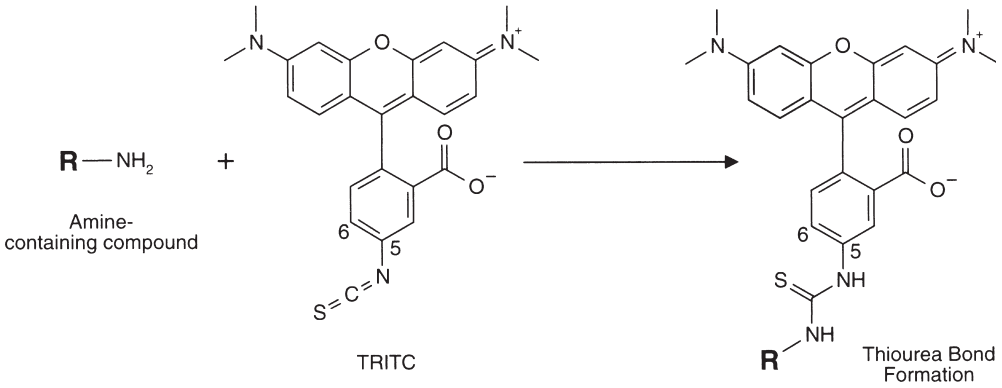

FIGURE 10.14 TRITC reacts with amine-containing molecules to create an isothiourea linkage.

the resultant QY of the conjugate will be depressed from expected values. Typically, modifications of proteins involve adding no more than eight to ten rhodamine molecules per molecule of protein, with a four to five substitution level considered optimal.

TRITC has been used in numerous applications involving fluorescence detection, including double-staining techniques with fluorescein-labeled probes (Mossberg and Ericsson, 1990), the synthesis of fluorescently labeled DNA probes (Smith *et al.*, 1985), as a label in homogeneous immunoassay systems (Nithipatikom and McGown, 1987), investigating specific interactions of proteins with cell surfaces (Hochman *et al.*, 1988), and as an important fluorescent tag of antibodies in immunohistochemical staining techniques (Davidson and Hilchenbach, 1990). The fluorescent dye also has been used to investigate dynein-dependent transport of virus proteins (Ramanathan *et al.*, 2007), the trafficking of the prion protein (Campana *et al.*, 2007), the distribution of FAT1 isoforms in migrating cells (Braun *et al.*, 2007), and the development of a dual immunofluorescence system for confocal microscopy (Entwistle and Noble, 2011). Many thousands of additional references cite the use of TRITC in labeling molecules in fluorescence detection applications.

The level of TRITC modification in a macromolecule can be determined by measuring its absorbance at or near its characteristic absorption maximum (~575 nm). The number of fluorochrome molecules per molecule of protein is known as the F/P ratio. This value should be measured for all derivatives prepared with fluorescent tags. The ratio is especially important in predicting the behavior of antibodies labeled with TRITC. For a TRITC-labeled protein, the ratio of its absorbance at 575 nm to 280 nm should be between 0.3 and 0.7.

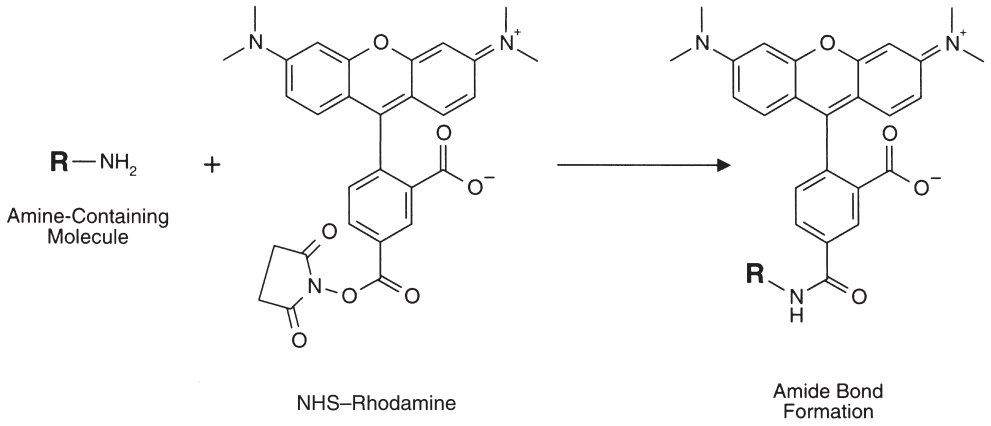
A general protocol for the modification of proteins, particularly immunoglobulins, with TRITC is given below. Modifications to the amount of reagent added to the reaction may be done to optimize the F/P ratio.

Protocol

1. Prepare a protein solution in 0.1-*M* sodium carbonate, pH 9.0, at a concentration of at least 2 mg/ml.
2. In a darkened lab, dissolve TRITC (Thermo Fisher) in dry DMSO at a concentration of 1 mg/ml. Do not use old TRITC, as breakdown of the isothiocyanate group over time may decrease coupling efficiency. Protect from light by wrapping in aluminum foil or using amber vials.
3. In a darkened lab, slowly add 50 µl of TRITC solution to each milliliter of protein solution. Gently mix the protein solution as the TRITC is added.
4. React for at least 8 h at 4°C in the dark or 2 to 4 h at room temperature.
5. The reaction may be quenched by the addition of ammonium chloride to a final concentration of 50-m*M*. Some protocols also include at this point the addition of 0.1% xylene cylanol and 5% glycerol as a photon absorber and protein stabilizer, respectively. React for a further 2 h to stop the reaction by blocking remaining isothiocyanate groups.
6. Purify the derivative by gel filtration using a PBS buffer or another suitable buffer for the particular protein being modified. The use of a desalting resin (e.g., Excellulose, Thermo Fisher) or similar matrices with low exclusion limits works well. To obtain complete separation, the column size should be 15 to 20 times the size of the applied sample. Fluorescent molecules often nonspecifically stick to gel filtration supports, so reuse of the column is not recommended.

2.3. NHS–Rhodamine

NHS–rhodamine is an amine-reactive fluorescent probe that contains a carboxy-succinimidyl ester group off the No. 5 or 6 carbons on rhodamine's lower ring structure (Kellogg *et al.*, 1988). The 5- and 6-isomers are virtually identical in their reactivity and fluorescent



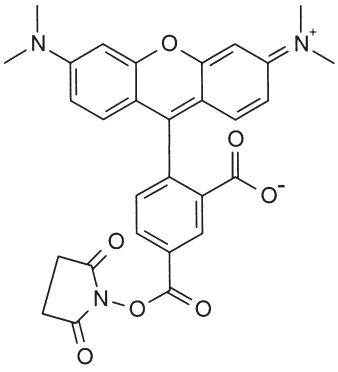


FIGURE 10.15 NHS–rhodamine can be used to label amine-containing molecules such as proteins by reaction with its NHS ester group.

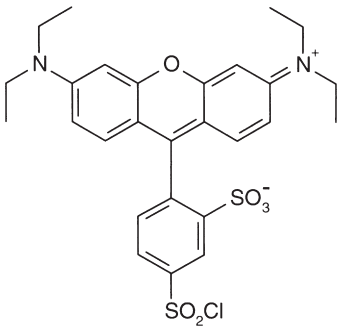
characteristics. Similar to TRITC (described previously), NHS–rhodamine can be used to label proteins and other macromolecules that contain primary amine groups. The isomeric forms of the fluorescent probe are available in mixed and purified forms (Invitrogen, Thermo Fisher). The pure forms are particularly important for labeling nucleic acid probes that will be separated by electrophoresis (Chehab and Kan, 1989). The NHS ester labeling reaction proceeds rapidly at slightly alkaline pH values, resulting in a stable, amide-linked derivative (Chapter 3, Section 1.4; Figure 10.15).

The fluorescent properties of NHS–rhodamine are similar to TRITC. The wavelength of maximal absorbance or excitation for the reagent is 544 nm and its emission maximum is 576 nm, exhibiting a visual color of orange–red. Its molar extinction coefficient at 546 nm in a methanol environment is 63,000 $M^{-1}cm^{-1}$. Other components in solution as well as the pH (in aqueous buffers) can change this value.

NHS–rhodamine is insoluble directly in aqueous solution and should be dissolved in organic solvent prior to addition of a small aliquot to a buffered reaction medium. Concentrated stock solutions may be prepared in DMSO or DMF. Such solutions are relatively stable for short periods if protected from light, but should be prepared fresh. Reaction conditions should be maintained at the optimal reactivity for NHS esters, which is pH 7 to 9.

NHS–rhodamine has been used in numerous applications, including the detection of specific DNA sequences (Chehab and Kan, 1989), studying the behavior of microtubules and actin filaments in living *Drosophila* embryos (Kellogg *et al.*, 1988), investigation into the light-initiated breakup of microtubules (Vigers *et al.*, 1988), studying ω-conotoxin-sensitive channels in neurons (Jones *et al.*, 1989), investigating growth cones during axon elongation (Tanaka and Kirschner, 1991), and studying the pathways of mitotic spindle assembly *in vitro* (Sawin and Mitchison, 1991). NHS–rhodamine has also been used to perform fluorescent studies of membrane protein complexes (Wittig *et al.*, 2007), to investigate the cross-bridge between microtubules (Li *et al.*, 2007), to study a multi-enzyme network in digestion (Delcroix *et al.*, 2006), and to label self-assembling CpG DNA nanoparticles for antigen delivery (Rattanakiat *et al.*, 2012).

The following generalized protocol relates to the labeling of IgG with NHS–rhodamine. Optimization of the level of rhodamine incorporation may have to be done with other proteins or other macromolecules.



Protocol

1. Dissolve an immunoglobulin to be labeled in ice-cold, 50-m*M* sodium bicarbonate, pH 8.5, at a concentration of 10 mg/ml.
2. Dissolve NHS–rhodamine at a concentration of 1 mg/ml in DMSO. Protect from light.

3. In a darkened lab, slowly add 50 to 100 µl of the NHS–rhodamine solution to each milliliter of the antibody solution with mixing. Wrap the vessel with aluminum foil to protect from light.
4. Place the sample on ice and react for 2 h.
5. Remove unreacted NHS–rhodamine and reaction byproducts by gel filtration or dialysis.

2.4. Lissamine™ Rhodamine B Sulfonyl Chloride

The Lissamine form of rhodamine B consists of diethyl modifications on the two nitrogens of the upper rings of the basic rhodamine molecule as well as two sulfonate groups added at the 3- and 5-carbon positions of the lower ring. Lissamine rhodamine B sulfonyl chloride is an amine-reactive reagent made by converting the No. 5 sulfonate group to a reactive sulfonyl halide. Reaction with proteins and other amine-containing molecules results in the formation of sulfonamide bonds (Figure 10.16). Lissamine is a trademark of Imperial Chemical Industries.

The spectral characteristics of protein conjugates made with Lissamine rhodamine B derivatives are of longer wavelength than those of tetramethylrhodamine—more toward the red region of the spectrum. In addition, modified proteins have better chemical stability and are somewhat easier to purify than those made from TRITC (discussed previously). Lissamine derivatives also make more photostable probes than the fluorescein derivatives (Section 1).

Lissamine rhodamine B sulfonyl chloride is relatively insoluble in water, but may be dissolved in DMF prior to the addition of a small aliquot to an aqueous reaction. Do not dissolve in DMSO, as sulfonyl chlorides will readily react with this solvent (Boyle, 1966). The compound has a maximal absorptivity at 556 nm with an extremely high extinction coefficient of up to 93,000 $M^{-1}cm^{-1}$ (in methanol) in highly purified form. Its emission maximum occurs at 576 nm, emitting red luminescence.

A sulfonyl chloride rapidly reacts with amines on proteins and other molecules to form stable sulfonamide bonds. It also may react with tyrosine OH groups, aliphatic alcohols, thiols, and imidazole groups (such as histidine side chains). Conjugates of sulfonyl chlorides with sulfhydryls and imidazole rings are unstable, while esters formed with alcohols are subject to nucleophilic displacement (Nillson and Mosbach, 1984; Scouten and Van der Tweel, 1984). The only stable derivative with proteins is therefore the sulfonamide, formed by reaction with ε-lysine and N-terminal amines. Optimal conditions for coupling are non-amine-containing buffers in the pH range of 9 to 10. Phosphate, bicarbonate, or borate buffers are recommended for the modification reaction. Avoid the presence of other nucleophiles that can cross-react with the sulfonyl chloride (e.g., amine-containing components or sulfhydryl-containing reducing agents). In aqueous solutions, hydrolysis is a competing reaction, but occurs more slowly with sulfonyl halides than with the corresponding acid chlorides of carboxylate groups. Unreacted, hydrolyzed probe is

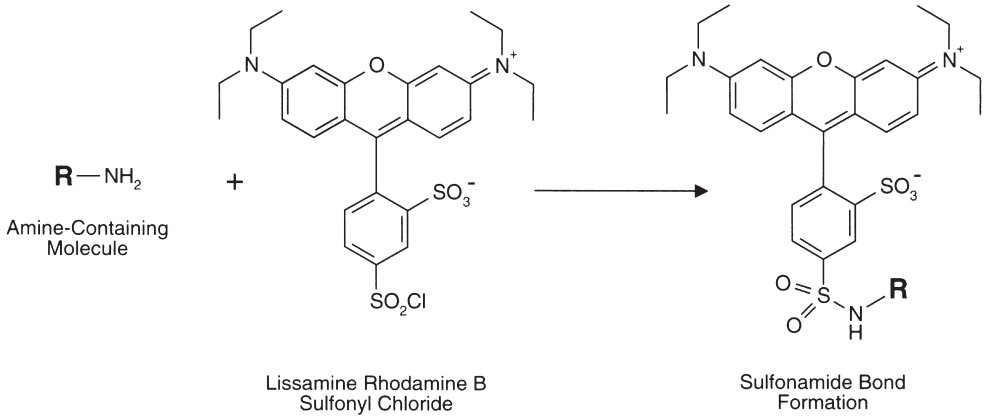


FIGURE 10.16 Lissamine rhodamine B sulfonyl chloride reacts with amine-containing molecules to produce stable sulfonamide bonds.

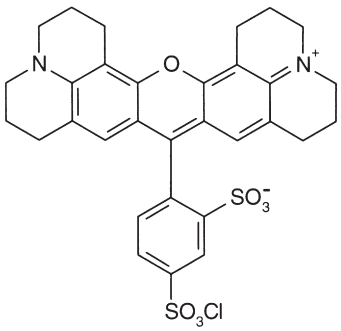
the water soluble sulforhodamine B fluorophore that is easily removed by gel filtration or dialysis.

Lissamine rhodamine B sulfonyl chloride has been used in numerous applications, including multiple-labeling techniques in microscopy (Wessendorf, 1990), for confocal microscopy techniques (Tsien and Wagoner, 1990), in the study of fibronectin receptors (Duband *et al.*, 1988), for investigations into microtubule and intermediate filament association (Geiger and Singer, 1980), for the labeling of glycoconjugates (Wilchek *et al.*, 1980), for studying regulation of the Na^+,K^+–ATPase system (Sipe *et al.*, 1991), and for investigations into the redox potential within mitochondria (Chazotte and Hackenbrock, 1991). The dye has also been used to study the shape of giant unilamellar vesicles as model plasma membranes (Gudheti *et al.*, 2007), to investigate the activity of xyloglucan xylogucosyl transferase (Hrmova *et al.*, 2007), to study the switching of neurofilaments between mobile and stationary states (Trivedi *et al.*, 2007), and in the synthesis of bioactive fluorescent analogues of the marine alkaloid discorhabdin C (Lam *et al.*, 2012). Hundreds of additional biological studies have used this fluorescent probe.



The following protocol is a general guide for labeling biological macromolecules with Lissamine rhodamine B sulfonyl chloride. Optimization of the fluorophore incorporation level (F/P ratio) may have to be done for specific labeling experiments.

Protocol

1. Dissolve the amine-containing macromolecule to be labeled (i.e., a protein) in 0.1-*M* sodium carbonate/bicarbonate buffer, pH 9.0, at a concentration of 1 to 5 mg/ml.
2. Dissolve Lissamine rhodamine B sulfonyl chloride (Invitrogen) in DMF at a concentration of 1 to 2 mg/ml. Protect from light and use immediately.
3. In a darkened lab and with gentle mixing, slowly add 50 to 100 µl of the fluorophore solution to the protein solution.
4. React for 1 h at room temperature in the dark.
5. Remove excess fluorophore by gel filtration using a desalting resin or by dialysis.

2.5. Texas Red Sulfonyl Chloride

Texas Red sulfonyl chloride is the active halogen derivative of sulforhodamine 101. This important derivative of the basic rhodamine molecule possesses dual aliphatic rings off the upper-ring nitrogens and sulfonate groups on the No. 3- and 5-carbon atoms of its lower ring component. The sulfonyl chloride group can react with primary amines in proteins and other molecules to form stable sulfonamide bonds (Figure 10.17). The group, however, can hydrolyze in the presence of moisture. For this reason, only fresh Texas Red sulfonyl chloride should be used for modification experiments.

Texas Red Sulfonyl Chloride
MW 577
Excitation = 556 nm
Emission = 576 nm
ε at 556 nm = 93,000 $M^{-1}cm^{-1}$

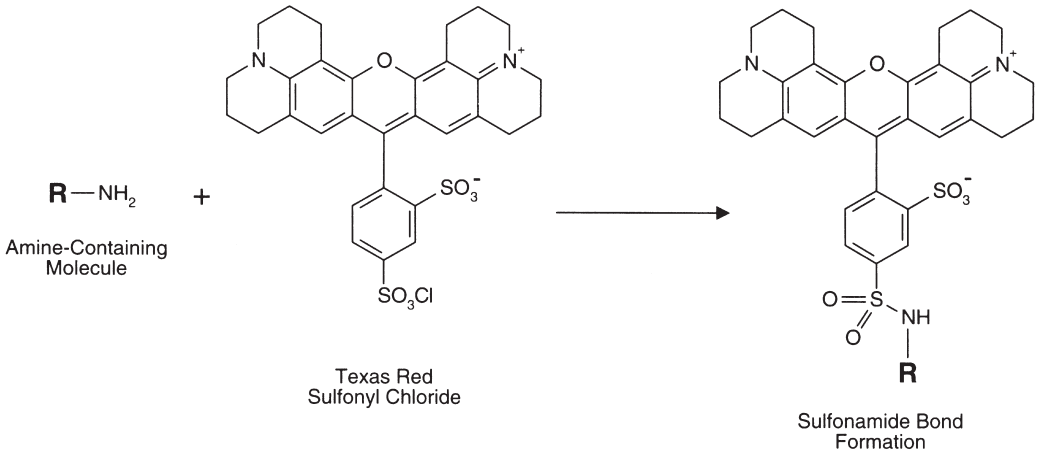


FIGURE 10.17 Texas Red sulfonyl chloride can be used to label amine-containing molecules through sulfonamide bond formation.

The intense Texas Red fluorophore has a QY that is inherently higher than the tetramethylrhodamine or Lissamine rhodamine B derivatives. Texas Red's luminescence is shifted maximally into the red region of the spectrum, and its emission peak only minimally overlaps with that of fluorescein. This makes Texas Red derivatives one of the best choices of labels for use in double-staining techniques.

Texas Red sulfonyl chloride has a maximal excitation at 589 nm and a maximum emission at 615 nm when dissolved in methanol. The extinction coefficient of the compound dissolved in acetonitrile is 85,000 $M^{-1}cm^{-1}$ at 596 nm. The only disadvantage of this fluorophore is its poor excitation by the standard argon laser at 488 nm. However, since both Texas Red and fluorescein are weakly excited by an argon laser at 514 nm, it makes them fairly good pairs for use in laser confocal microscopy or flow cytometry (Mossberg and Ericsson, 1990). The fluorophore is particularly appropriate for excitation by the 568-nm line produced by an argon–krypton mixed laser used on some confocal devices. Compared to other rhodamine derivatives, Texas Red fluorophores display low background in staining techniques and are among the most photostable probes available.

This rhodamine dye derivative has been used to produce purine-scaffold fluorescent probes (Taldone *et al.*, 2011), to study glomerular sieving by use of a dye-labeled albumin (Saleh *et al.*, 2012), and to investigate synaptic activity using patch-clamp chips (Martina *et al.*, 2011).

Texas Red sulfonyl chloride is soluble in DMF or acetonitrile and may be dissolved as a concentrated stock solution in either solvent prior to the addition of a small aliquot to an aqueous reaction medium. Avoid the use of DMSO, as sulfonyl chlorides react with this solvent (Boyle, 1966). The solid and all solutions made from it must be protected from light to avoid photodecomposition. Prepare the stock solution immediately before use.

A sulfonyl chloride group rapidly reacts with amines in the pH range of 9 to 10 to form stable sulfonamide bonds. Under these conditions, it also may react with tyrosine OH groups, aliphatic alcohols, thiols, and histidine side chains. Conjugates of sulfonyl chlorides with sulfhydryls and imidazole rings are unstable, while esters formed with alcohols are subject to nucleophilic displacement (Nillson and Mosbach, 1984; Scouten and Van der Tweel, 1984). The only stable derivative with proteins therefore is the sulfonamide, formed by reaction with ε-lysine and N-terminal amines. For coupling, the reaction media should use only non-amine-containing buffers, such as phosphate, borate, or bicarbonate (avoid Tris, imidazole, or glycine).

A suggested protocol on the use of this fluorescent probe is described below. Optimization may be necessary to achieve the best level of fluorescent modification (F/P ratio) for a particular application.

Protocol

1. Dissolve the protein or macromolecule to be labeled in 0.1-*M* sodium carbonate, pH 9.0, at a concentration of 1 to 5 mg/ml.
2. Dissolve Texas Red sulfonyl chloride (Thermo Fisher, Invitrogen) in acetonitrile at a concentration of 20 mg/ml. Prepare fresh and protect from light. Use a fume hood for all operations using organic solvents.
3. In subdued lighting conditions, add 50 µl of the Texas Red sulfonyl chloride solution to each milliliter of the protein solution. Mix well.
4. React for 1 h at room temperature.
5. Remove excess fluorophore and reaction byproducts by gel filtration using a desalting resin or by dialysis.

Determine the level of fluorophore incorporation (the F/P ratio) by measuring the absorbance of the labeled protein at 520 nm and 280 nm. Labeled proteins having a 520 nm/280 nm ratio of absorbency of 0.3 to 0.8 should perform well in most applications (Titus *et al.*, 1982).

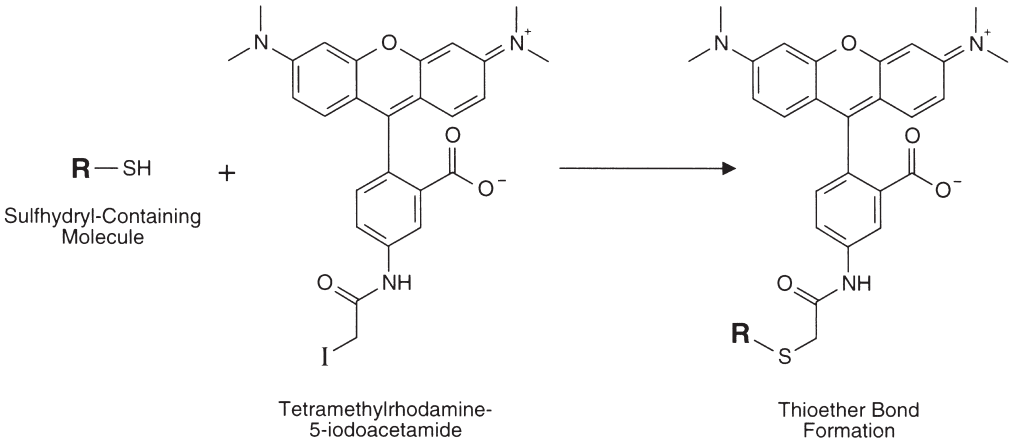
At the time of writing, over 15,000 references cited the use of Texas Red for labeling biological molecules or in bioconjugate detection applications.

2.6. Sulfhydryl-Reactive Rhodamine Derivatives

Rhodamine derivatives containing a sulfhydryl-reactive group off the lower ring structure are available to direct the modification reaction to more limited sites on target molecules. Coupling through sulfhydryls instead of amines can help to avoid active centers in proteins, thus preserving activity in the fluorescent probe complex. Sulfhydryl reaction sites can be naturally available through free cysteine side chains, generated by reduction of disulfides, or created by the use of thiolation reagents (Chapter 2, Section 4.1).

2.7. Tetramethylrhodamine-5-(and 6)-iodoacetamide

The iodoacetamido derivatives of tetramethylrhodamine possess a sulfhydryl-reactive iodoacetyl group (Chapter 2, Section 4.2, and Chapter 3, Section 2.1) at either the 5- or 6-carbon position on their lower ring. The isomers are commercially available only in mixed form (Invitrogen), but some reactivity and specificity differences between the purified 5- and 6-derivatives



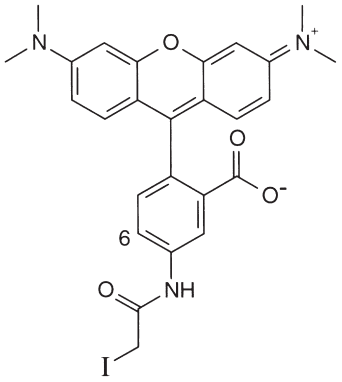


FIGURE 10.18 This iodoacetamide derivative of tetramethylrhodamine can be used to label sulfhydryl groups to form a thioether bond formation.

toward various sulfhydryl sites in proteins may be observed (Ajtai *et al.*, 1992).

The iodoacetyl group of both isomers reacts with sulfhydryls under slightly alkaline conditions to yield stable thioether linkages (Figure 10.18). They do not react with unreduced disulfides in cystine residues or with oxidized glutathione (Gorman *et al.*, 1987). The thioether bonds are hydrolyzed under conditions necessary for complete protein hydrolysis prior to amino acid analysis.

Tetramethylrhodamine-5-iodoacetamide
MW 569
Excitation = 540 nm
Emission = 567 nm
ε at 540 nm = 76,000 $M^{-1}cm^{-1}$

Care must be taken to protect these reagents from light, not only to maintain the fluorescent yield of the rhodamine derivative, but also to protect the iodoacetyl group from light-catalyzed breakdown. Tetramethylrhodamine-5-(and-6)-iodoacetamide is soluble in DMF and DMSO. Concentrated stock solutions may be prepared in these solvents prior to addition of a small aliquot to an aqueous reaction mixture. Protect solutions from light by wrapping in aluminum foil and working in subdued light. Quenching reactions with cysteine, glutathione, or mercaptosuccinic acid will sometimes facilitate removal of unconjugated fluorophore by dialysis or gel filtration.

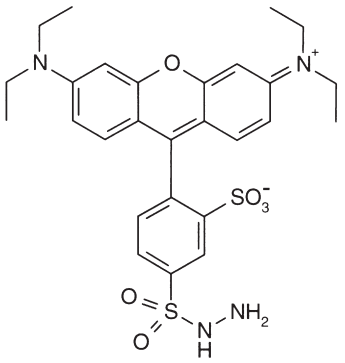
The spectral properties of these derivatives are similar to native rhodamine. The excitation maximum occurs at about 543 nm and its emission peak at 567 nm, producing light in the orange–red region of the spectrum. The extinction coefficient of tetramethylrhodamine-5-(and-6)-iodoacetamide in methanol at its wavelength of maximum absorptivity, 542 nm, is 81,000 $M^{-1}cm^{-1}$.

The fluorescent probe has been used extensively to label numerous proteins and other biomolecules, including actin (Glacy, 1983; Wang, 1985; Meige and Wang, 1986), myosin light chains (Mittal *et al.*, 1987), α-actin (Simon and Taylor, 1988; Stickel and Wang, 1988), blood coagulation factor Va (Isaacs *et al.*, 1986), and histones (Murphy *et al.*, 1982). The dye has also been used to study conformational changes in proteins (Heuck *et al.*, 2007), the binding region of protein C on factor Va (Yegneswaran *et al.*, 2007), how flavonoids affect actin functions (Boehl *et al.*, 2007), and the stretching of rigor cross-bridges in skeletal muscle fibers (Ushakov *et al.*, 2011). Hundreds of additional publications cite the use of this dye for various biological detection applications.

The following protocol for labeling proteins with tetramethylrhodamine-5-(and-6)-iodoacetamide represents a general guideline. The procedure should be optimized for each macromolecule being labeled to obtain the best F/P ratio to produce intense fluorescence and high activity in the final complex.

Protocol

1. Prepare a 20-m*M* tetramethylrhodamine-5-(and-6)-iodoacetamide solution by dissolving 11.3 mg per milliliter of DMF. Prepare fresh and protect from light.
2. Dissolve the protein to be modified at a concentration of 5 to 10 mg/ml in 50-m*M* sodium phosphate, pH 7.5.
3. Slowly add 25 to 50 µl of the tetramethylrhodamine-5-(and-6)-iodoacetamide solution to each milliliter of the protein solution while mixing.
4. React for 2 h at 4°C in the dark.
5. Remove excess reactant and reaction byproducts by gel filtration using a desalting resin or by dialysis.



2.8. Aldehyde-/Ketone- and Cytosine-Reactive Rhodamine Derivatives

Hydrazide groups can be coupled directly to aldehydes and ketones to form relatively stable hydrazone linkages (Chapter 3, Section 5.1). Two rhodamine derivatives are commonly available that contain a sulfonyl hydrazine group off their No. 5 carbon on the lower ring structure (Invitrogen). They are based on the Lissamine and Texas Red structures and may be used to label aldehyde- or ketone-containing molecules with an intensely fluorescent probe. Although most biomolecules don't contain aldehyde or ketone groups in their native state, carbohydrates, glycoproteins, RNA, and other molecules containing sugar residues (or diols) can be oxidized with sodium periodate to produce reactive formyl groups. The use of modification reagents that generate aldehydes upon coupling to a molecule also can be used to produce a hydrazide-reactive site (Chapter 2, Section 4.4).

DNA and RNA may be modified with hydrazide-reactive probes by reacting their cytosine residues with bisulfite to form reactive sulfone intermediates. These derivatives undergo transamination to couple with hydrazide- or amine-containing probes (Draper and Gold, 1980) (Chapter 23, Section 2.1).

2.9. Lissamine Rhodamine B Sulfonyl Hydrazine

Lissamine rhodamine B sulfonyl hydrazine is a hydrazide derivative of sulforhodamine B that can spontaneously react with aldehyde- or ketone-containing molecules to form a covalent, hydrazone linkage (Figure 10.19). It also can be used to label cytosine residues in DNA or RNA by use of the bisulfite activation procedure (Chapter 23, Section 2.1). The resulting fluorescent derivative exhibits an excitation maximum at a wavelength of 556 nm and a maximal emission wavelength of 580 nm when dissolved in methanol. In the same solvent, the compound has an extinction coefficient of approximately 75,000 $M^{-1}cm^{-1}$.

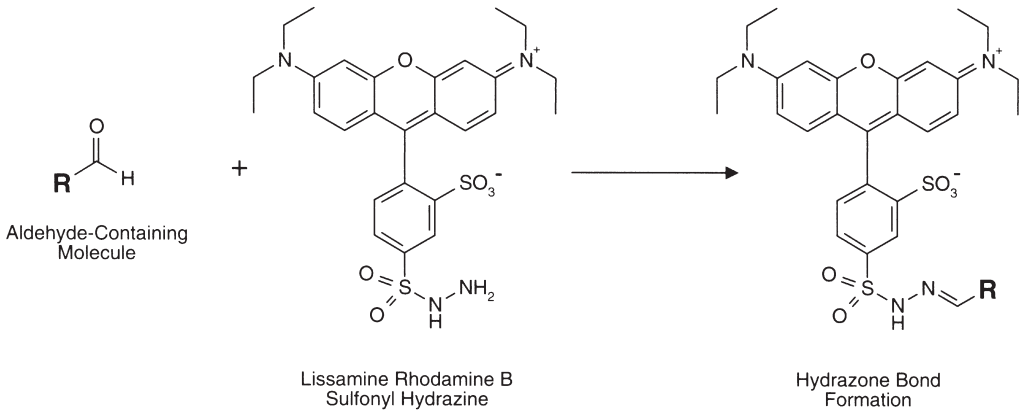


FIGURE 10.19 Lissamine rhodamine B sulfonyl hydrazine reacts with aldehyde groups to form hydrazone linkages.

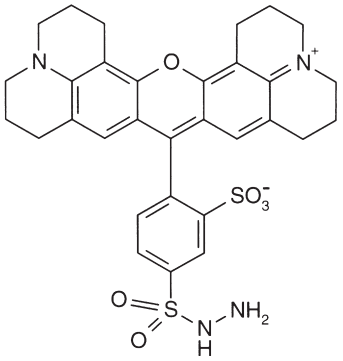
Lissamine rhodamine B sulfonyl hydrazine is soluble in DMF. The reagent may be dissolved in this solvent as a concentrated stock solution before adding a small aliquot to an aqueous reaction medium. The compound itself and all solutions made with it should be protected from light to avoid decomposition of its fluorescent properties.



This dye has been used to create a dual-wavelength staining method for glycoproteins in polyacrylamide gels (Chiang *et al.*, 2011), to fluorescently label a PEG-phosphatidyl ethanolamine-based polymer for incorporation into liposomes (Biswas *et al.*, 2011), and to track liposomal fusion with cells (Dutta *et al.*, 2011).

Generalized protocols for the use of hydrazine probes reactive toward aldehyde residues can be found in Section 1 of this chapter. These procedures are directed at the labeling of cell surface glycoproteins or glycoproteins in solution. Substitution of Lissamine rhodamine B sulfonyl hydrazine for the fluorescein-5-thiosemicarbazide reagent described in that section can be done without difficulty. Some optimization may be necessary to achieve the best level of fluorescent modification for each particular application.

2.10. Texas Red Hydrazide

Texas Red hydrazide is a derivative of Texas Red sulfonyl chloride made by reaction with hydrazine (Invitrogen). The result is a sulfonyl hydrazine group on the No. 5 carbon position of the lower ring structure of sulforhodamine 101. The intense Texas Red fluorophore has a QY that is inherently higher than either the tetramethylrhodamine or Lissamine rhodamine B derivatives of the basic rhodamine molecule. Texas Red's luminescence is shifted maximally into the red region of the spectrum, and its emission peak only minimally overlaps with that of fluorescein. This makes derivatives of this fluorescent probe among the best choices of labels for use in double staining techniques.

The hydrazide derivative can be used to modify aldehyde- or ketone-containing molecules, including cytosine residues using the bisulfite activation procedure described in Chapter 23, Section 2.1. The sulfonyl hydrazine group of Texas Red hydrazide reacts with aldehydes or ketones in target molecules to form hydrazone bonds (Figure 10.20). Carbohydrates and glycoconjugates can be specifically labeled at the polysaccharide portion if the required aldehydes are first formed by periodate oxidation or another such method (Chapter 2, Section 4.4).

Texas Red Hydrazide
MW 621
Excitation = 580 nm
Emission = 604 nm
ε at 580 nm = 80,000 $M^{-1}cm^{-1}$

Texas Red hydrazide has a maximal excitation wavelength of 580 nm and a maximum emission at 604 nm when dissolved in methanol. Its extinction coefficient in the same solvent is 80,000 $M^{-1}cm^{-1}$ at 580 nm. The only disadvantage of this fluorophore is its poor excitation by an argon laser at 488 nm. However, since both

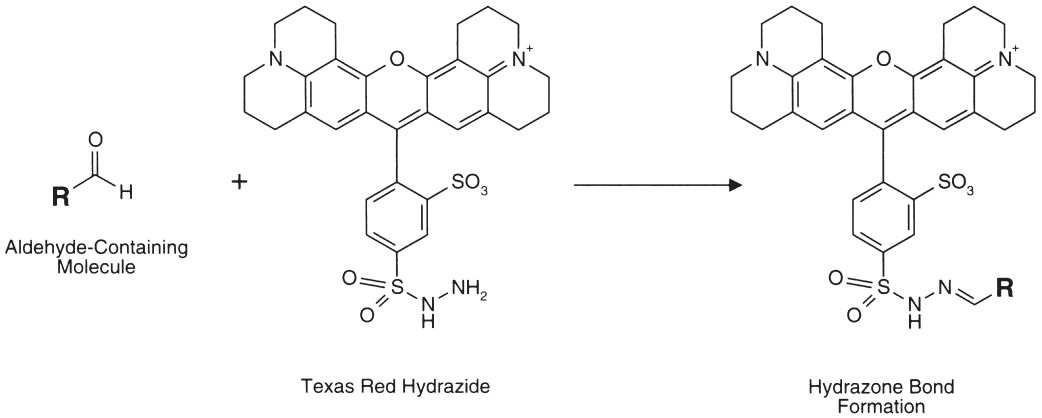


FIGURE 10.20 Texas Red hydrazide reacts with aldehydes to create hydrazone bonds.

Texas Red and fluorescein are weakly excited by an argon laser at 514 nm, it makes them fairly good pairs for use in laser confocal microscopy or flow cytometry (Mossberg and Ericsson, 1990). The fluorophore is particularly appropriate for excitation by the 568-nm line produced by an argon–krypton mixed laser used on some confocal devices. White-light illumination also can be used to excite the dye, while its emission is detected using an appropriate filter. Compared to other rhodamine derivatives, Texas Red fluorophores display low background in staining techniques and are among the most photostable probes available.

Texas Red hydrazide is soluble in DMF and may be dissolved as a concentrated stock solution in this solvent prior to the addition of a small aliquot to an aqueous reaction medium. The solid and all solutions made from it must be protected from light to avoid photodecomposition. Prepare the stock solution fresh immediately before use. A suggested protocol on the use of this fluorescent probe may be obtained by following the method outlined for fluorescein-5-thiosemicarbazide in Section 1 of this chapter. Optimization may be necessary to achieve the best level of fluorescent modification (F/P ratio) for a particular application.

This dye has been used to study the cellular internalization of various proteins and molecules (Ratelade *et al.*, 2011), in a fucose-specific labeling procedure for a vascular-targeting antibody (Zuberbuhler *et al.*, 2012), and in the fluorescent labeling of carbon nanotubes (Yoshimura *et al.*, 2011).

3. COUMARIN DERIVATIVES

Coumarin (2H-1-benzopyran-2-one) is a naturally occurring substance found in tonka beans, lavender oil, and sweet clover (Merck Index **11**:2563) (Figure 10.21). Many of its derivatives are highly fluorescent compounds that are widely studied (Schimitschek *et al.*, 1974; Ernsting *et al.*, 1982; Eschrich and Morgan, 1985; Jones *et al.*, 1984, 1985; Baranowska- Kortylewicz and Kassis, 1993a,b). The 7-amino-4-methylcoumarin derivatives have excellent fluorescent properties useful for labeling biological molecules with a detectable tag

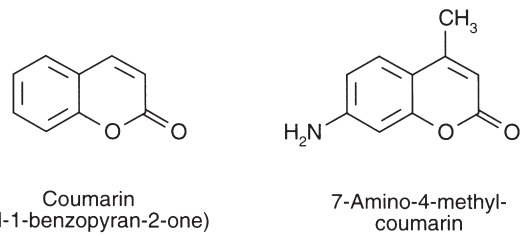

FIGURE 10.21 The basic structural characteristics of coumarin fluorophores.

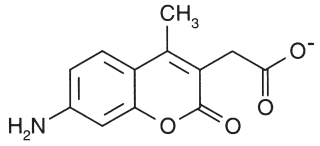
(Uchino *et al.*, 1979; Bos, 1981). Particularly, the 3-acetic acid derivative of this molecule, known as AMCA, provides a carboxylate group from which to create easily reactive groups suitable for coupling to proteins and other molecules.

Aminomethylcoumarin derivatives possess intense fluorescent properties within the blue region of the visible spectrum. Their emission range is sufficiently removed from other common fluorophores that they are excellent choices for double-labeling techniques. In fact, coumarin fluorescent probes are very good donors for excited-state energy transfer to fluoresceins.



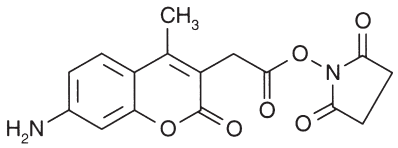
The following sections describe the most popular derivatives of aminomethylcoumarin used to label proteins and other biological macromolecules.

3.1. Amine-Reactive Coumarin Derivatives

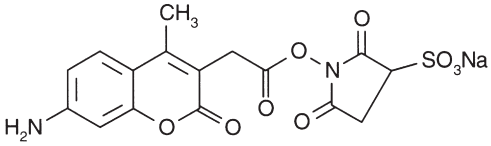
Three main forms of amine-reactive AMCA probes are commonly available. One of them is simply the free acid form of AMCA, which can be used to couple to amine-containing molecules using the carbodiimide reaction (Chapter 4, Section 1). The other two are active-ester derivatives of AMCA—the water-insoluble NHS ester and the water soluble sulfo-NHS ester forms—both of which spontaneously react with amines to create stable amide linkages. All of them react under mild conditions with primary amines in proteins and other molecules to form highly fluorescent derivatives.

3.2. AMCA

AMCA, or 7-amino-4-methylcoumarin-3-acetic acid, is a fluorescent probe that exhibits a spectacular blue fluorescence (Khalfan *et al.*, 1986) (Thermo Fisher). AMCA absorbs light at a wavelength of 345 nm and luminesces in the range of 440 to 460 nm. Its emission wavelength is in a region that does not overlap with the emission spectra of other major fluorescent probes. This makes double-staining techniques particularly effective with this fluorophore. AMCA also has pronounced stability toward photobleaching, retaining its full fluorescence more than three times longer than fluorescein-based probes. AMCA derivatives, and labeled molecules fluoresce with a bright-blue color upon excitation. This color is easily visualized using fluorescent microscopes or imagers. The blue emission color avoids problems of autofluorescence associated with high background. In addition, the large Stokes shift of the molecule minimizes interference from Rayleigh light scatter effects during excitation. The fluorescent intensity of AMCA is not affected by changes in pH in the range of 3 to 10. This is in marked contrast to other fluorescent probes, such as fluorescein, which display considerable variability in their emission spectra with pH.



AMCA
7-Amino-4-methyl-
coumarin-3-acetic acid
MW 233
Excitation = 345–350 nm
Emission = 440–460 nm



AMCA may be coupled to amine-containing molecules through the use of the carbodiimide reaction using EDC (Chapter 4, Section 1.1). EDC will activate the carboxylate on AMCA to a highly reactive *O*-acylisourea intermediate. Attack by a nucleophilic primary amine group on the carbonyl of this ester results in the formation of an amide bond (Figure 10.22). Derivatization of AMCA off its carboxylate group causes no major effects on its fluorescent properties. Thus, proteins and other macromolecules may be labeled with this intensely blue probe and easily detected by fluorescence microscopy and other techniques.

3.3. AMCA–NHS and AMCA–Sulfo-NHS

AMCA–NHS, succinimidyl-7-amino-4-methylcoumarin-3-acetic acid, is an amine-reactive derivative of AMCA containing an NHS ester on its carboxylate group (Thermo Fisher). The result is reactivity directed toward amine-containing molecules, forming amide linkages with the AMCA fluorophore (Figure 10.23). Proteins labeled with AMCA show little to no effect on the isoelectric point of the molecule.

AMCA–NHS
Succinimidyl-7-amino-
4-methylcoumarin-3-acetic acid
MW 330

AMCA–Sulfo-NHS
Sulfosuccinimidyl-7-amino-
4-methylcoumarin-3-acetic acid
MW 431

Reaction of AMCA–NHS with proteins proceeds efficiently in the pH range of 7 to 9. Avoid buffers containing amines which can compete in the coupling reaction, such as Tris or glycine, and avoid imidazole buffers since they promote hydrolysis of the NHS ester.

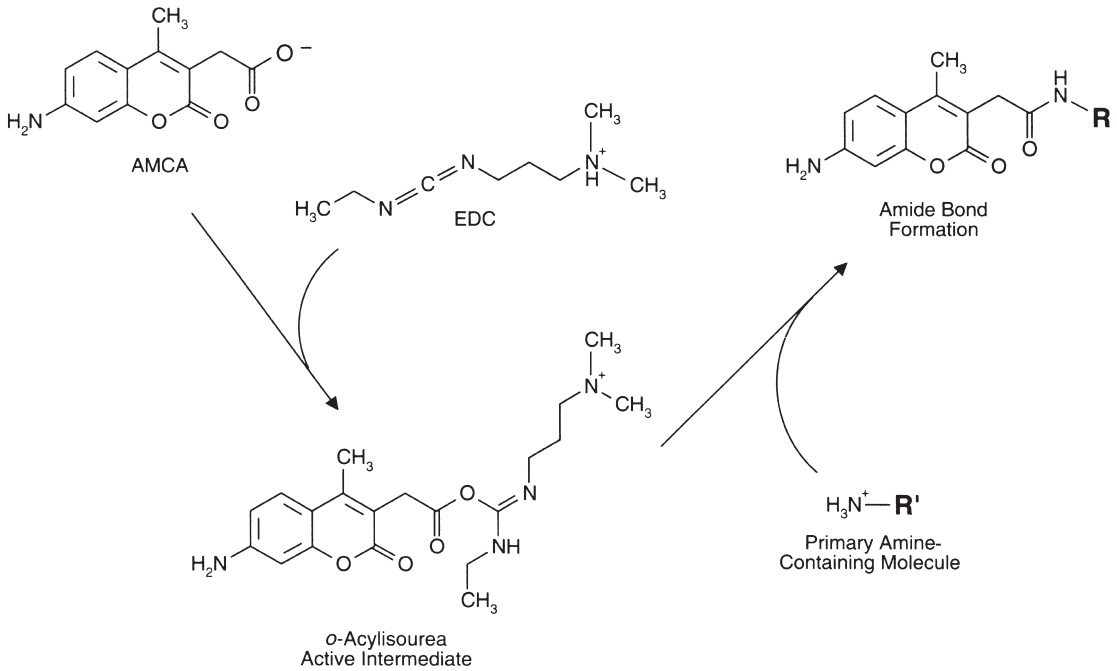


FIGURE 10.22 AMCA may be linked to amine-containing molecules through its carboxylate group using a carbodiimide reaction with EDC.

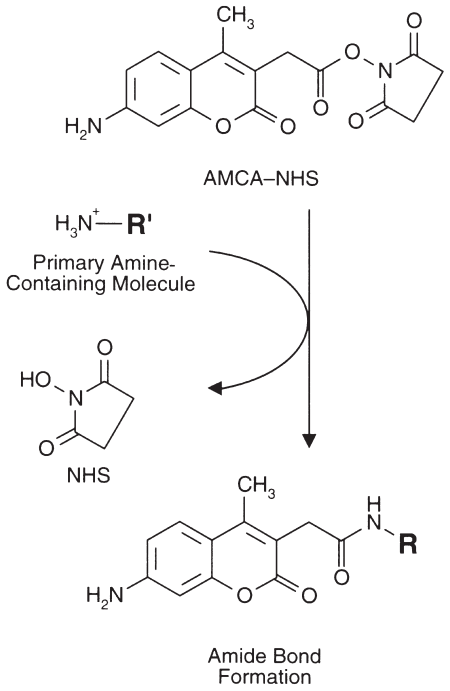

FIGURE 10.23 AMCA–NHS reacts with amines to form amide bonds.

AMCA–NHS is relatively insoluble in aqueous buffers. The compound must first be dissolved in organic solvent prior to adding a small aliquot to the reaction mixture. A concentrated stock solution may be prepared in DMSO and stored up to 2 weeks refrigerated or frozen without loss of activity. The solid and all solutions of AMCA–NHS should be protected from light to avoid photobleaching of the fluorophore.

AMCA–sulfo-NHS is an analog of AMCA–NHS which contains a sulfonate group on its NHS ring (Thermo Fisher). The negative charge of this group provides enough polarity to promote water solubility for the entire reagent in its activated form. The reactivity and properties of AMCA–sulfo-NHS are identical to those of AMCA–NHS.

These reactive dyes have been used for the modification of peptides (Mentinova *et al.*, 2012), to study the trafficking and release of *Leishmania* metacyclic HASPB on macrophage invasion (MacLean *et al.*, 2012), to investigate the structure and activity relationships of quinolone-type molecules against *Trypanosoma brucei* (Hiltensperger *et al.*, 2012), and as a labeled secondary antibody for general immunofluorescence detection assays (De Oliveira *et al.*, 2011).

Preparing an optimal fluorescent conjugate is largely dependent upon the degree of modification with the label. The following protocol is generalized for the labeling of a protein with AMCA–NHS. For particular labeling experiments, it is often necessary to vary the amount of fluorophore added to the reaction mixture to obtain the best combination of protein activity and fluorescent intensity in the conjugate. Too much label and nonspecific binding or fluorescent quenching may result; too little label and the complex will not possess enough fluorescent intensity to be sufficiently detectable.

Protocol

1. Dissolve the protein to be modified in 50-m*M* sodium borate, pH 8.5, at a concentration of 10 mg/ml. Other buffers may be used for an NHS ester reaction, including 0.1-*M* sodium phosphate, pH 7.5 (Chapter 3, Section 1.4).
2. Dissolve AMCA–NHS (Thermo Fisher) in DMSO at a concentration of 2.6 mg/ml. Protect from light.
3. In subdued lighting conditions, slowly add 50 to 100 µl of the AMCA–NHS stock solution to each milliliter of the protein solution, with gentle mixing.
4. React for 1 h at room temperature in the dark.
5. Remove excess reagent and reaction byproducts by gel filtration using a desalting resin. The sample volume should be no more than about 5 to 8% of the column volume.

The F/P ratio of the purified, labeled protein may be determined by measuring the absorbance at 345 nm and 280 nm. Ratios between 0.3 and 0.8 usually produce labeled molecules having acceptable levels of fluorescent intensity and good retention of protein activity. AMCA-labeled proteins may be lyophilized without significant loss of fluorescence. The addition of bovine serum albumin (15 mg/ml) or another such stabilizer is often necessary to retain solubility of the freeze-dried, labeled protein after reconstitution.

3.4. Sulfhydryl-Reactive Coumarin Derivatives

Two derivatives of aminomethylcoumarin are available for labeling sulfhydryl-containing molecules. The ability to label SH groups in proteins provides a means of directing the modification reaction to a limited number of sites, possibly avoiding active centers or binding regions better than when using amine-reactive probes. The first sulfhydryl-reactive probe discussed in this section makes use of a pyridyl disulfide group on the AMCA derivative and forms a reversible disulfide bond with thiol-containing molecules. The second probe is an iodoacetyl compound made from a diethyl and aminophenyl derivative of the basic aminomethylcoumarin structure, which forms a stable thioether linkage with thiol groups.

3.5. AMCA–HPDP

AMCA–HPDP is *N*-[6-(7-amino-4-methylcoumarin-3-acetamido)hexyl]-3′-(2′-pyridyldithio)propionamide.

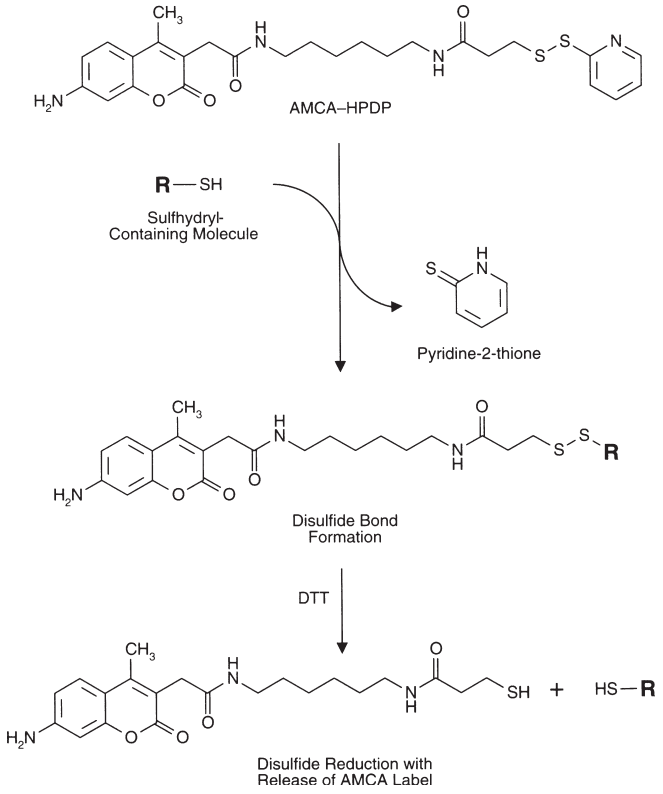

FIGURE 10.24 AMCA–HPDP reacts with sulfhydryl groups through its pyridyl disulfide end to form reversible disulfide bonds.

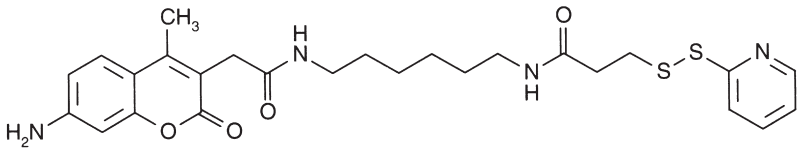
It is formed from AMCA plus a 1,6-diaminohexyl spacer off the carboxylate that has been additionally modified at its terminal end with SPDP (Chapter 6, Section 1.1). The result is a long spacer arm terminating in a pyridyl disulfide group reactive toward free sulfhydryl residues. The reaction of this group with a thiol creates a disulfide bond between the AMCA fluorophore and the molecule being modified. Thus, the fluorescent tag can be specifically cleaved by reduction with DTT or other disulfide reducing agents (Figure 10.24).

The required sulfhydryl residues can be naturally occurring on a protein, created by reduction of cystine crosslinks or by thiolation (Chapter 2, Section 4.1). For the labeling of antibody molecules, mild reduction with 2-mercaptoethylamine, DTT, or TCEP results in free sulfhydryl groups in the hinge region. Labeling in this area is advantageous to direct the modification away from antigen binding regions. Sulfhydryl residues also may be created on oligonucleotides without difficulty (Chapter 23, Section 2.2).



Although the reaction of a sulfhydryl-containing molecule with AMCA–HPDP results in the release of the chromogenic leaving group, pyridine-2-thione, using it to quantify the extent of modification may be difficult, because it absorbs at 343 nm, which is in the same region as AMCA itself (345 nm). The emission range of the AMCA probe is about 440 to 460 nm, in the blue region of the spectrum. It has been used as a fluorescent label in the study of *S*-nitrosylation (Lopez-Sanchez *et al*., 2012; Raju *et al*., 2012).

The following protocol is a suggested method for labeling a protein with AMCA–HPDP. It is assumed that the presence of a sulfhydryl on the protein has been documented or created. The reaction conditions can be carried out in a variety of buffers between pH 6 and 9. Avoid the presence of extraneous sulfhydryl-containing compounds (such as disulfide reductants) that will compete in the reaction. The inclusion of EDTA in the modification buffer prevents metal-catalyzed sulfhydryl oxidation. Optimization for a particular labeling experiment should be performed to obtain the best level of fluorophore incorporation.

Protocol

1. Dissolve the sulfhydryl-containing protein to be labeled in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2, at a concentration of 10 mg/ml.
2. Dissolve AMCA–HPDP in DMSO at a concentration of 0.5 mg/ml. Protect from light.
3. In subdued lighting conditions, add 50 to 100 µl of the AMCA–HPDP stock solution to each milliliter of sulfhydryl-containing protein solution. Mix.
4. React for 1 h at room temperature in the dark with occasional mixing.
5. Remove excess fluorophore and reaction by-products by gel filtration using a desalting resin.

To determine the F/P ratio of the labeled protein, measure the absorbance of the purified preparation at 345 nm and 280 nm. Ratios of 345 nm/280 nm within the range of 0.3 to 0.8 usually result in fluorescent

AMCA–HPDP

3-acetamido)hexyl]-3'-(2'-pyridyldithio)propionamide
Excitation = 345 nm
Emission = 440-460 nm

conjugates with a good balance of high-intensity luminescence, low nonspecific binding, and excellent retention of biological activity within the protein component.

3.6. DCIA

DCIA is 7-diethylamino-3-[(4′-(iodoacetyl)amino) phenyl]-4-methylcoumarin, a derivative of the basic aminomethylcoumarin structure that contains a sulfhydryl-reactive iodoacetyl group and a diethyl substitution on its amine. This particular coumarin derivative is among the most fluorescent UV-excitable iodoacetamide probes available (Invitrogen) (Sippel, 1981).

The iodoacetyl group of DCIA reacts with sulfhydryls under slightly alkaline conditions to yield stable thioether linkages (Figure 10.25). They do not react with unreduced disulfides in cystine residues or with oxidized glutathione (Gorman *et al.*, 1987).

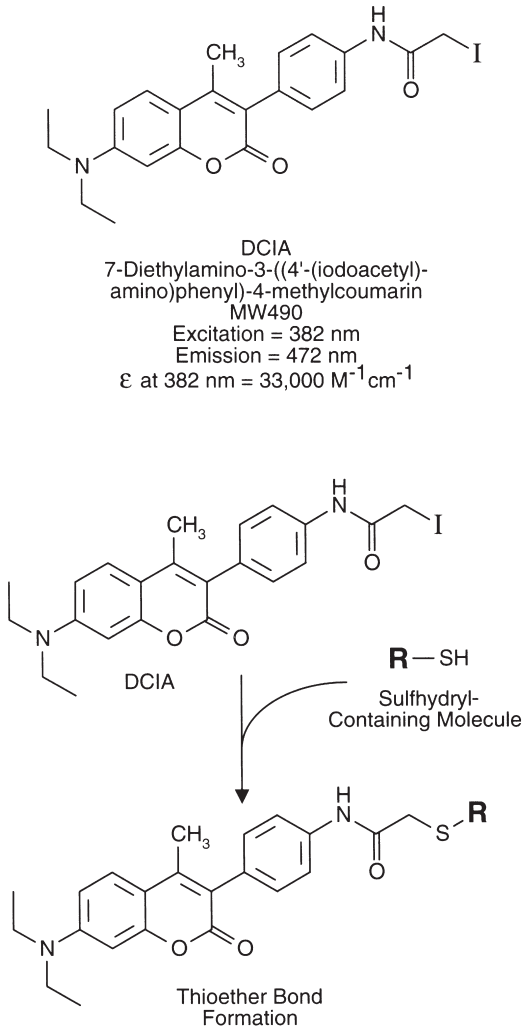

FIGURE 10.25 DCIA through its iodoacetamide group can modify sulfhydryls in proteins and other molecules to form thioether linkages.

Care must be taken to protect iodoacetyl reagents from light, not only to maintain the fluorescent yield of the coumarin component, but also to protect the iodoacetyl group from light-catalyzed breakdown. DCIA is soluble in DMF and DMSO. Concentrated stock solutions may be prepared in either solvent prior to addition of a small aliquot to a reaction mixture. Protect solutions from light by wrapping vessels in aluminum foil and working in subdued light.

The spectral properties of this fluorophore are similar to those of other coumarin derivatives. The excitation maximum occurs at about 382 nm and its emission peak at 472 nm, producing light in the blue region of the spectrum. The extinction coefficient of DCIA at its wavelength of maximum absorbance, 382 nm, is 33,000 $M^{-1}\,cm^{-1}$ (in methanol).

DCIA has been used to label numerous proteins and other biomolecules, including phospholipids (Silvius *et al.*, 1987); to study the interaction of mRNA with the 30S ribosomal subunit (Czworkowski *et al.*, 1991); in the investigation of cellular thiol components by flow cytometry (Durand and Olive, 1983); in the detection of carboxylate compounds using peroxyoxalate chemiluminescence (Grayeski and DeVasto, 1987); for general sulfhydryl labeling (Sippel, 1981); and in the development of advanced FRET methods to study protein–lipid interactions (Fernandes *et al.*, 2012).

A general protocol for the use of DCIA for fluorescently labeling proteins that contain sulfhydryl residues may be obtained by following the method discussed for AMCA–HPDP (previous section). After purification of the labeled protein, the F/P ratio of fluorophore incorporation may be determined by measuring its 382 nm/280 nm absorbance ratio.

3.7. Aldehyde- and Ketone-Reactive Coumarin Derivatives

Hydrazide groups can be coupled directly to aldehyde and ketone groups to form relatively stable hydrazone linkages (Chapter 3, Section 5.1). One AMCA derivative is commonly available that contains a hydrazine group modification on its carboxylate. Although most biomolecules don't contain aldehyde or ketone groups in their native state, carbohydrates, glycoproteins, RNA, and other molecules that contain sugar residues can be oxidized with sodium periodate to produce reactive formyl groups. The use of modification reagents that generate aldehydes upon coupling to a molecule also can be used to produce a hydrazide-reactive site (Chapter 2, Section 4.4).

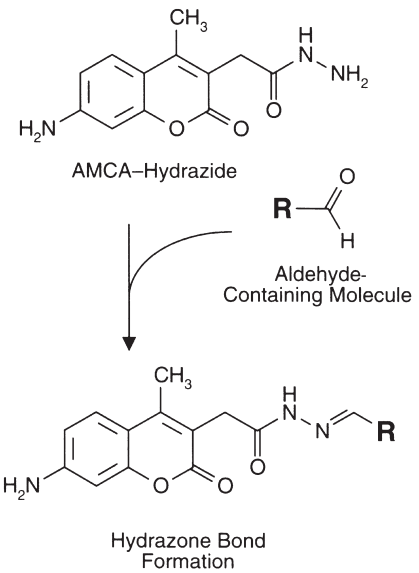
DNA and RNA may be modified with hydrazide-reactive probes by reacting their cytosine residues with bisulfite to form reactive sulfone intermediates. These derivatives can undergo transamination reactions with

hydrazide- or amine-containing probes to yield covalent bonds (Draper and Gold, 1980) (Chapter 23, Section 2.1).

3.8. AMCA–Hydrazide

AMCA–hydrazide is 7-amino-4-methylcoumarin-3-acetyl hydrazide, a hydrazine derivative off the carboxyl group of the basic AMCA molecule (Thermo Fisher). AMCA-based fluorophores are highly stable toward photobleaching. Molecules labeled with this probe retain their fluorescent intensity over three times longer than a fluorescein label when exposed to light. In addition, AMCA derivatives exhibit a large Stokes shift of over 100 nm, thus they are minimally affected by Rayleigh scattering effects during excitation. The blue light emitted by these labels is in a region of the spectrum well removed from the emission characteristics of other major fluorescent probes. This means that double-staining techniques easily can be used with an AMCA label. AMCA also exhibits little luminescence dependency on pH over the range of pH 3 to 10.

The hydrazide derivative of AMCA can be used to modify aldehyde- or ketone-containing molecules, including cytosine residues using the bisulfite activation procedure described in Chapter 23, Section 2.1. AMCA–hydrazide reacts with these target groups to form hydrazone bonds (Figure 10.26). Carbohydrates and glycoconjugates can be labeled specifically at their polysaccharide portion if the required aldehydes are first formed by periodate oxidation or another such method (Chapter 2, Section 4.4). The dye has been used to study the UV photodissociation of chromophore-labeled oligosaccharides (Ko and Brodbelt, 2011) and to label reactive peptides in site-specific tagging methods (Eldridge and Weiss, 2011).



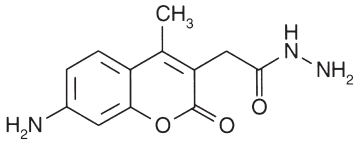


FIGURE 10.26 AMCA–hydrazide can be used to label aldehyde-containing molecules, such as periodate-oxidized carbohydrates.

AMCA–Hydrazide
7-Amino-4-methylcoumarin-
3-acetyl hydrazide
MW 247. 1
Excitation = 345 nm
Emission = 440–460 nm

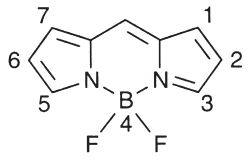
AMCA–hydrazide has a maximal excitation wavelength of 345 nm and a maximum emission wavelength in the range of 440–460 nm. A solution of AMCA in PBS at a concentration of 16.7 ng/ml (71.61 nmoles/ml) gives an absorbance at 345 nm of about 1.28. This translates into a molar extinction coefficient at this wavelength of about 13,900 $M^{-1}\,cm^{-1}$. Different solvents and conditions may alter this value somewhat.

AMCA–hydrazide is soluble in DMSO or DMF and may be dissolved as a concentrated stock solution in either of these solvents prior to the addition of a small aliquot to an aqueous reaction medium. The solid and all solutions made from the fluorophore must be protected from light to avoid photo-decomposition. Freshly prepare the stock solution immediately before use. A suggested protocol on the use of this fluorescent probe may be obtained from the following method on the labeling of periodate-oxidized IgG. Optimization may be necessary to achieve the best level of fluorescent modification (F/P ratio) for a particular application.

Protocol for Oxidation of IgG Carbohydrate Residues with Sodium Periodate

1. Dissolve the antibody to be labeled in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5, at a concentration of at least 10 mg/ml. The immunoglobulin must be glycosylated to work in this procedure.
2. Dissolve sodium periodate in water to a final concentration of 100-m*M*. Protect from light. Add 0.1 ml of this stock periodate solution to each milliliter of the antibody solution.
3. React for 15 min at room temperature, protected from light.
4. Quench the reaction by addition of 0.1 ml of glycerol per milliliter of reaction volume, mix, and then react for an additional 15 min. Remove excess reagents by gel filtration using a desalting column, and perform the chromatography using the phosphate buffer.
5. Adjust the concentration of IgG in the purified preparation to 1 mg/ml by the addition of 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.5.

Protocol for Modification of Oxidized IgG with AMCA–Hydrazide



1. Dissolve AMCA–hydrazide in DMF at a concentration of 0.4 mg/ml. Protect from light.
2. Add 50 to 100 µl of the AMCA–hydrazide stock solution to each milliliter of the oxidized antibody solution. Note: At a level of 50 µl probe addition, polyclonal human IgG will be modified at a level that gives an F/P ratio of about 0.113. Since the labeling occurs only at the oxidized carbohydrate sites, the fluorophore incorporation typically is less than that observed when using amine-reactive probes.
3. React for 30 min at room temperature in the dark.
4. Remove excess fluorophore by dialysis or gel filtration using a desalting resin. Protect the labeled immunoglobulin from light.

Determine the F/P ratio by measuring the absorbance at 345 nm and 280 nm.

4. BORON DIPYRROMETHENE DERIVATIVES

Fluorescent dye compounds constructed from a core structure consisting of boron-dipyrromethene tricyclic ring system (e.g., 4-bora-3a, 4a-diaza-*s*-indacene) are a class of dyes all characterized by a bound boron atom in their center (Loudet and Burgess, 2007; Arroyo *et al.*, 2009; Schmitt *et al.*, 2009; Tram *et al.*, 2009; Boens *et al.*, 2012). These derivatives often go by the trade name BODIPY (Life Technologies), and a broad variety of compounds have been reported that have a wide range of fluorescence properties throughout the visible region of the spectrum. They are noted for their sharp excitation and emission peaks, but they also have a relatively small Stokes shift and can be sensitive to dye–dye quenching effects and environmental conditions, which cause changes in brightness and QY.

BODIPY fluorophores are a class of probes based on the fused, multi-ring structure, 4,4-difluoro-4-bora-3a,4a-diaza-*s*-indacene (Figure 10.27) (Invitrogen) (U.S. patent 4,774,339). This fundamental molecule can be modified, particularly at its 1, 3, 5, 7, and 8 carbon positions, to produce new fluorophores with different characteristics. The modifications cause spectral shifts in its excitation and emission wavelengths and can provide sites for chemical coupling to label biomolecules.

The BODIPY Structure
4,4-Difluoro-4-bora-
3a,4a-diaza-*s*-indacene

FIGURE 10.27 The basic structure of boron dipyrromethene (BODIPY) fluorophores.

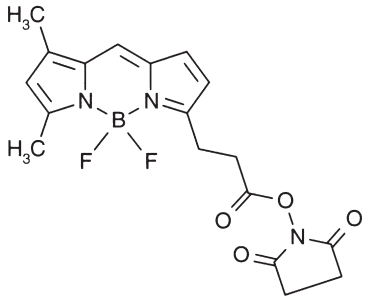
These dyes have been used for a wide range of applications, including in the development of FRET probes (Shao *et al.*, 2011), in the formation of light-harvesting metal-organic frameworks (Lee *et al.*, 2011), in the construction of dye-sensitized solar cells (Kolemen *et al.*, 2011), as labels of nucleotide derivatives to study DNA methylation (Falck *et al.*, 2011), in the study of the dissociation constant of the streptavidin–biotin interaction (Raphael *et al.*, 2011), and conjugated to targeting molecules for photodynamic therapy (Kamkaew *et al.*, 2012).

The BODIPY derivatives typically have high extinction coefficients and excellent QY, often greater than 0.8. Their spectral characteristics are relatively insensitive to changes in pH. Luminescent changes with shifts in pH usually are due to reconfiguration of a fluorophore's π-electron cloud if an atom on the ring system becomes protonated or unprotonated. Since the BODIPY structure lacks an ionizable group, alterations in pH have no effect on its spectral attributes.

The emission spectra of BODIPY derivatives normally display narrow bandwidths, providing intensely fluorescent labels for biomolecules. Unfortunately, they also have very small Stokes shifts, typically on the order of only 10 to 20 nm. Excitation at the optimal wavelength may cause some interference in measurements at the emission wavelength due to light scattering or cross-over from the wide bandwidth of the excitation source. The dyes usually require excitation at sub-optimal wavelengths to prevent this problem.

The following sections discuss the major BODIPY derivatives that are reactive toward particular functional groups in proteins and other molecules.

4.1. Amine-Reactive Boron Dipyrromethene Dyes



A number of BODIPY derivatives that contain reactive groups able to couple with amine-containing molecules are commonly available. The derivatives either contain a carboxylate group, which can be reacted with an amine in the presence of a carbodiimide to create an amide bond, or an NHS ester derivative of the carboxylate, which can react directly with amines to form amide linkages. The three discussed in this section are representative of this amine-reactive BODIPY family. The two NHS ester derivatives react under alkaline conditions with primary amines in molecular targets to form stable, highly fluorescent derivatives.

The carboxylate derivative can be coupled to an amine using the EDC/sulfo-NHS reaction discussed in Chapter 4, Section 1.2.

The only disadvantage of using BODIPY fluorophores to label amines in macromolecules is the tendency for fluorescence quenching to occur if too many sites on one molecule are modified. Especially with proteins, using an amine-reactive probe usually results in multiple sites being modified on each molecule. All fluorophores experience some quenching effect if the degree of substitution is high, because dye–dye interactions are possible that can transfer energy from an excited-state fluorophore to a ground-state fluorophore before luminescence occurs. BODIPY probes, however, are especially notorious for dye–dye quenching effects. For this reason, the manufacturer (Invitrogen) recommends that the amine-reactive BODIPY probes only be used to modify substances that have the potential for just one substitution per molecule. In this sense, BODIPY fluorophores are particularly well-suited for tagging DNA probes at the 5′ end or lipid molecules on their head groups. Oligonucleotides modified to contain an amine on their 5′ phosphate group (Chapter 23, Section 2.1) are good candidates for labeling with this fluorophore. Other BODIPY probes that contain reactivity toward non-amine functionalities such as sulfhydryls or polysaccharides may be more effective at labeling macromolecules like proteins, since these groups occur at more limited sites within the molecules and the modification level can be better controlled.

4.2. BODIPY FL C_3-SE

BODIPY FL C_3-SE is 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid, succinimidyl ester (Invitrogen). The derivatization to the base BODIPY molecule results in fluorescent properties which mimic fluorescein in its emission wavelength. The molecule thus emits light in the green region of the spectrum. The NHS ester on its propionic side chain provides amine reactivity, resulting in amide bond linkages with modified molecules (Figure 10.28).

BODIPY FL C_3-SE
4,4-Difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid, succinimidyl ester
MW 389
Excitation = 502 nm
Emission = 510 nm
ε at 502 nm = 77,000 $M^{-1}cm^{-1}$

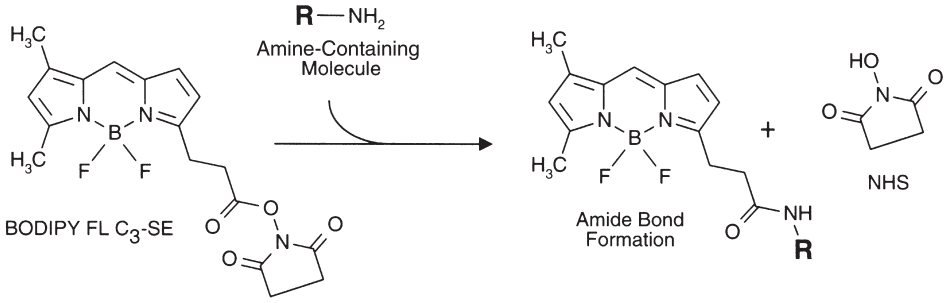
This fluorophore has an excitation maximum at 502 nm and an emission maximum at 510 nm. The small Stokes shift of only 8 nm creates some difficulty in discrete excitation without contaminating the emission measurement with scattered or overlapping light. The extinction coefficient of the molecule in methanol is about 77,000 $M^{-1}cm^{-1}$ at 502 nm.

BODIPY FL C_3-SE is insoluble in aqueous solution, but may be dissolved in DMF or DMSO as a concentrated stock solution prior to addition of a small aliquot to a reaction. For aqueous reactions, a pH range of 7 to 9 is optimal. Avoid amine-containing buffers. The reaction also may be done in organic solvent.

Since BODIPY fluorophores are easily quenched if substitutions on a molecule exceed a 1:1 stoichiometry, modification of proteins with this fluorophore probably will not yield satisfactory results. However, for labeling molecules which contain only one amine group, BODIPY FL C_3-SE will give intensely fluorescent derivatives.

4.3. BODIPY 530/550 C_3

BODIPY 530/550 C_3 is 4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionic acid (Invitrogen).



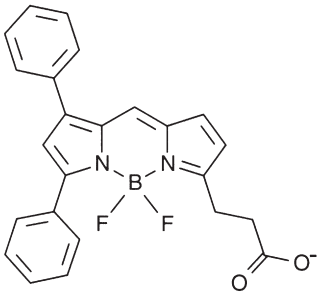


FIGURE 10.28 The terminal NHS ester on the linker arm of this BODIPY derivative can be used to modify amine-containing molecules, forming amide bond linkages.

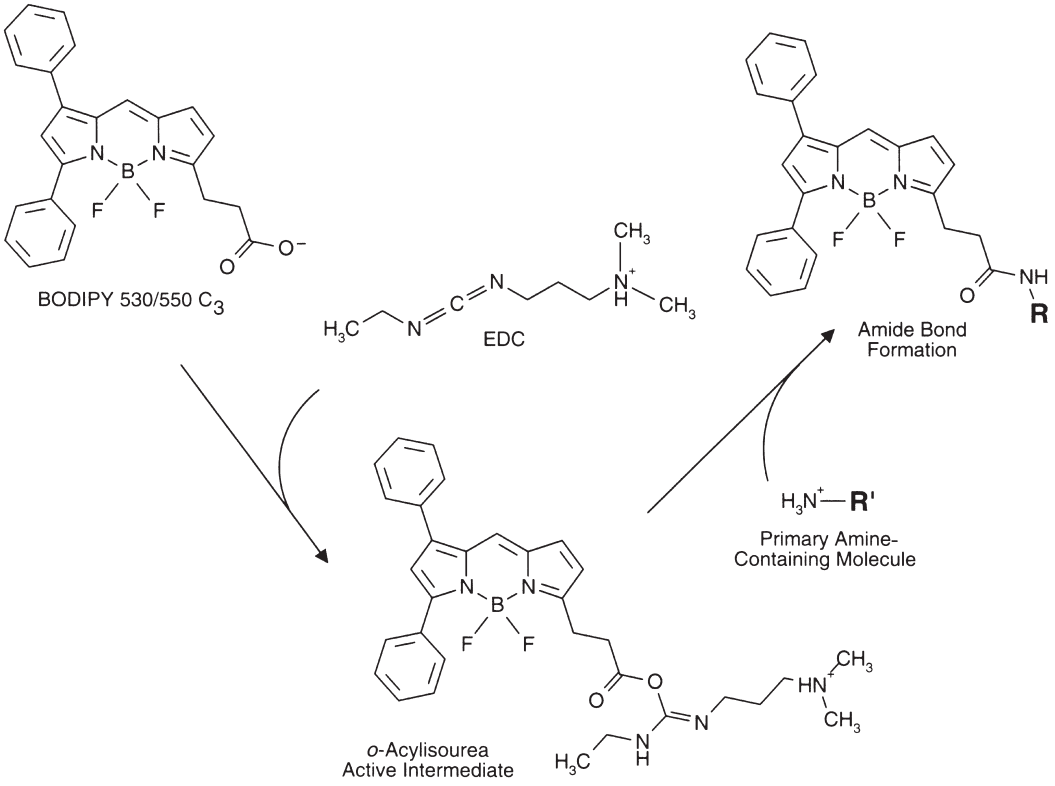
This derivative of the basic BODIPY structure contains two phenyl rings off the No. 5 and 7 carbon atoms and a propionic acid group on the No. 3 carbon atom. The carboxylate group may be used to attach the fluorophore to amine-containing molecules via a carbodiimide reaction to create an amide bond. The substituents on this BODIPY fluorophore result in alterations to its spectral properties, pushing its excitation and emission maximums up to higher wavelengths.

The excitation maximum for the molecule occurs at 535 nm and its emission at 552 nm. Its Stokes shift is slightly greater than some of the other BODIPY fluorophores, producing a 17-nm separation between excitation and emission peaks. BODIPY 530/550 C_3 has an extinction coefficient in methanol of about 62,000 $M^{-1}cm^{-1}$ at 535 nm.

BODIPY 530/550 C_3 is insoluble in aqueous solution, but it may be dissolved in DMF or DMSO as a concentrated stock solution prior to addition of a small aliquot to a reaction. Coupling to amine-containing molecules may be done using the EDC/sulfo-NHS reaction as discussed in Chapter 4, Section 1.2 (Figure 10.29). However, modification of proteins with this fluorophore probably will not yield satisfactory results, since BODIPY fluorophores are easily quenched if substitutions on a molecule exceed a 1:1 stoichiometry. For labeling molecules which contain only one amine group, such as DNA probes modified at the 5′ end to contain an amine (Chapter 23, Section 2.1), BODIPY 530/550 C_3 will give intensely fluorescent derivatives.

4.4. BODIPY 530/550 C_3-SE

BODIPY 530/550 C_3-SE is 4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-s-indacene-3-propionic



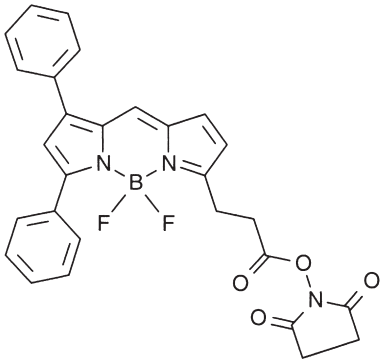


FIGURE 10.29 This BODIPY fluorophore contains a carboxylate group that can be attached to amine-containing molecules using a carbodiimide reaction.

acid, succinimidyl ester (Invitrogen). The compound is an analog of BODIPY 530/550 C3 that contains an active NHS ester on its propionic acid side chain (Chapter 3, Section 1.4). The ester reacts with primary amines to form stable amide bonds.

BODIPY 530/550 C_3-SE
4,4-Difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-s-indacene-3-propionic acid, succinimidyl ester
MW 513
Excitation = 533 nm
Emission = 550 nm
ε at 533 nm = 70,000 $M^{-1}cm^{-1}$

The excitation maximum for BODIPY 530/550 C_3-SE occurs at 533 nm and its emission at 550 nm. Its Stokes shift is relatively small and may not be enough to avoid completely problems of excitation-light interference in emission measurements. The molecule has an extinction coefficient in methanol of about 70,000 $M^{-1}cm^{-1}$ at 533 nm.

BODIPY 530/550 C_3-SE is insoluble in aqueous solution, but may be dissolved in DMF or DMSO as a concentrated stock solution prior to addition of a small aliquot to a reaction. Coupling to amine-containing molecules proceeds by nucleophilic attack at the carbonyl group, release of the NHS leaving group, and formation of an amide linkage (Figure 10.30). The reaction may be done in buffered environments having a pH range of 7 to 9. However, modification of proteins with this fluorophore may not yield satisfactory results, since BODIPY fluorophores are easily quenched if substitutions on a molecule result in a high molar ratio of incorporation. For labeling molecules which contain only one amine group, such as DNA probes modified at the 5′ end to contain an amine (Chapter 23, Section 2.1), BODIPY 530/550 C_3-SE will give intensely fluorescent derivatives.

4.5. Aldehyde-/Ketone-Reactive Boron Dipyrromethene Dyes

Hydrazide groups react with aldehyde and ketone groups to form hydrazone linkages (Chapter 3, Section 5.1). Three BODIPY derivatives are available that contain a hydrazine group modification of carboxylate side chains. Biomolecules such as proteins that do not normally possess aldehyde residues can be modified to contain them by a number of chemical means (Chapter 2, Section 4.4).

In addition, DNA and RNA may be modified with hydrazide-containing fluorophores by a transamination reaction of their cytosine residues using bisulfite as a catalyst (Chapter 23, Section 2.1) (Draper and Gold, 1980).

4.6. BODIPY 530/550 C_3 Hydrazide

BODIPY 530/550 C_3 hydrazide is 4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl hydrazide, a derivative of the basic BODIPY structure that contains two phenyl rings off the No. 5 and 7 carbon atoms and a propionic acid hydrazide group on the No. 3 carbon atom (Invitrogen). The hydrazide group reacts with aldehyde- or ketone-containing molecules to form hydrazone linkages (Figure 10.31). The compound may be used to label glycoproteins or other carbohydrate-containing molecules

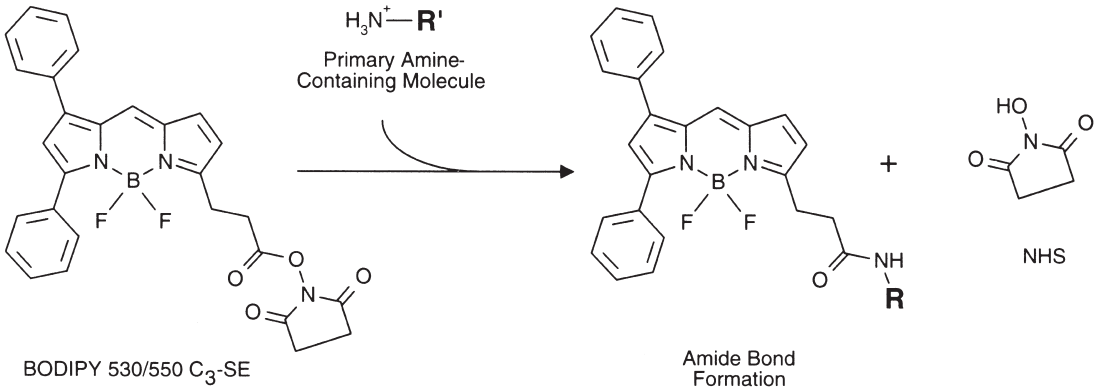

FIGURE 10.30 The NHS ester group of this BODIPY compound provides amine reactivity, which can be used to label proteins through amide bond linkages.

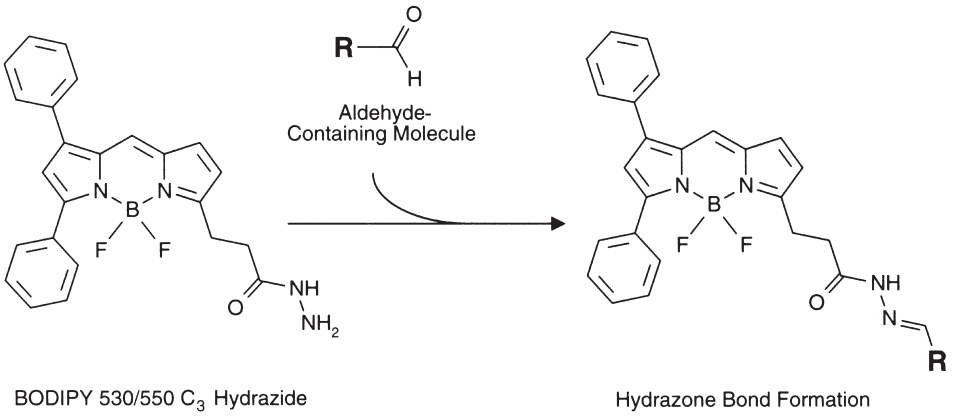

FIGURE 10.31 The side-chain hydrazide group of this BODIPY derivative can be used to label aldehyde-containing molecules. Glycoconjugates may be labeled after oxidation of carbohydrates with sodium periodate to produce the required aldehydes.

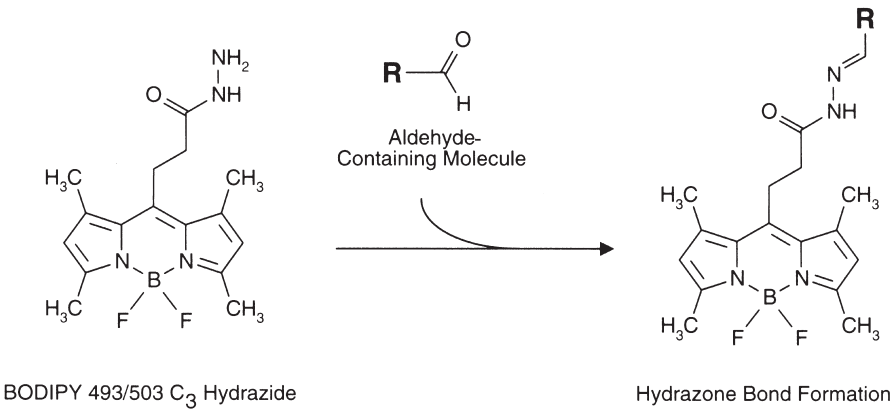

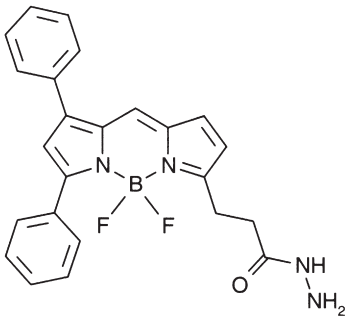

FIGURE 10.32 Reaction of this BODIPY fluorophore with aldehyde groups creates hydrazone linkages.

after oxidation of their polysaccharide portions with sodium periodate to yield aldehydes.

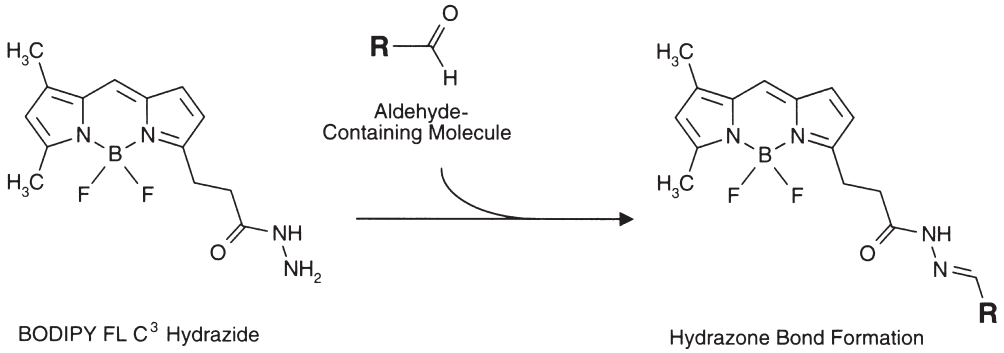
BODIPY 530/550 C_3 Hydrazide
4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl hydrazide
MW 430
Excitation = 534 nm
Emission = 551 nm
ε at 534 nm = 79,000 $M^{-1}cm^{-1}$

The excitation maximum for BODIPY 530/550 C_3 hydrazide occurs at 534 nm and its emission at 551 nm. The molecule has an extinction coefficient in methanol of about 79,000 $M^{-1}cm^{-1}$ at 534 nm.

BODIPY 530/550 C_3 hydrazide is insoluble in aqueous solution, but may be dissolved in DMF or methanol as a concentrated stock solution prior to addition of a small aliquot to a reaction. Coupling to aldehyde-containing molecules occurs rapidly with the formation a hydrazone linkage. The reaction may be done in buffered environments having a pH range of 5 to 10. However, modification of glycoproteins with this fluorophore may not yield satisfactory results, since BODIPY fluorophores are easily quenched if substitutions on a molecule result in a high molar ratio of incorporation.

4.7. BODIPY 493/503 C_3 Hydrazide

BODIPY 493/503 C_3 hydrazide is 4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene-8-propionyl hydrazide (Invitrogen). Unlike BODIPY 530/550 C_3 hydrazide, this BODIPY derivative contains substituents that shift to lower wavelengths the spectral characteristics of its fluorescence. The molecule is highly reactive toward aldehyde-containing compounds, including glycoproteins which have been oxidized with sodium periodate to create the requisite groups (Figure 10.32).



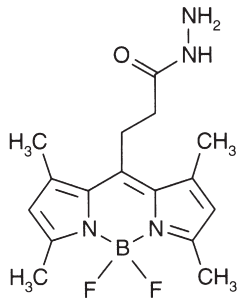


FIGURE 10.33 Modification of aldehyde-containing molecules can be done through this BODIPY derivative's hydrazide group.

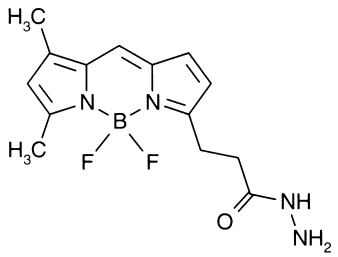


BODIPY 493/503 C_3 Hydrazide
4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene-8-propionyl hydrazide
MW 334
Excitation = 498 nm
Emission = 506 nm
ε at 498 nm = 92,000 $M^{-1}cm^{-1}$

The excitation maximum for BODIPY 493/503 C_3 hydrazide occurs at 498 nm and its emission at 506 nm. Since this is an extremely small Stokes shift, it may be difficult to avoid completely problems of excitation light scattering interference in critical emission measurements unless sub-optimal excitation wavelengths are used. The molecule has an extinction coefficient in methanol of about 92,000 $M^{-1}cm^{-1}$ at 493 nm.

BODIPY 493/503 C_3 hydrazide is insoluble in aqueous solution, but may be dissolved in DMF or DMSO as a concentrated stock solution prior to addition of a small aliquot to a reaction mixture. Coupling to aldehyde-containing molecules occurs rapidly with the formation of a hydrazone linkage. The reaction may be done in buffered environments having a pH range of 5 to 10. However, modification of glycoproteins with this fluorophore may not yield satisfactory results, since BODIPY fluorophores are easily quenched if substitutions on a molecule result in a high molar ratio of incorporation. Limiting the modification level by the reaction to no more than a 2- to 4-fold molar excess of probe to the amount of glycoconjugate present may overcome this quenching problem.

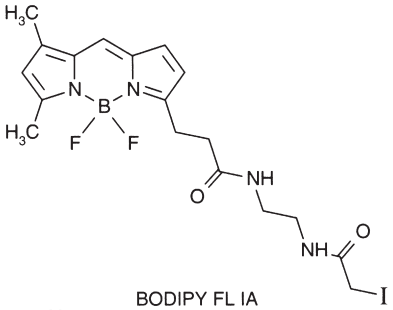
4.8. BODIPY FL C_3 Hydrazide

BODIPY FL C_3 hydrazide is 4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl hydrazide (Invitrogen). Unlike the two BODIPY hydrazide derivatives discussed above, this derivative contains substituents that produce luminescent characteristics similar to that of fluorescein, particularly with regard to fluorescing in the green region of spectrum. The molecule is highly reactive toward aldehyde-containing compounds, including glycoproteins that have been oxidized with sodium periodate to create the requisite aldehyde groups (Figure 10.33).

BODIPY FL C_3 Hydrazide
4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl hydrazide
MW 306
Excitation = 503 nm
Emission = 510 nm
ε at 503 nm = 71,000 $M^{-1}cm^{-1}$

The excitation maximum for BODIPY FL C_3 hydrazide occurs at 503 nm and its emission at 510 nm. The extremely small Stokes shift makes it difficult to avoid problems of excitation-light interference in critical emission measurements unless sub-optimal excitation wavelengths are used. The molecule has an extinction coefficient in methanol of about 71,000 $M^{-1}cm^{-1}$ at 503 nm.

BODIPY FL C_3 hydrazide is insoluble in aqueous solution, but may be dissolved in DMF or methanol as a concentrated stock solution prior to addition of a small



aliquot to a reaction mixture. Coupling to aldehyde-containing molecules occurs rapidly with the formation of a hydrazone linkage. The reaction may be done in buffered environments having a pH range of 5–10. However, modification of glycoproteins with this fluorophore may result in fluorescent quenching effects if substitutions on a molecule are at a high molar ratio of incorporation. Limiting the modification level by reacting no more than a 2- to 4-fold molar excess of probe to the amount of glycoconjugate present may help to overcome the quenching problem.

4.9. Sulfhydryl-Reactive Boron Dipyrromethene Dyes

Three BODIPY derivatives are available for labeling sulfhydryl-containing molecules. The ability to label SH groups in proteins with sulfhydryl-reactive probes provides a means of directing the modification reaction to a more limited number of sites than occurs when using amine-reactive chemistries. Directed coupling potentially can avoid active centers or binding regions. The first two sulfhydryl-reactive probes discussed in this section make use of iodoacetyl derivatives off the basic BODIPY molecule. The third probe is a bromomethyl derivative that also has good reactivity toward sulfhydryls.

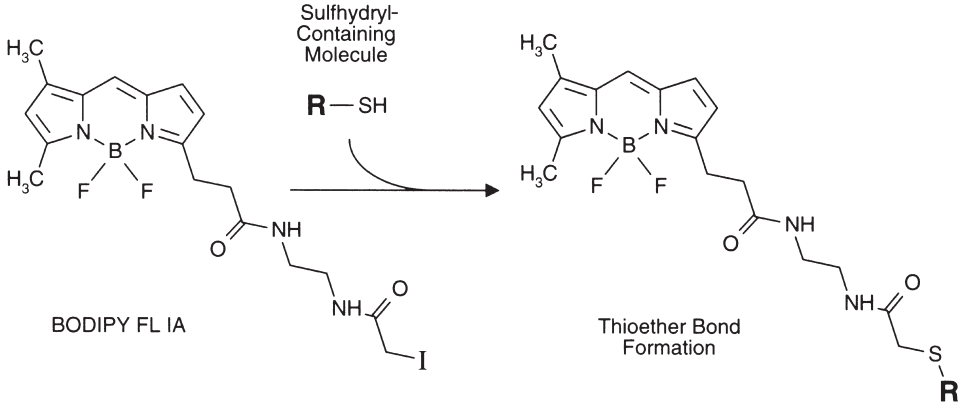
4.10. BODIPY FL IA

BODIPY FL IA is *N*-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl)-*N*′-iodoacetylethylenediamine, an intensely fluorescent derivative of the basic BODIPY structure which is useful in modifying sulfhydryl groups (Invitrogen). The iodoacetyl group reacts with SH groups in proteins and other molecules to form a stable thioether linkage (Figure 10.34). The reactive group is at the end of a reasonably long spacer arm, providing enough length to avoid steric problems in modifying sulfhydryls not easily accessible at the surface of macromolecules.

BODIPY FL IA
N-(4,4-difluoro-5,7-dimethyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl)-*N*'-iodoacetylethylenediamine
MW 502
Excitation = 504 nm
Emission = 510 nm
ε at 504 nm = 79,000 $M^{-1}cm^{-1}$

The spectral characteristics of BODIPY FL IA somewhat mimic the green luminescence of fluorescein, thus the origin of the FL designation in its name. The excitation maximum for the probe occurs at 504nm and its emission at 510nm. The extremely small Stokes shift makes it difficult to avoid problems of excitation-light interference in critical emission measurements unless sub-optimal excitation wavelengths below its excitation maximum are used. The molecule has an extinction coefficient in methanol (containing 1% sodium acetate and 1% 2-mercaptoethanol) of about 79,000 $M^{-1}cm^{-1}$ at 504nm.

BODIPY FL IA is insoluble in aqueous solution, but may be dissolved in DMF or DMSO as a concentrated stock solution prior to addition of a small aliquot to a reaction mixture. Coupling to sulfhydryl-containing molecules occurs rapidly with the formation of a thioether linkage. The reaction may be done in 50-m*M* sodium borate, 5-m*M* EDTA, pH 8.3. The main consideration is to protect the iodoacetyl derivative from light which may generate iodine and reduce the reactivity of the probe. In addition, to avoid the fluorescence quenching effects that are often a problem with BODIPY probes, react no more than a 2- to 4-fold molar excess of probe to the amount of sulfhydryl groups present. Oligonucleotides containing a sulfhydryl modification at their 5′ ends (Chapter 23,



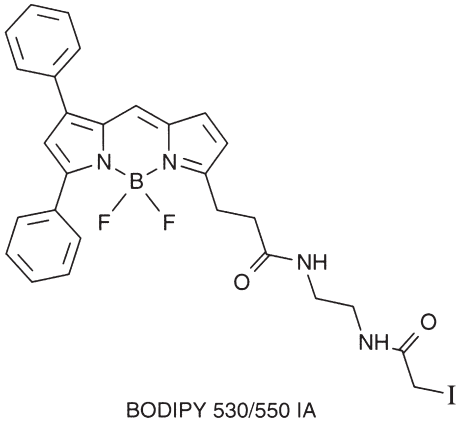


FIGURE 10.34 The long linker arm of this BODIPY derivative contains a sulfhydryl-reactive iodoacetamide group that can couple with a thiol group in proteins and other molecules to form a thioether bond.

Section 2.2) may be coupled with BODIPY FL IA, yielding highly fluorescent probes.

4.11. BODIPY 530/550 IA

BODIPY 530/550 IA is *N*-(4,4-difluoro-5,7-diphenyl-4-bora-3a,4a-diaza-*s*-indacene-3-propionyl)-*N′*-iodoacetylethenediamine, a derivative similar to that of BODIPY FL IA, but containing two phenyl groups rather than two methyl substituents in the No. 5 and 7 positions. This change in structure results in modulation of the spectral characteristics such that its excitation and emission wavelengths and its Stokes shift are all increased. The spacer arm off the No. 3 carbon atom of the basic BODIPY core contains a terminal iodoacetyl group, which reacts with sulfhydryl groups in proteins and other macromolecules to create stable thioether linkages (Figure 10.35).

The excitation maximum for BODIPY 530/550 IA occurs at 534nm and its emission at 552nm. The Stokes shift is greater than the "FL" BODIPY derivatives, having an 18nm differential between excitation and emission wavelengths. The molecule has an extinction coefficient in methanol (containing 1% sodium acetate and 1% 2-mercaptoethanol) of about 69,000 $M^{-1}cm^{-1}$ at 534nm.

BODIPY 530/550 IA is insoluble in aqueous solution, but may be dissolved in DMF or DMSO as a concentrated stock solution prior to addition of a small aliquot to a reaction mixture. Coupling to sulfhydryl-containing molecules occurs rapidly with the formation a thioether linkage. The reaction may be done in 50-m*M* sodium borate, 5-m*M* EDTA, pH 8.3. The main consideration is to protect the iodoacetyl derivative from light which may generate iodine and reduce the reactivity of the probe. To limit the degree of fluorescent quenching in the resultant conjugate, the probe should be reacted at no more than a 2- to 4-fold molar excess over the amount of target molecule present.

4.12. Br-BODIPY 493/503

Br-BODIPY 493/503 is 8-bromomethyl-4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene, a small BODIPY derivative containing a short, sulfhydryl-reactive bromomethyl group. The modifications to the core molecule result in modulation of its spectral characteristics such that, after conjugation, its excitation and emission wavelengths are reduced somewhat from other BODIPY probes. The reagent can be coupled to SH-containing molecules to produce a thioether linkage (Figure 10.36).

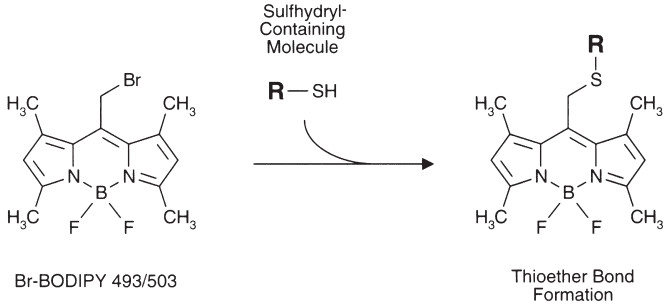

FIGURE 10.36 Br-BODIPY can be used to modify sulfhydryl-containing molecules to form thioether linkages.

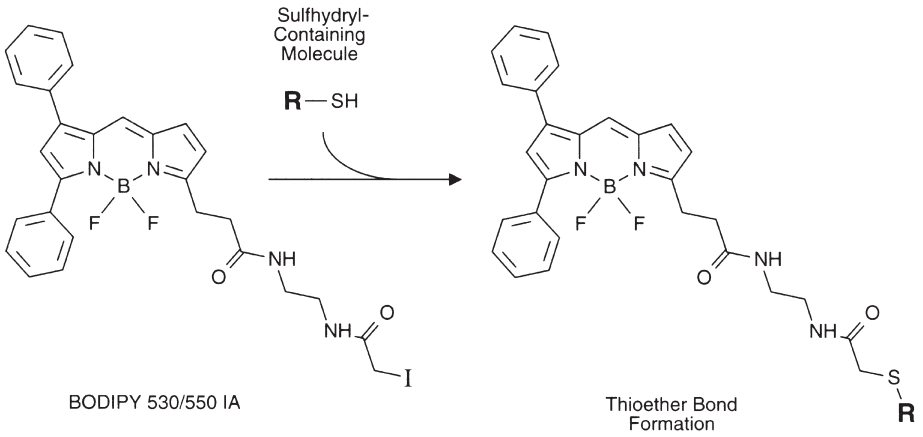

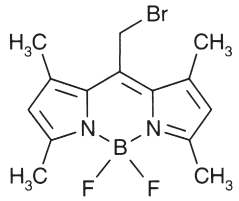

FIGURE 10.35 The iodoacetamide group of this BODIPY fluorophore can react with sulfhydryl-containing molecules to form thioether linkages.

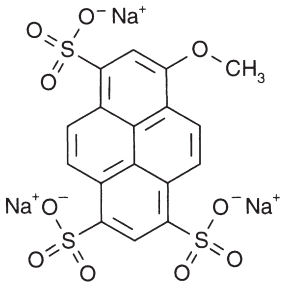


Br-BODIPY 493/503
8-Bromomethyl-4,4-difluoro-1,3,5,7-tetramethyl-4-bora-3a,4a-diaza-*s*-indacene
MW 341
Excitation = 515 nm
Emission = 525 nm
ε at 515 nm = 55,000 $M^{-1}cm^{-1}$

The excitation maximum for Br–BODIPY 493/503 is 515 nm and its emission occurs at 525 nm when dissolved in methanol. Upon coupling to a sulfhydryl compound, however, the excitation wavelength of the adduct decreases to 493 nm and its emission drops to 503 nm. The very small 10-nm Stokes shift may be a problem, particularly in avoiding interference due to of excitation-light scattering in critical emission measurements. Sub-optimal excitation wavelengths below the excitation maximum may be used to reduce extraneous light contamination. The molecule has an extinction coefficient in methanol of about 55,000 $M^{-1}cm^{-1}$ at 515 nm.

Br-BODIPY 493/503 is insoluble in aqueous reaction mixtures, but may be dissolved in DMF or DMSO as a concentrated stock solution prior to addition of a small amount to a buffered solution. Coupling to sulfhydryl-containing molecules is rapid, leading to the formation a thioether linkage. The reaction may be done in 50-m*M* sodium borate, 5-m*M* EDTA, pH 8.3. An important consideration is to protect the iodoacetyl derivative from light which may generate iodine and reduce the reactivity of the probe.

5. PYRENE DERIVATIVES

Fluorescent dyes having a core structure based on a pyrene ring system (or four fused benzene rings) are characterized as having strong emission characteristics in the blue region of the spectrum. Pyrene derivatives can be rather hydrophobic and unsuitable for use in bioconjugation unless they contain sulfonate groups on the rings, which provide dramatically increased water solubility. One family of pyrene dyes, termed Cascade Blue (Life Technologies), is available in a broad range of different forms. Other pyrene-type dyes are available from Thermo Fisher and Dyomics. All of these compounds also have various reactivities toward functional groups on biomolecules, which allows labeling of virtually any targeting molecule for use in assays. Pyrene-type dyes have been used for a wide range of applications,

8-Methoxypyrene-1,3,6-trisulfonic acid, trisodium salt

FIGURE 10.37 The basic structure of pyrene-based fluorophores.

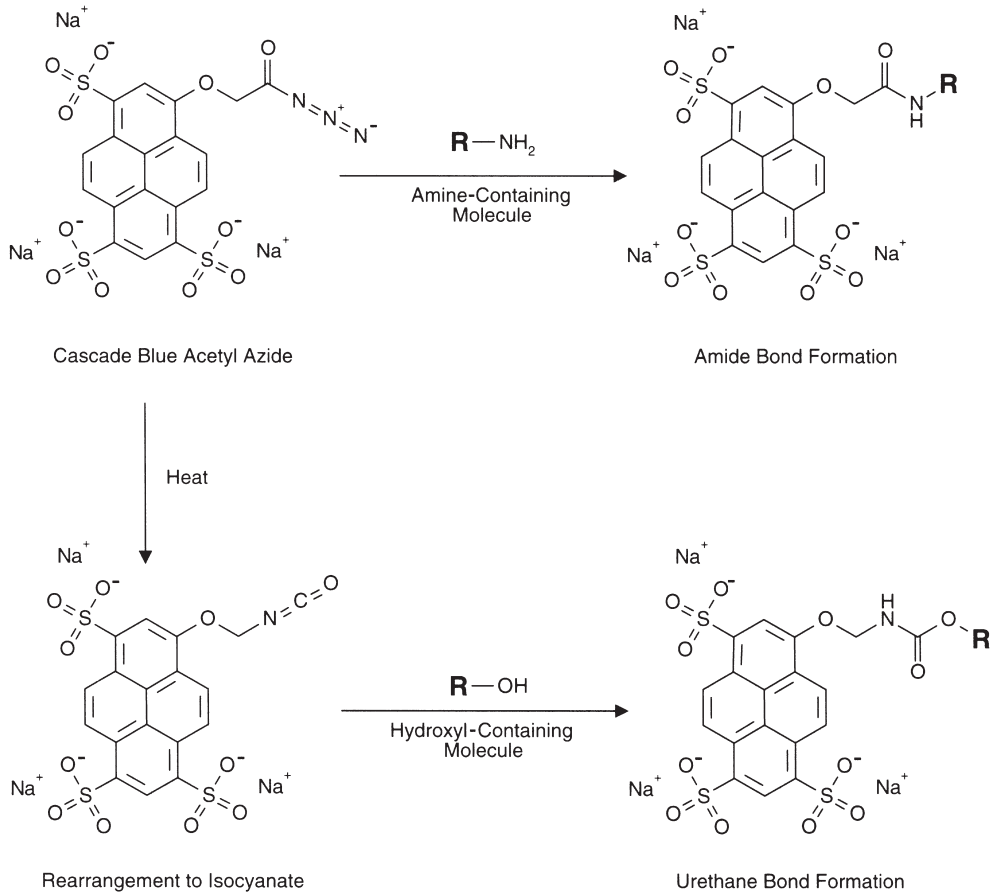
including in the study of polymer dynamics (Beija *et al.*, 2011), to investigate biopolymer structure (Cantor, 2012), in the labeling and detection of nanoparticle constructs (Kainz *et al.*, 2011), in conjugates of oligonucleotide probes (Juskowiak, 2011), and in the labeling of antibodies for use in cellular imaging (Guo *et al.*, 2011).

Cascade Blue derivatives are fluorescent probes having strong luminescence in the blue region of the spectrum (Invitrogen). The basic Cascade Blue molecule is derived from a trisulfonated pyrene backbone (Figure 10.37) (Whitaker *et al.*, 1991). Other sulfonated pyrene derivatives are commercially available from other sources as well (e.g., Thermo Fisher). This dye type is a reactive analog of 8-methoxypyrene-1,3,6-trisulfonic acid, which is a blue fluorescent neural tracer. The fluorophore emits light in a region removed from the luminescent signal of fluorescein or Lucifer Yellow, making it a good choice for multi-labeling applications. The dye can be used along with Lucifer Yellow CH and sulforhodamine 101 for three-color mapping of neuronal components and processes. Cascade Blue derivatives have relatively high absorptivity, good QY (typically about 0.54), excellent water solubility due to the presence of the negatively charged sulfonate groups, and good photostability. Labeling proteins and other macromolecules with Cascade Blue derivatives can be done with little fluorescent quenching due to dye–dye interactions.

The following sections discuss the most important Cascade Blue derivatives that are available for covalent modification purposes.

5.1. Amine-Reactive Cascade Blue Acetyl Azide

One Cascade Blue derivative is available for creating linkages with amine-containing molecules. The acetyl azide functionality of this reagent reacts with primary amines at ambient temperatures or below to create amide bond derivatives (Lanier and Recktenwald, 1991; Oparka *et al.*, 1991). At elevated temperatures (80°C in DMF), the acetyl azide group rearranges to form an



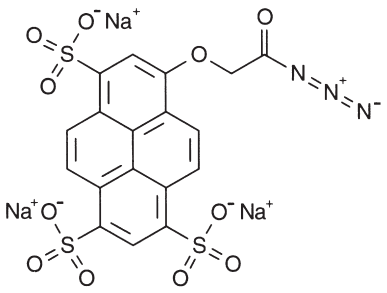


FIGURE 10.38 The acetyl azide group of this Cascade Blue derivative has dual functions. It can react with amine groups to form amide bonds, or it can be converted to an isocyanate at elevated temperature to couple with hydroxyl functional groups, which creates a carbamate linkage.

isocyanate that can react with hydroxyl-containing molecules to form a urethane linkage (Figure 10.38). The Cascade Blue urethane derivatives of macromolecules are extremely fluorescent and can be detected down to femtogram quantities (Takadate *et al.*, 1985). This dye has been used in a fluorescence lifetime assay to analyze the complex between cytochrome *b* and an anti-$p22^{phox}$ antibody (Taylor *et al.*, 2012).

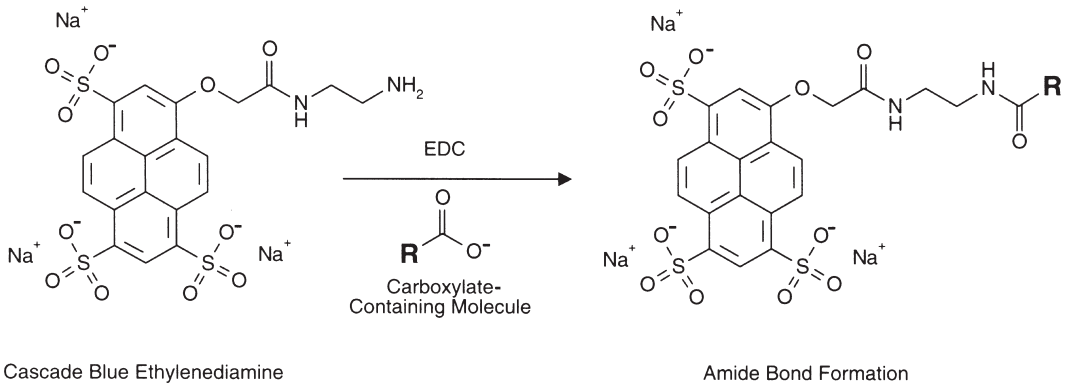
Cascade Blue Acetyl Azide
MW 607
Excitation = 375, 400 nm
Emission = 410 nm
ε at 375 nm = 27,000 $M^{-1}cm^{-1}$

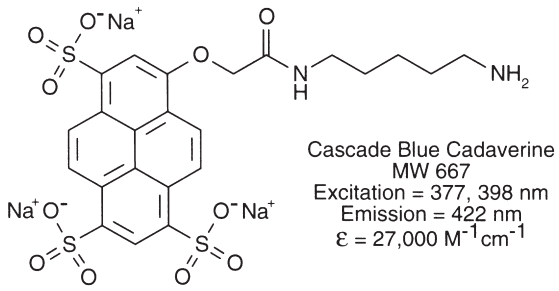
This fluorophore has excitation maxima at 375 nm and 400 nm and an emission maximum at 410 nm. The small Stokes shift may create some difficulty in discrete excitation without contaminating the emission measurement with scattered or overlapping light. The extinction coefficient of the molecule in water is about 27,000 $M^{-1}cm^{-1}$. Cascade Blue and Lucifer Yellow derivatives can be simultaneously excited by light of less than 400 nm, resulting in two-color detection at 410 nm and 530 nm.

Cascade Blue acetyl azide is soluble in aqueous solution, but the reactive azide group will hydrolyze and should be used immediately in a conjugation reaction. A concentrated stock solution may be prepared in water and dissolved quickly, and an aliquot quickly added to a buffered reaction medium. For aqueous reactions, a pH range of 7 to 9 is optimal. Avoid amine-containing buffers.

5.2. Carboxylate-Reactive Cascade Blue Cadaverine and Cascade Blue Ethylenediamine

Cascade Blue cadaverine and Cascade Blue ethylenediamine both contain a carboxamide-linked diamine





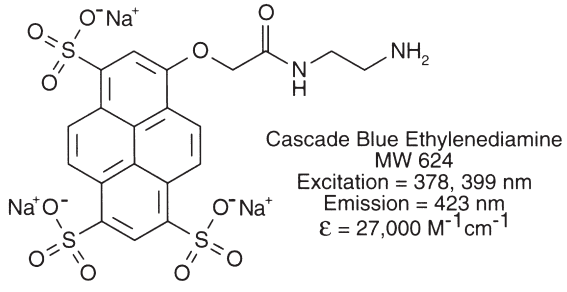


FIGURE 10.39 The terminal primary amine group on the linker arm of this Cascade Blue derivative can be coupled to carboxylate-containing molecules using a carbodiimide reaction.

spacer off the 8-methoxy group of the pyrene trisulfonic acid backbone. The cadaverine version contains a 5-carbon spacer, while the ethylenediamine compound has only a 2-carbon arm. Both can be coupled to carboxylic acid-containing molecules using a carbodiimide reaction (Chapter 4, Section 1). Since Cascade Blue derivatives are water soluble, the carbodiimide EDC can be used to couple these fluorophores to proteins and other carboxylate-containing molecules in aqueous solutions at a pH range of 4.5 to 7.5. The reaction forms amide bond linkages (Figure 10.39).

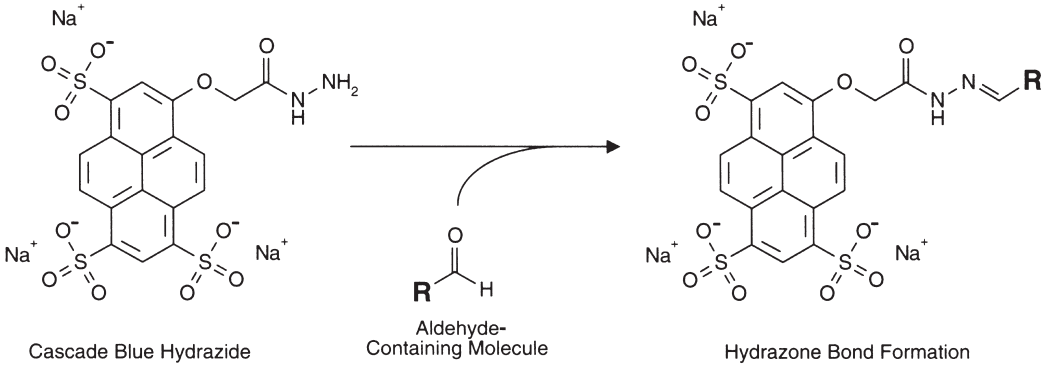
These fluorophores have excitation maxima at 377 to 378 nm and at 398 to 399 nm and emission maxima at 422 to 423 nm. The extinction coefficient of the molecules in water is about 27,000 $M^{-1}cm^{-1}$. The Cascade Blue derivatives can be used along with Lucifer Yellow derivatives and simultaneously excited by light of less than 400 nm, resulting in two-color detection at 422 nm and 530 nm.

Cascade Blue diamine derivatives are soluble in aqueous solution. A concentrated stock solution may be prepared in water and dissolved quickly, and an aliquot immediately added to a buffered reaction medium. For aqueous reactions, 0.1-*M* MES, pH 4.7 to 6.5, may be used to stabilize the pH during the coupling process. Avoid amine- or carboxylate-containing buffers such as Tris or glycine, since these can compete with the coupling reaction.

5.3. Aldehyde-/Ketone-Reactive Cascade Blue Hydrazide

Cascade Blue hydrazide is a carboxy-hydrazine derivative of the 8-methoxy group on the pyrene trisulfonic acid fluorophore. Hydrazide groups react with aldehyde and ketone groups to form relatively stable hydrazone linkages (Chapter 3, Section 5.1) (Figure 10.40). Although most biomolecules don't contain aldehyde or ketone groups in their native state, carbohydrates, glycoproteins, RNA, and other molecules that contain sugar residues can be oxidized with sodium periodate to produce reactive formyl groups. Modification reagents that generate aldehydes upon coupling to a molecule also can be used to produce hydrazide-reactive sites (Chapter 2, Section 4.4).

In addition, DNA and RNA may be modified with hydrazide-reactive probes by reaction of their cytosine residues with bisulfite to form reactive sulfone intermediates (Chapter 23, Section 2.1). These derivatives can undergo transamination reactions with hydrazide- or



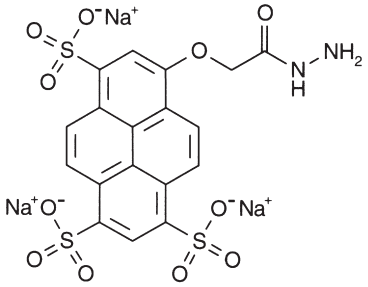


FIGURE 10.40 Cascade Blue hydrazide can be used to modify aldehyde-containing molecules to form hydrazone bonds, including modification of the reducing end of carbohydrates or in periodate-oxidized sugars.

amine-containing probes to yield covalent bonds (Draper and Gold, 1980). This dye has been used to investigate the integrin-mediated adhesion and proliferation of human MSCs (Krishna *et al.*, 2011), to analyze the vascular sequestration of fluorescent probes in plant cells (Oparka and Hawes, 2011), and to study the photostimulation of the dendritic arbor (Yang *et al.*, 2011).

This fluorophore has an excitation maximum at 400 nm and an emission maximum at 420 nm. The extinction coefficient of the molecule in aqueous solution at pH 7 is about 31,000 $M^{-1}cm^{-1}$. Cascade Blue hydrazide and Lucifer Yellow derivatives can be excited simultaneously by light of less than 400 nm, resulting in two-color detection at 420 nm and 530 nm.

Cascade Blue hydrazide is soluble in aqueous solution, and it should be stable if protected from light. A concentrated stock solution of the reagent may be prepared in water and an aliquot added to a buffered reaction medium to facilitate the transfer of small quantities. For aqueous reactions, a pH range of 5 to 9 will result in efficient hydrazone formation.

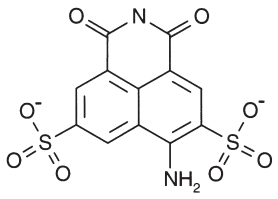

FIGURE 10.41 The basic structure of naphthalimide-based (Lucifer Yellow) fluorophores.

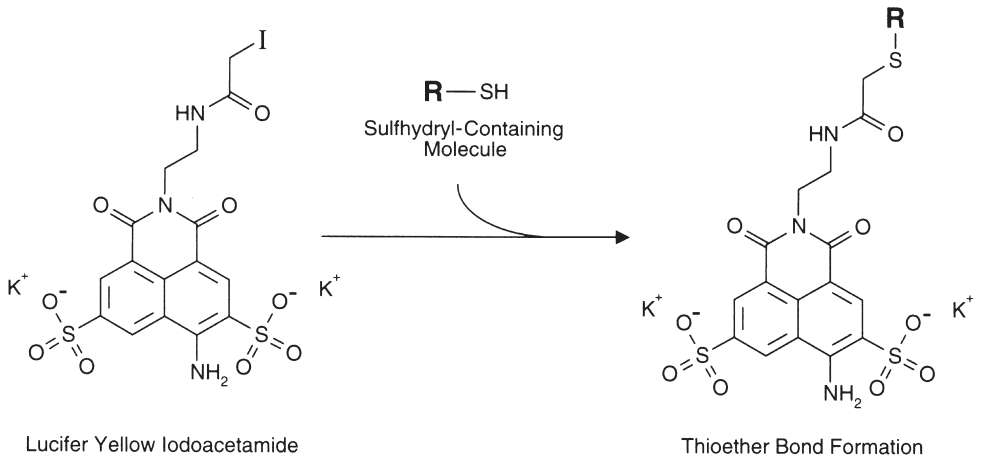
6. NAPHTHALIMIDE DERIVATIVES

Fluorescent dyes based on a core structure of naphthalimide have been used as conjugates, probes, and tracers of biological systems for decades. The sulfonate groups typically seen modifying the naphthalene outer rings provide water solubility to an otherwise hydrophobic aromatic bicyclic ring system. Many reactive naphthalimide compounds have been commercialized under the name Lucifer Yellow since its introduction in 1978 and they have been used in a wide range of applications (Hanani, 2011). As their popular name implies, the spectral characteristics of these dyes fall within the yellow region of the spectrum.

Lucifer Yellow derivatives are used extensively for cytochemical staining applications, especially in neurophysiology (Stewart, 1981a,b). The fluorophores are 3,6-disulfonate 4-aminonaphthalimide derivatives that can be further modified at their imide nitrogen to contain reactive groups suitable for conjugation with biomolecules (Figure 10.41). Cell staining with membrane-impermeant Lucifer Yellow dyes is usually carried out by osmotic shock, microinjection, or pinocytosis (Swanson *et al.*, 1987). Derivatives containing amines or hydrazide groups are fixable with



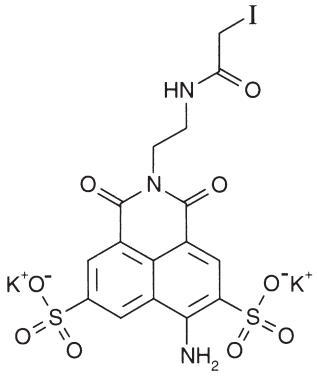


FIGURE 10.42 Lucifer Yellow iodoacetamide can be used to label sulfhydryl-containing molecules, forming thioether bonds.

formaldehyde or glutaraldehyde, coupling to nearby proteins or other amine-containing molecules intracellularly during the reaction. After periodate oxidation, glycoconjugates on cell surfaces or in solution may be labeled with the hydrazide derivative (Stewart, 1978). Sulfhydryl-containing molecules may be tagged with the iodoacetamide derivative.

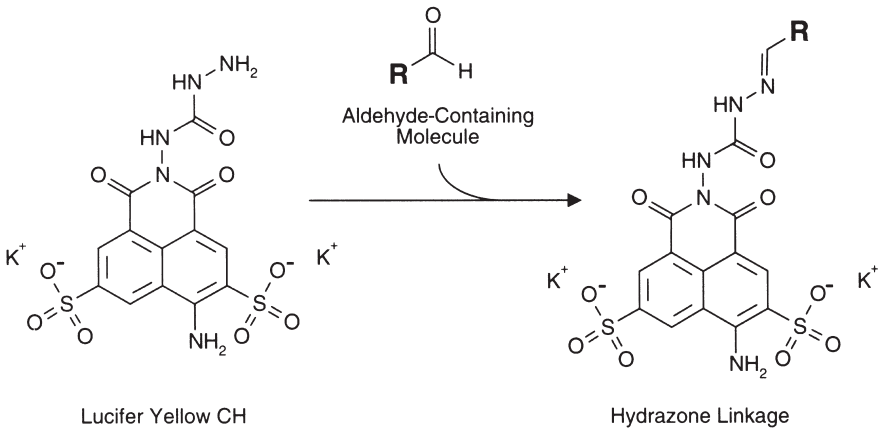
Lucifer Yellow probes are water soluble to at least 1.5%. The absorbance maximum of the derivatives occurs about 426 to 428 nm with an emission peak at about 530 to 535 nm, in the yellow region of the spectrum. The quantum yield of Lucifer dyes is about 0.25. The good intensity of luminosity from these dyes makes the detection of small quantities of labeled molecules possible intracellularly. The fluorescent conjugates are readily visible in living cells at concentrations that are nontoxic to cell viability. The low molecular weight and water solubility of these dyes allow passage of labeled compounds from one cell to another, potentially revealing molecular relationships between cells.

6.1. Sulfhydryl-Reactive Lucifer Yellow Iodoacetamide

One Lucifer Yellow derivative is available for labeling sulfhydryl-containing molecules. Lucifer Yellow iodoacetamide is a 4-ethyliodoacetamide derivative of the basic disulfonate aminonaphthalimide fluorophore structure (Invitrogen). The iodoacetyl groups react with SH groups in proteins and other molecules to form stable thioether linkages (Figure 10.42). The dye has been used as a FRET acceptor to study dityrosine in the juvenile hormone-binding protein (JHBP) (Bystranowska *et al.*, 2012), for structural analysis of a yeast prion strain (Marcelino-Cruz, 2011), for end-labeling of oligonucleotides (Zearfoss and Ryder, 2012), and to study oligomerization of αA- and αB-crystallins (Wu *et al.*, 2012).

The spectral characteristics of Lucifer Yellow iodoacetamide produce luminescence at somewhat higher wavelengths than the green luminescence of fluorescein, thus the yellow designation in its name. The excitation maximum for the probe occurs at 426 nm and its emission at 530 nm. The rather large Stokes shift makes sensitive measurements of emission intensity possible without interference by scattered excitation light. The 2-mercaptoethanol derivative of the fluorophore has an extinction coefficient at pH 7 of about 13,000 $M^{-1}cm^{-1}$ at 426 nm.

Lucifer Yellow iodoacetamide is soluble in aqueous solution due to its negatively charged sulfonate groups. A concentrated stock solution may be prepared in water prior to the addition of a small aliquot to a reaction mixture. Coupling to sulfhydryl-containing molecules occurs rapidly with the formation a thioether linkage. The reaction may be performed in 50-m*M* sodium borate, 5-m*M* EDTA, pH 8.3. The main consideration is



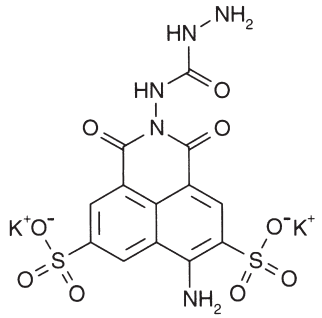


FIGURE 10.43 The hydrazide group of this Lucifer Yellow derivative can react with aldehyde-containing molecules to form hydrazone bonds.

to protect the iodoacetyl derivative from light, which will generate iodine and reduce the reactivity of the probe. The reaction may be limited to sulfhydryls (avoiding any amine derivatization) by maintaining a low molar excess of probe to the amount of sulfhydryl groups present. In addition, oligonucleotides containing a sulfhydryl modification at their 5′ ends (Chapter 23, Section 2.2) may be coupled with Lucifer Yellow iodoacetamide, yielding highly fluorescent, yellow probes.

6.2. Aldehyde-/Ketone-Reactive Lucifer Yellow CH

Lucifer Yellow CH is a carbohydrazide derivative of the basic disulfonate aminonaphthalimide fluorophore structure (Invitrogen). Hydrazide groups react with aldehyde and ketone groups to form relatively stable hydrazone linkages (Chapter 3, Section 5.1) (Figure 10.43). Although most biomolecules do not contain aldehyde or ketone groups in their native state, carbohydrates, glycoproteins, RNA, and other molecules that contain sugar residues can be oxidized with sodium periodate to produce reactive formyl groups. The use of modification reagents that generate aldehydes upon coupling to a molecule also can be used to produce hydrazide-reactive sites (Chapter 2, Section 4.4). In addition, DNA and RNA may be modified with hydrazide-reactive probes by reacting their cytosine residues with bisulfite to form reactive sulfone intermediates (Chapter 23, Section 2.1). These derivatives can undergo transamination reactions with hydrazide- or amine-containing probes to yield covalent bonds (Draper and Gold, 1980).

Lucifer Yellow CH
MW 522 (potassium salt)
MW 457 (lithium salt)
MW 479 (ammonium salt)
Excitation = 428 nm
Emission = 533–535 nm
ε at 428 nm = 12,000 $M^{-1}cm^{-1}$

Lucifer Yellow CH is commonly used as a neuronal tracer by staining cells and then fixing them with formaldehyde or glutaraldehyde. It also can be used to label glycoproteins or glycolipids on cell surfaces after periodate oxidation (Spiegel *et al.*, 1983; Lee and Fortes, 1985). The labeling of oxidized ribonucleotides and gangliosides can be performed similarly (Spiegel *et al.*, 1985; Sun *et al.*, 1988).

This fluorophore has an excitation maximum at 428 nm and an emission maximum at 534 nm. The extinction coefficient of the molecule in aqueous solution is about 12,000 $M^{-1}cm^{-1}$. Cascade Blue hydrazide and Lucifer Yellow CH derivatives can be excited simultaneously by light of less than 400 nm, resulting in the possibility for two-color detection at 420 nm and 534 nm.

Lucifer Yellow CH is soluble in aqueous solution, and it should be stable for a while if protected from light. The reagent is available as three different salts of the sulfonate groups. The ammonium salt of the fluorophore is soluble to a level of 9% in water, while the lithium and potassium salts have solubilities of 5% and 1%, respectively. A concentrated stock solution of the fluorophore may be prepared in water and an aliquot added to a buffered reaction medium to facilitate the transfer of small quantities. For aqueous reactions, a pH range of 5 to 9 will result in efficient hydrazone formation with aldehyde or ketone residues.

TABLE 10.1 **Properties of the Phycobiliproteins**

7. PHYCOBILIPROTEIN DERIVATIVES

Phycobiliproteins are intensely fluorescent proteins that function as components in the photosynthetic apparatus of eukaryotic blue–green algae and cyanobacteria (Glazer, 1981; Samarakoon *et al.*, 2012). The proteins are found as aggregates in phycobilisome particles near the chlorophyll regions (Kronick, 1986). In the native state, phycobiliproteins do not fluoresce; rather, excitation energy is designed to be efficiently transferred to chlorophyll molecules for utilization in synthetic processes within the cell. Once purified, however, excitation energy is released from phycobiliproteins as strong luminosity. The fluorescent quantum efficiencies of these proteins can be as high as 0.98, far better than most synthetic probes (Grabowski and Gantt, 1978). In addition, each biliprotein contains multiple chromophoric bilin prosthetic groups, conferring extremely high absorbance coefficients to each protein molecule. B-Phycoerythrin, for example, typically contains 34 chromophoric groups giving an effective, combined extinction coefficient at 545 nm of $2.4 \times 10^6 M^{-1} cm^{-1}$ (Glazer and Hixson, 1977). The strong absorption bands are in the visible region of the spectrum, extending from the green to the far red wavelengths. These absorption spectra extend over a broad range of potential excitation wavelengths, allowing for versatility in the excitation source employed and creating large Stokes shifts, thus minimizing interference from Rayleigh-scattered light (Loken, 1987).

Due to the presence of multiple fluorescent groups in each phycobiliprotein, conjugates of these molecules form extraordinarily luminescent probes. Labeling of macromolecules with phycobiliprotein derivatives can provide absorption coefficients 30-fold higher than labeling with small, synthetic fluorophores. Their ability to be monitored by fluorescing in the red region of the spectrum decreases potential interferences from indigenous biological fluorescence. The protected bilin (tetra-pyrrole) prosthetic groups are not easily affected by their external environment. They are not readily quenched by conjugation to another molecule or affected by other components in solution. The prosthetic group orientation within the protein molecules enables fluorescence to take place independent of pH or ionic strength. The excellent solubility of phycobiliproteins in aqueous solution allows easy chemical manipulation for modification or conjugation reactions, and their hydrophilic nature provides low nonspecific binding character in fluorescent detection applications.

There are three main classes of phycobiliproteins, differing in their protein structure, bilin content, and fluorescent properties. These are phycoerythrin, phycocyanin, and allophycocyanin. There are two main forms of phycoerythrin proteins commonly in use: B-phycoerythrin isolated from *Porphyridium cruentum* and R-phycoerythrin from *Gastroclonium coulteri*. There also are three main forms of pigments found in these proteins: phycoerythrobilin, phycourobilin, and phycocyanobilin (Glazer, 1985; Richa *et al.*, 2011). The relative content of these pigments in the phycobiliproteins determines their spectral properties. All of them, however, have extremely high absorption coefficients ranging from a magnitude of 10^5 to 10^6 and excellent QYs ranging from 0.51 up to 0.98.

The spectral properties of four major phycobiliproteins used as fluorescent labels can be found in Tables 10.1 and 10.2. The bilin content of these proteins ranges from a low of 4 prosthetic groups in C-phycocyanin to the 34 groups of B- and R-phycoerythrin. Phycoerythrin derivatives can, therefore, be used to create the most intensely fluorescent probes possible using these proteins. The fluorescent yield of the most luminescent phycobiliprotein molecule is equivalent to about 30 fluoresceins or 100 rhodamine molecules. Streptavidin–phycoerythrin conjugates, for example, have been used to detect as few as 100 biotinylated antibodies bound to receptor proteins per cell (Zola *et al.*, 1990).

Conjugation of phycobiliproteins to targeting components such as antibodies, avidin, biotin, or other molecules preserves the binding or activity of the attached

TABLE 10.2 Spectral Properties of Phycobiliproteins

Phycobiliprotein	Molecular Weight	Absorption Max (nm)	EC ($M^{-1}cm^{-1}$)	Emission Max (nm)	Fluorescence QY
B-phycoerythrin	240,000	546, 565	2,410,000	575	0.98
R-phycoerythrin	240,000	496, 546, 565	1,960,000	578	0.82

constituent and does not alter the spectral characteristics of the bilin prosthetic groups. Common heterobifunctional crosslinking agents can be used to create phycobiliprotein conjugates, including SPDP (Chapter 6, Section 1.1), SMCC (Chapter 6, Section 1.3), and SMPB (Chapter 5, Section 1.6) (Oi *et al.*, 1982). These crosslinkers react with amine groups on the phycobiliproteins, producing activated intermediates able to couple with sulfhydryl-containing molecules. Thiolation reagents such as 2-iminothiolane, *N*-succinimidyl-*S*-acetylthioacetate (SATA), and SAMSA (Chapter 2, Section 4.1) can be used to create thiols on the secondary molecule to effect the final coupling reaction.

Glazer and Stryer (1983) reported on the preparation and use of tandem phycobiliprotein conjugates wherein B-phycoerythrin is crosslinked to allophycocyanin to create an energy donor–acceptor pair. The B-phycoerythrin component can be excited at 545 nm, emitting energy at 575 nm that can be accepted by allophycocyanin (APC), which in turn emits light at 660 nm. The result is a large shift in the spectral characteristics from that of the individual proteins, increasing the effective Stokes shift to over 100 nm. Conjugation of such tandem pairs to other proteins can create superior fluorescent reagents.

Phycobiliproteins can also be modified with reactive organic fluorescent probes to produce tandem dyes having modulated emission properties. In this sense, dyes having excitation wavelengths that overlap with the emission wavelength of a phycobiliprotein can be used to extend the emission of the tandem complex farther into the red region. For instance, a Cy5-type dye (see Section 8) can be used to modify R-phycoerythrin (RPE) to produce a conjugate that can be excited at the normal wavelengths used for RPE, but emit light at the Cy5 range of 660 to 665 nm instead of the typical 575-nm emission for the phycobiliprotein itself. Fluorescence resonance energy transfer (FRET) of excitation energy from the bilin units in RPE to the Cy5 dyes modifying the protein results in the red-shifted emission characteristics of the tandem dye construct. In an optimized tandem dye conjugate, the fluorescence emission of the phycobiliprotein is almost entirely eliminated by the FRET signaling to the organic dye (Tian and Pappas, 2011; Tian, 2012).

Preparation of a series of phycobiliprotein tandem dyes allows multiplexed analysis of different targets in a sample. In addition, since RPE can be excited by the argon-ion laser at 488 nm, a fluorescein-labeled probe can be used concurrently with RPE alone and RPE-tandem conjugates to create a multiplexed system of different fluorescent probes that can be used simultaneously. Table 10.3 shows the different combinations of dyes that can be used in this type of assay with RPE and APC.

The following protocol is a generalized method for creating sulfhydryl-reactive phycobiliprotein reagents for coupling to SH containing molecules. The procedure uses the heterobifunctional crosslinker SPDP (Chapter 6, Section 1.1). Other amine- and sulfhydryl-reactive crosslinking agents may be used in a similar manner, such as sulfo-SMCC or the hydrophilic NHS-PEG_n-maleimide crosslinkers (Chapter 18). The discrete PEG-based crosslinkers will create conjugates of phycobiliproteins that have low nonspecific binding character due to the biocompatible nature of the PEG groups.

7.1. Protocol

1. Dialyze the phycobiliprotein into 50-m*M* sodium borate, 0.3-*M* NaCl, pH 8.5. Note: Commercial preparations of these proteins come as an ammonium sulfate suspension. After dialysis, adjust the protein solution to a concentration of 1 mg/ml. Higher protein concentrations may be used, but the amount of crosslinking reagent added to each milliliter of the reaction should be proportionally scaled up as well. Protect the protein solution from undue exposure to light.
2. Dissolve SPDP at a concentration of 6.2 mg/ml in DMSO (makes a 20-m*M* stock solution). Alternatively, LC-SPDP may be used and dissolved at a concentration of 8.5 mg/ml in DMSO (also makes a 20-m*M* solution). If the water soluble sulfo-LC-SPDP is used, a stock solution in water may be prepared just prior to adding an aliquot to the reaction. In this case, prepare a 10-m*M* solution of sulfo-LC-SPDP by dissolving 5.2 mg/ml in water. Since an aqueous solution of the crosslinker will degrade by hydrolysis of the sulfo-NHS ester, it should be used quickly to prevent significant loss of activity. If a sufficiently

TABLE 10.3 Tandem Dye Fluorescence Properties

large amount of phycobiliprotein will be modified, the solid may be added directly to the reaction mixture without preparing a stock solution in water to allow accurate weighing of Sulfo-LC-SPDP.

3. Add 25 µl of the stock solution of either SPDP or LC-SPDP in DMSO to each milliliter of the protein solution. If sulfo-LC-SPDP is used, add 50 µl of the stock solution in water to each milliliter of protein solution.
4. Mix and react for at least 30 min at room temperature. Longer reaction times, even overnight, will not adversely affect the modification.
5. Purify the modified protein from reaction byproducts by dialysis using a membrane with a low-molecular-weight cutoff or gel filtration using desalting resin and a buffer consisting of 50-m*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2.

The SPDP-activated phycobiliprotein may be reacted with a sulfhydryl-containing protein to create a fluorescent conjugate linked through disulfide bonds.

8. CYANINE DYE DERIVATIVES

One of the most popular fluorescent dye types for labeling biomolecules is built from two cationic, aromatic, nitrogenous ring structures linked by an unsaturated polymethine bridge. One of the rings must have a quanternized nitrogen atom possessing a positive charge. The ring structure types can be highly varied, from five or six membered heterocycles to multiple fused ring systems. The polymethine bridge to a great extent determines the fluorescence character of the dye as well as contributing to the naming convention that distinguishes each dye within a family of similar structures. Thus, the general structure of all cyanine dyes can be represented by

$$X{-}(CH{=}CH)_n{-}CH{=}Y$$

where X and Y are the nitrogenous rings at both ends of the polymethine bridge and n can vary from 0 to 3. The name of a cyanine dye often has a number following it, which reflects the number of carbon atoms in the polymethine chain. Thus, if $n = 0$, the dye is called a monomethine cyanine dye; if $n = 1$, it is called a tricyanine or Cy3; if $n = 2$, it is a pentacyanine or Cy5; and if $n = 3$, it is a heptacyanine or Cy7.

The longer the polymethine bridge in a cyanine dye, the higher the absorbance and emission wavelengths become. In general, for each incremental increase of n, the absorbance and emission characteristics of the dye increase by about 100 nm. Thus, Cy3 dyes typically display excitation and fluorescence in the mid-500 nm range, Cy5 has spectral properties in the mid-600 nm range, and Cy7 in the mid-700 nm range.

Though the bridge structure significantly affects the spectral character of a cyanine dye, the heterocyclic rings also can contribute heavily to its properties. For instance, the structure of the ring systems can highly affect the absorptivity and brightness of a particular cyanine dye. Some heterocycle structures, such as the commonly used indol rings of many commercial cyanine compounds, have extremely high extinction

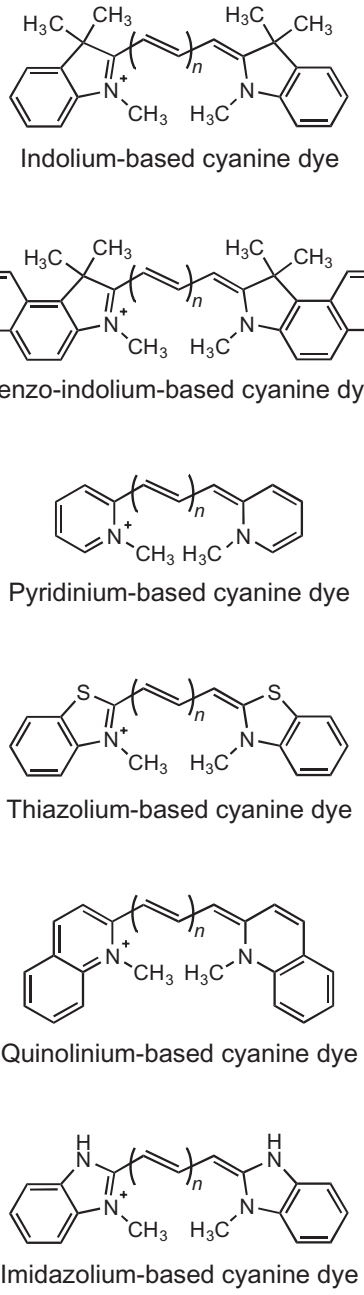
coefficients and thus provide intensely bright fluorescent labels. Other constituents on the heterocyclic rings can provide a blue shift or a red shift in the spectral characteristics of a dye. This is the basis for creating intermediate Cy dyes having fluorescent properties between the standard ones. For instance, Cy5.5 falls between the emission wavelengths of Cy5 and Cy7, completely due to an alternative fused ring structure (e.g., benzo-indolium groups; see Figure 10.44). The relative fluorescence effects of different ring systems and numerous possible substitutions on these rings often can be predicted from decades of investigation and data (Michaela, 2002). Thus, many commercial suppliers of these dyes have fine-tuned their properties to make them more suitable for certain applications.

The nonreactive base structures of cyanine dyes (or carbocyanines) have been used for many years as components in photographic emulsions to increase the range and sensitivity of film and also in CD-R and DVD-R optical disks to record digital information. A major innovation came when Ernst *et al.* (1989) and Waggoner *et al.* (1993) recognized that cyanine dyes would make excellent labels for fluorescence detection and, for this reason, they synthesized reactive dye derivatives that could then be covalently attached to proteins and other molecules.

The nitrogenous ring structures at each end of a cyanine dye can be the same (symmetrical structure) or different (unsymmetrical), depending on the heterocycle type and constituents on the rings. Reactive cyanine dyes nearly always contain unsymmetrical structures due to the presence of a reactive arm on one end to facilitate conjugation to biomolecules or the presence of one or more negatively charged groups designed to increase water solubility.

The earliest cyanine dye labels were relatively hydrophobic due to the lack of hydrophilic groups or having only a minimal number of charged groups on the molecules. These dyes, while intensely fluorescent, often cause aggregation or precipitation of labeled proteins, especially if more than just a few fluorescent molecules are attached to a single biomolecule. Dye–dye interactions due to ring stacking or hydrophobic interactions also cause fluorescence quenching, because energy transfer can take place between dye molecules, negating the emission of light.

To make cyanine dyes more biocompatible for protein labeling, sulfonate groups typically are added to the ring systems or at the ends of short spacer arms protruding from the base dye structure (Mujumdar *et al.*, 1993; Southwick *et al.*, 2005). The addition of sulfonate groups provides a negative charge character that helps solubilize the cyanine dye in aqueous solution and prevents dye–dye interactions through like-charge repulsion. In general, the more sulfonates that a cyanine dye possesses, the greater will be its hydrophilicity and the lower its tendency to bind nonspecifically to hydrophobic structures on proteins or other molecules. Cyanine dyes of this type having from two to four sulfonate groups are available commercially, with three or four sulfonates per dye giving the best results for bioconjugation purposes in aqueous solution.



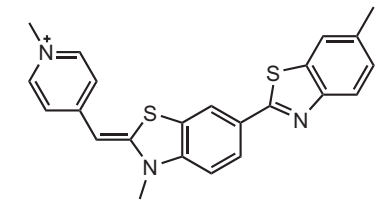


FIGURE 10.44 The common nitrogenous ring structures of cyanine-type dyes. Indolium-based dye derivatives are the most frequently used fluorescent labels due to the high extinction coefficient of the indol groups. Antibodies and proteins labeled with these dyes can provide bright fluorescent signals for highly sensitive detection assays.

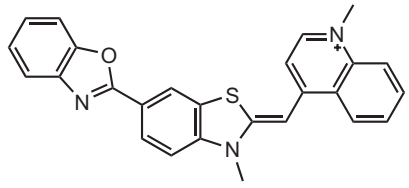

Cyanine dyes also are used as labels for oligonucleotide probes. Unlike the hydrophilic cyanine dyes valuable for protein labeling, the use of dye–phosphoramidite compounds to synthesize DNA or RNA probes typically requires the use of more hydrophobic dye structures to make them compatible with the solvents and reactions of oligonucleotide synthesis. Thus, indol cyanines containing few or no sulfonates are used in these applications to label oligos for applications such as array detection, hybridization assays, and RT-PCR.

In addition, small unsymmetrical cyanine compounds have been designed that bind to the minor groove of DNA to measure DNA concentration or stain DNA by fluorescence. These derivatives often contain a positive charge character with short crescent shapes to wrap around the helical structure of double-stranded oligonucleotides. As minor groove binding dyes interact with DNA, they typically undergo a slight twist in their molecular structure, which dramatically increases fluorescence QY and brightness. For example, the minor groove binding dye BOXTO displays a 300-fold increase in fluorescence when binding to double-stranded DNA (Karlsson *et al.*, 2003).

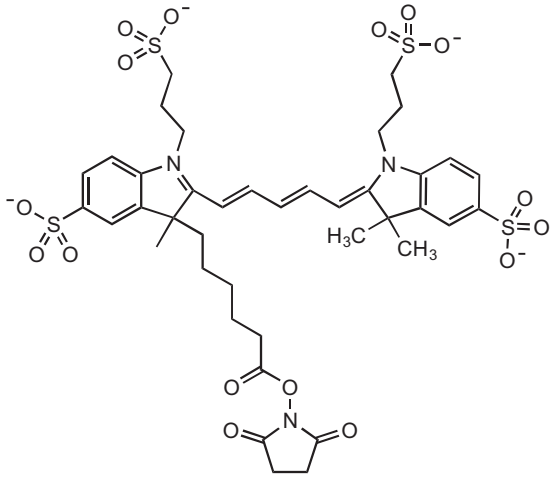
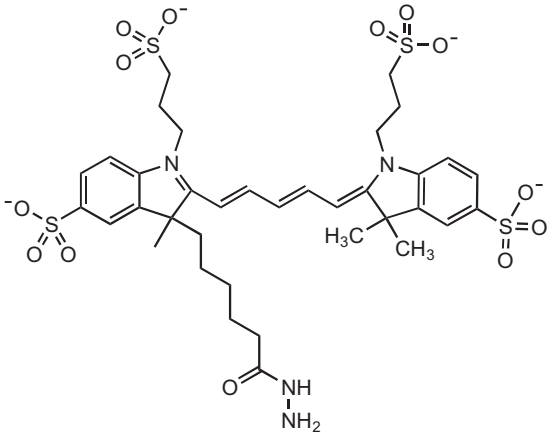
MW 422.52

Most companies selling cyanine dyes do not reveal their exact structures. This is likely due to each company keeping proprietary the small synthetic tweaks that create unique fluorescence properties for their dyes. However, some structures are available through published documents, such as patents and early publications (Leung *et al.*, 2005). Figure 10.45 illustrates some of these structures, which may not reflect precisely what any one company actually offers today but does give an idea of the types of modifications that can be made to add water solubility and reactivity.

Cyanine dyes are commercially available in a number of different structural configurations containing appropriate reactive groups to couple with many of the major functional groups (Thermo Fisher, GE Healthcare, Invitrogen, Sigma, Dyomics, Atto-Tec, and Denovo Biolabels). Most of these dyes contain sulfonate groups to increase their biocompatibility, but careful comparisons should be made, as most companies do not provide structures. The following sections describe some of the reactive cyanine dye reagents and the protocols used to label proteins and other molecules.



8.1. Amine-Reactive Cyanine Dyes



Amine-reactive cyanine dyes typically contain an NHS ester group on the end of a short hydrocarbon spacer for attachment to biomolecules. The NHS ester can react with amine groups on proteins to form amide bond linkages (Figure 10.46). This reaction is efficient at physiological pH or under slightly more alkaline conditions. While poly-sulfonated dye molecules are very water soluble, it is best first to prepare a stock solution in organic solvent to prevent NHS ester hydrolysis prior to adding a small aliquot to a reaction mixture.

The following protocol for protein labeling with an NHS-ester cyanine dye is based on the Thermo Fisher instructions for use of DyLight dyes. When preparing a fluorescently labeled protein the degree of modification should be optimized to provide maximal fluorescence signal while not affecting the activity or binding potential of the protein for other molecules. In fact, dye loadings of greater than about 8 fluorescent labels per protein will result in fluorescence quenching due to energy transfer between dye molecules. Higher loadings will not result in greater fluorescence signals, only greater potential to interfere with protein activity. Therefore, limit the molar excess of dye over protein to a level that will provide less than about eight substitutions per protein molecule.

Protocol

1. Dissolve a protein or antibody to be labeled with an NHS-ester cyanine dye in 0.1-*M* sodium phosphate buffer, pH 7.2 to 7.5, at a concentration of 1 to 10 mg/ml. The higher the concentration of protein, the greater will be the yield of the labeling reaction. Other buffers may also be used, including borate buffer or carbonate buffer, but higher pH reactions will result in greater hydrolysis of the NHS ester and may decrease labeling efficiency. Avoid amine-containing buffers such as Tris or imidazole. Also, avoid the addition of thiol reducing agents or

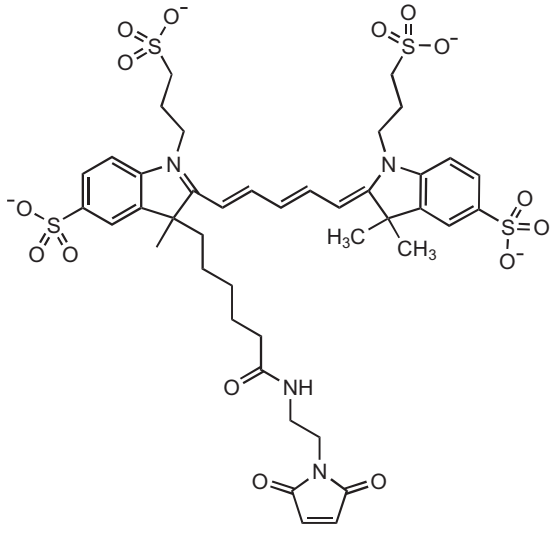


FIGURE 10.45 Typical Cy5 derivatives contain negatively charged sulfonate groups for water solubility and a side chain terminating in a reactive group for covalent coupling. The most common reactive groups are NHS esters for labeling amines, maleimide groups for coupling to thiols, and hydrazide groups for labeling aldehydes.

glycerol, as these also will react with the NHS ester. If the protein concentration is below 1 mg/ml, the molar excess of dye added to the reaction will have to be greatly increased to maintain yield of the reaction.

2. In a fume hood, dissolve the NHS-ester cyanine dye in DMF at a concentration of 10-m*M*. Protect all dye solutions from light.
3. With mixing, add a quantity of the dye solution to the protein solution to provide the desired molar excess of dye over protein. For instance, for an antibody dissolved in buffer at 10 mg/ml, the addition of 66 µl of dye solution will give a 10-fold molar excess of dye over protein. Note: For dyes that are rather hydrophobic in character, the mole excess of dye over the amount of protein present may have to be scaled back to prevent precipitation of the conjugate or dye–dye quenching from occurring (e.g., 5-fold mole excess). For highly hydrophilic dye

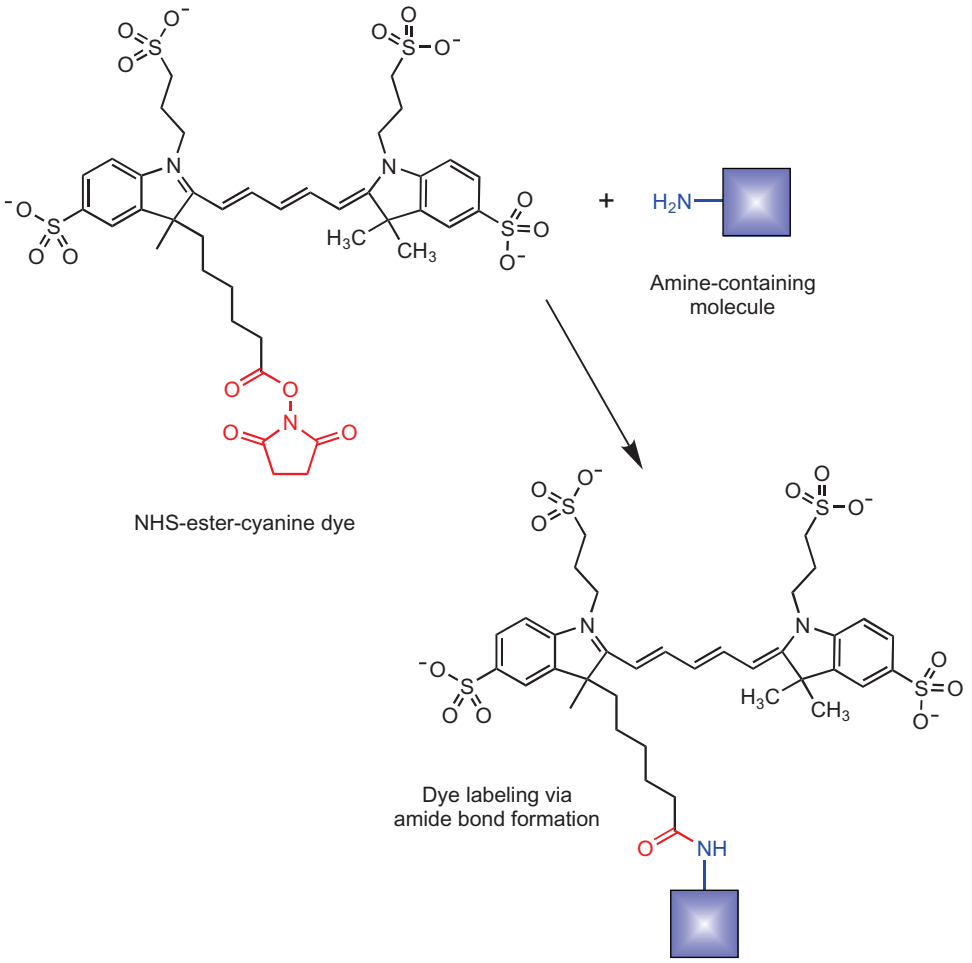

FIGURE 10.46 An NHS-ester-containing cyanine dye can be used to label amine-containing proteins or other molecules to form amide bonds.

derivatives, such as those containing at least three to four sulfonate groups or PEG modifications, then a 10-fold mole excess is appropriate.

4. React for 1 h at room temperature with gentle mixing.
5. Purify the labeled protein from excess dye and reaction by-products using dialysis or gel filtration on a desalting resin.

8.2. Thiol-Reactive Cyanine Dyes

Cyanine dyes that have a thiol-reactive group are typically maleimide derivatives. Maleimide groups react with sulfhydryls under neutral pH conditions to form a thioether linkage (Figure 10.47). Since thiols are present in proteins in limited amounts, dye labeling through these groups often will result in modifications that occur only at discrete locations on the molecule. Labeling thiol groups also may be done using peptides that have been synthesized with terminal cysteine residues or using oligonucleotides containing a 5′ thiol group.

The pH of a maleimide conjugation reaction should be in the range of 6.5 to 7.5 to ensure specificity toward thiol groups. Higher pH conditions will begin to result in cross-reactions with amines through a Michael addition process. Coupling to proteins can be done through disulfide reduction or through use of a thiolation reagent (Chapter 2, Section 4.1). Reduction of disulfides may be performed using immobilized TCEP (Thermo Fisher), which effectively forms free thiols on proteins and peptides while not contaminating a reaction with the reducing agent.

The following protocol is based on the methods recommended by Thermo Fisher for use of the cyanine dye DyLight 649. Antibody reduction is based on the methods of Sun *et al.* (2005) and results in partially reduced bispecific immunoglobulin containing available thiols in the hinge region for labeling.

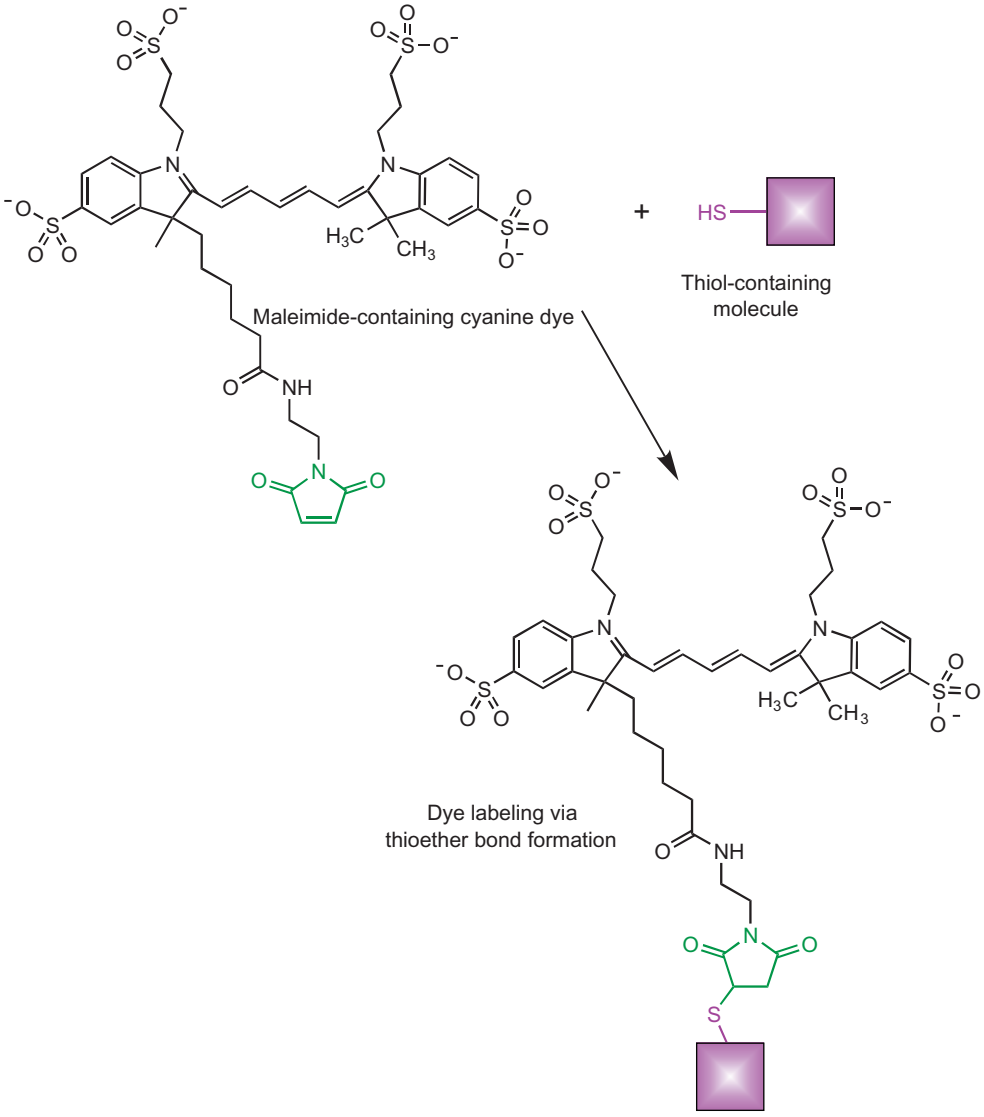

FIGURE 10.47 A maleimide-containing cyanine dye can be used to label thiol-containing molecules to form thioether bonds.

Protocol for Partial Reduction of IgG Antibody

1. Dissolve an IgG antibody in 50-m*M* sodium phosphate, 150-m*M* NaCl, 10-m*M* EDTA, pH 7.2 (reaction buffer), at a concentration of 1 to 10 mg/ml.
2. Dissolve TCEP in reaction buffer at a concentration of 10-m*M* and readjust the pH if necessary.
3. Add a quantity of the TCEP solution to the antibody solution with mixing to achieve a 2.75 molar excess of the reducing agent over the amount of antibody present.
4. Incubate for 2 h at 37°C.

The reduced antibody can be used immediately to label with a maleimide-based cyanine dye using the following protocol.

Protocol for Labeling Reduced Antibody with Thiol-Reactive Cyanine Dye

5. In a fume hood, dissolve the maleimide-containing cyanine dye in DMF at a concentration of 10-m*M*. Protect all dye solutions from light.
6. With mixing, add a quantity of the dye solution to the antibody solution to provide the desired molar excess of dye. For instance, for an antibody dissolved in buffer at 10 mg/ml, the addition of 66 µl of dye solution will give a 10-fold molar excess of dye over protein.
7. React for 2 h at room temperature with gentle mixing.
8. Purify the labeled protein from excess dye and reaction byproducts using dialysis or gel filtration on a desalting resin. Protect the labeled protein from light to avoid photobleaching the dye and losing fluorescence intensity.

8.3. Carbonyl-Reactive Cyanine Dyes

Cyanine-type dyes containing hydrazide functional groups may be used to label molecules containing carbonyl groups, especially aldehydes (Figure 10.48). Aldehydes may be created on carbohydrates, sugars, and glycans by periodate oxidation, which cleaves the carbon–carbon bonds between diols to form reactive formyl groups. Thus, glycoproteins and other glycoconjugates can be labeled specifically with a cyanine fluorescent dye only through carbohydrate components, which often avoids binding sites or active centers. Hydrazide-containing cyanine dyes also may be used to detect glycoproteins in cells, tissues, gels, or on western blots after periodate oxidation. In this regard, bands containing glycoproteins can be detected in a sample separately from the rest of the non-glycosylated protein pool (Thermo Fisher).

Glycan molecules that have been released from a protein by enzymatic means also can be labeled at their reducing ends by a hydrazide-containing cyanine dye. This reaction results in a single fluorescent label on the C-1 carbon of the innermost sugar of the glycan tree. The labeled glycan can be tracked through separation steps or detected for its specific interactions with carbohydrate binding proteins (see Chapter 2, Section 4.6).

Hydrazide-based cyanine dyes are reactive with common formaldehyde fixatives for cell and tissue studies. This enables these dyes to function as general stains for protein-rich areas within cells, and they get crosslinked into place by the formaldehyde reaction process.

The following protocol relates to the labeling of glycoproteins with hydrazide-containing cyanine dyes. Similar methods can be used to detect glycoproteins in other applications, such as within electrophoresis gels or on blots. For methods related to the labeling of glycans at their reducing ends with hydrazide reagents, see Chapter 11, Section 6.7.

Protocol

1. Dissolve a glycoprotein to be labeled in 50-m*M* sodium phosphate, pH 7 (reaction buffer), at a concentration

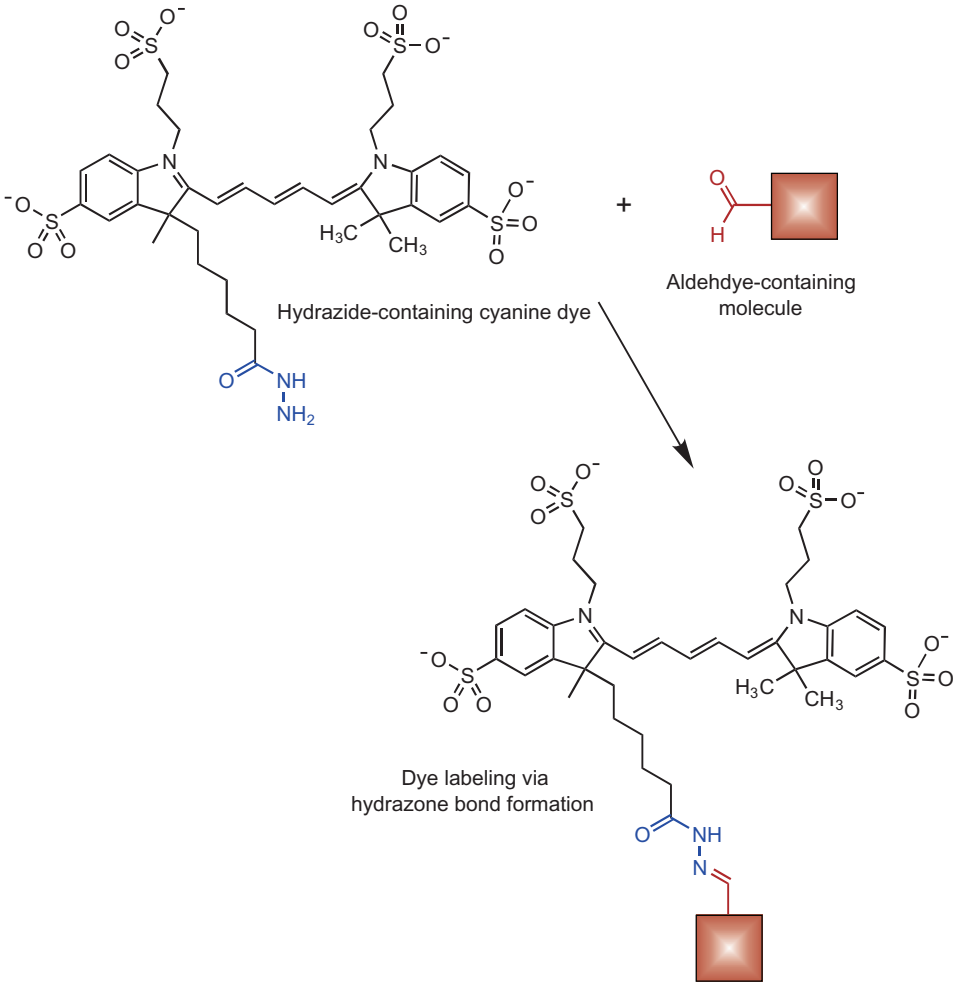

FIGURE 10.48 A cyanine dye containing a hydrazide group can be used to label glycans at their reducing end or other reducing sugars, forming a hydrazone linkage. Glycoproteins also can be labeled after periodate oxidation to form aldehyde groups.

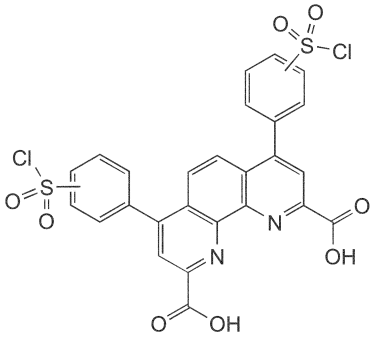
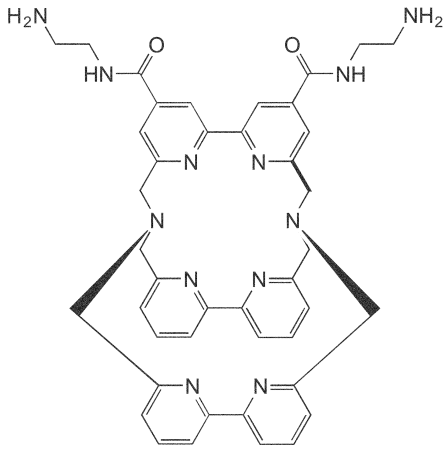
of 1 to 10 mg/ml. For sialic acid modification, place the sample in ice to cool to near 0°C.



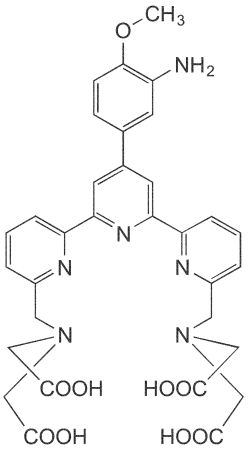
2. Dissolve sodium metaperiodate in reaction buffer at a concentration of 10 mg/ml (0.046-*M*). Protect from light. To obtain approximately a 1-m*M* concentration of sodium periodate in the reaction solution (suitable for oxidizing only sialic acid residues), add 21.8 µl of this stock solution to each milliliter of the glycoprotein solution to be oxidized. Maintain the solution on ice. For general oxidation of carbohydrates other than just sialic acid, add 218 µl of the stock solution to obtain an approximate final concentration of 10-m*M* periodate in the reaction. Use room-temperature conditions for general carbohydrate oxidation. Wrap the vial containing the reaction solution with aluminum foil to protect from light. The use of an amber vial is also suitable for this purpose.
3. React for 15 to 30 min at room temperature.
4. Quench the reaction by immediate gel filtration on a desalting column. If a dextran-based resin is used for the chromatography, the support itself will react with sodium periodate to quench excess reagent. Alternatively, *N*-acetylmethionine may be added to quench the reaction, because the thioether of the methionine side chain will react with periodate to form sulfoxide or sulfone products (Geoghegan and Stroh, 1992). In addition, sodium sulfite (Na_2SO_3) was used by Stolowitz *et al.* (2001) to quench the periodate oxidation of HRP in solution. To quench the reaction with cellular samples, wash the cells with buffer to remove remaining traces of periodate.
5. In a fume hood, dissolve the hydrazide-cyanine dye in DMF at a concentration of 10-m*M*. Protect all dye solutions from light.
6. With mixing, add a quantity of the dye solution to the oxidized antibody solution to provide the desired molar excess of dye. For instance, for an antibody dissolved in buffer at 10 mg/ml, the addition of 66 µl of dye solution will give a 10-fold molar excess of dye over protein.
7. React for 2 hours at room temperature with gentle mixing.
8. Purify the labeled protein from excess dye using dialysis or gel filtration on a desalting resin. Protect the labeled protein from light to avoid photobleaching the dye and losing fluorescence intensity.

9. LANTHANIDE CHELATES FOR TIME-RESOLVED FLUORESCENCE



Lanthanide metals are sometimes called rare earths and are located in period 6 of the periodic table of elements with atomic numbers 57 to 71, beginning with lanthanum (although there is some discrepancy over exactly where they start and end). Due to their unique electronic properties, lanthanide ions display luminescent properties with very sharp emission peaks. Unfortunately, the metal ions alone have extremely low extinction coefficients of no more than about 1–10 $M^{-1}cm^{-1}$, which makes them poorly fluorescent. The dim nature of lanthanide luminescence can be overcome by associating the metal ion with a chromophore group that can act as a light antenna. Lanthanide metals can form nine coordination bonds with ligands, creating three-faced centered trigonal prism structures. Coordinated in this way in an organic chelate structure that also contains a strongly absorbing chromophore nearby, the dimness of lanthanide metal luminescence can be transformed into an extraordinarily bright complex. The appropriate antenna group is one that can absorb energy and transfer it to the lanthanide metal, which then emits light at specific wavelengths, depending on which lanthanide element is in the coordination complex. For a review of chelating compounds for lanthanide luminescence, including their use in the development of time-resolved immunoassays, see Hagan and Zuchner (2011), Mathis and Bazin (2011), and Arnaud and Georges (2003). Some examples of antenna-chelate structures are shown in Figure 10.49. Figure 10.50 illustrates the principle of lanthanide luminescence.

Fluorescent labels built from lanthanide chelating groups of this type are extremely useful in biological applications due to their large Stokes shift (nearly 290 nm), no overlap between excitation and emission peaks, and very long fluorescent lifetimes. When bound by a chelating group that completely envelops and interacts with most of the lanthanide's nine possible coordination sites, the metal also is protected from any solvent-quenching effects that may reduce luminescence (Pietraszkiewicz *et al.*, 1993). If the antenna-chelating group also contains a reactive group, then the lanthanide–chelate complex can be covalently linked as a label on targeting molecules or affinity ligands. The result is one of the most intensely fluorescent probes available for biological detection applications.



The fluorescence lifetimes of lanthanide chelates are among the longest of all fluorescent compounds. Whereas most organic fluors or inorganic nanocrystals have lifetimes measured in the nanosecond or picosecond range, lanthanide chelates typically emit light for microseconds to milliseconds. The advantage of this long-lived emission is that time-gated measurements can be taken, which detect lanthanide luminescence long after emission from other organic fluors has decayed to zero. In complex biological samples, there are often many organic components that have fluorescent properties, especially in the lower visible or UV regions of the spectrum. When using lanthanide chelates as fluorescent probes and labels, any indigenous

sample fluorescence can be eliminated before the chelate emission is measured. This "time-resolved" luminescence technique virtually abolishes background fluorescence and makes detection and assays using lanthanide chelates among the most sensitive fluorescence measurements possible. For reviews of time-resolved fluorescence using lanthanide chelates in biological assays, see Patsenker *et al.* (2011), Hagan and Zuchner (2011), Mathis and Bazin (2011), Soini and Kojola (1983), Soini *et al.* (1990), Diamandis and Christopoulos (1990), Hemmila (1985), Diamandis (1993), and Hemmila (1998).

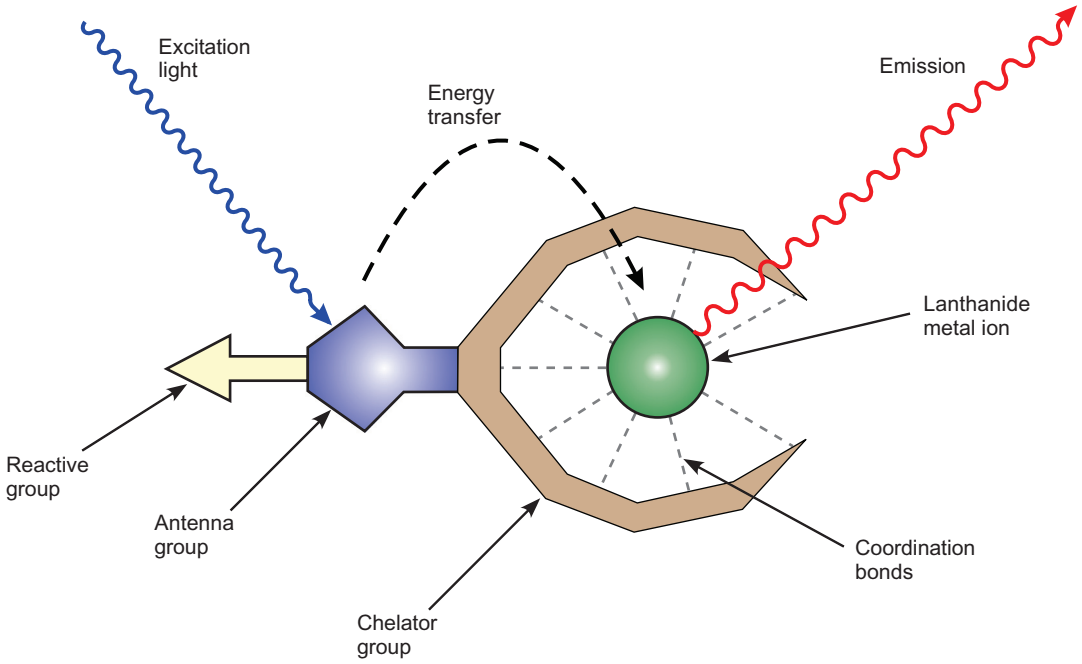

FIGURE 10.50 The principle of enhanced lanthanide luminescence using antenna–chelator compounds. The organic dye antenna group absorbs energy and transfers it to the lanthanide metal ion coordinated within the chelate structure. The best chelating groups fully coordinate the metal and protect it from the quenching effects of water. The lanthanide atom then emits light at a longer wavelength, which is characteristic of the lanthanide metal. Lanthanide chelates also contain a reactive group that can be used to attach covalently the label to targeting molecules.

Different lanthanide metals also produce different emission spectrums and different intensities of luminescence at their emission maximums. Therefore, the relative sensitivity of time-resolved fluorescence also is dependent on the particular lanthanide element complexed in the chelate. The most popular metals along with the order of brightness for lanthanide chelate fluorescence are europium(III) > terbium(III) > samarium (III) > dysprosium(III). For instance, Huhtinen *et al.* (2005) found that lanthanide chelate nanoparticles used in the detection of human prostate antigen produced relative signals for detection using europium, terbium, samarium, and dysprosium of approximately 1.0:0.67:0.16:0.01, respectively. The emission wavelength for each of these lanthanides is also different. Terbium has a main peak of luminescence in the range of 545 nm, dysprosium at about 575 nm, europium at about 615 nm, and samarium at approximately 645 nm (although there are other emission bands for all of these lanthanide metals as well).

In assays, europium chelates usually produce the greatest sensitivity in an assay, followed closely by terbium chelates. Another advantage of europium is that it has the longest fluorescent lifetime of all the lanthanides, making it the best choice for time-resolved applications. For these reasons, most applications of lanthanide fluorescence use europium or terbium chelates to modify biological molecules, as they provide the brightest conjugates achievable when using this technology.

Another advantage of lanthanide chelates is their lack of self-quenching effects. Since the excitation and emission peaks do not overlap for a given lanthanide metal, the chelates do not quench each other if modified at high density on other molecules or immobilized close together on surfaces or particles. Therefore, creating complexes having multiple lanthanide chelating groups is a strategy that can dramatically increase the total fluorescence of a detection conjugate. This property differs from organic fluorescent reagents, as dyes usually start to quench if as few as six to eight fluorescent labels modify a single protein. By contrast, it is possible to form polymer or particle labels containing dozens, hundreds, or even thousands of lanthanide chelating groups, which are capable of increasing the fluorescent signal in assays equal to the sum of the total number of groups present. Using this approach, Huhtinen *et al.* (2005) created nanoparticle labels containing hundreds of fluorescent lanthanides. Similarly, Scorilas (2000) created polyvinylamine polymer chains with multiple europium chelates and also added biotin labels to form huge complexes with streptavidin in solution. Such reagents dramatically increase the lanthanide luminescence signal in immunoassays or other detection applications beyond that possible with standard organic fluors.

Lanthanide chelates also can be used in fluorescence resonance energy transfer (FRET) applications with other fluorescent probes and labels (Figure 10.51).

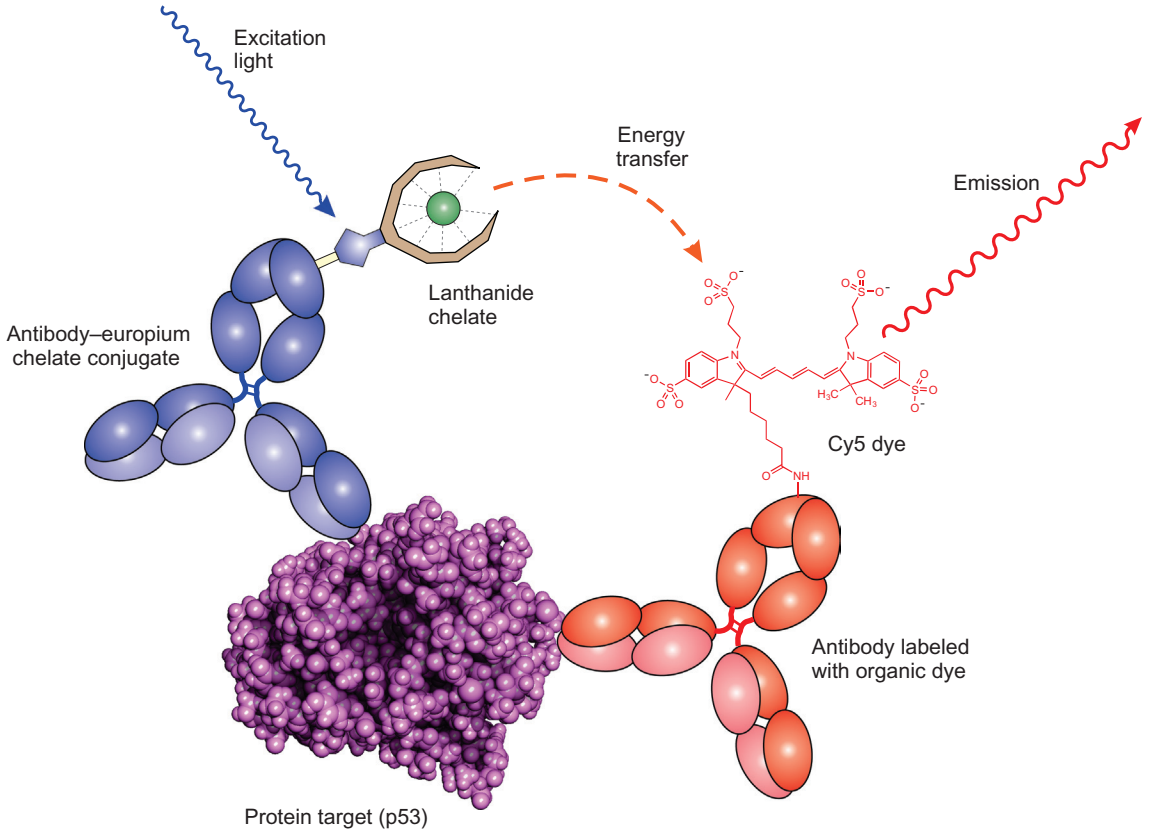

FIGURE 10.51 Time-resolved FRET assay systems involve energy transfer between the lanthanide chelate and an organic dye (or a fluorescent phycobiliprotein) that are brought together as two labeled molecules bind to an analyte. In this illustration, an antibody labeled with a lanthanide chelate is used along with a Cy5-labeled antibody to detect a protein target in solution. Excitation of the lanthanide label results in energy transfer and excitation of the cyanine dye only if they are held within close enough proximity to allow efficient FRET to occur. Under these conditions, excitation of the lanthanide chelate results in cyanine dye emission, which will not occur if the labeled antibodies have not bound to a target.

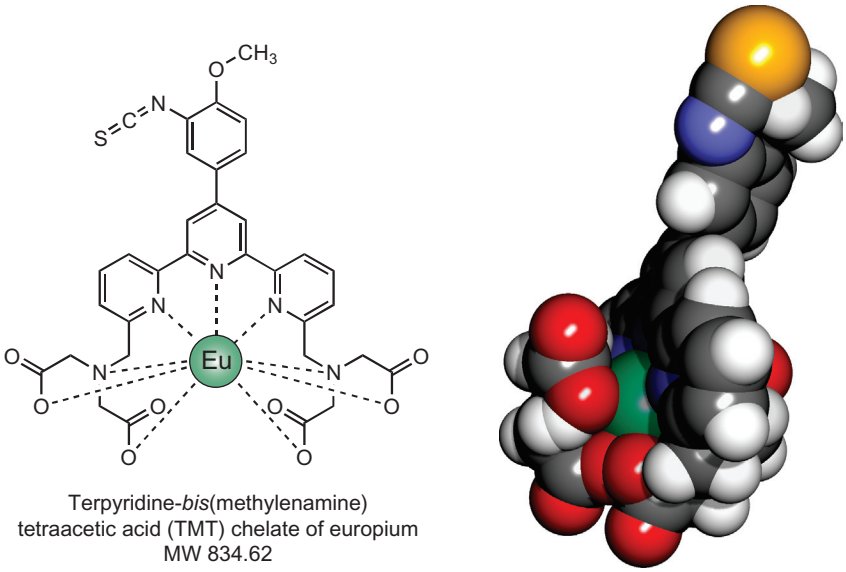
In this application, the time-resolved (TR) nature of lanthanide luminescent measurements can be combined with the ability to tune the emission characteristics through energy transfer to an organic fluor (Comley, 2006). TR-FRET, as it is called, is a powerful method to develop rapid assays with low background fluorescence and high sensitivity, which can equal the detection capability of enzyme assays (Selvin, 2000).

FRET signaling is limited by the distance requirements for energy transfer between fluorescent molecules. The donor molecule must be constrained within the immediate molecular vicinity of the acceptor fluorescent molecule. FRET systems can be described in terms of the Förster radius, which is the distance at which energy transfer efficiency is 50% (Förster, 1948; Lakowicz, 1999). For energy transfer between organic fluors, the Förster radius is usually no more than about 15 to 20 Å. This means that for FRET signaling to occur with high retention of fluorescence yield, the donor and acceptor molecules must be in extreme proximity, held much closer than the radius of the average globular protein.

Lanthanide chelates have distinct advantages in FRET systems, because their Förster radius can be on the order of 80 to 100 Å. This means that two biological molecules coming together in solution, one labeled with a donor lanthanide chelate and the other labeled with an acceptor organic fluor, usually are positioned close enough to undergo efficient energy transfer. Thus, lanthanide TR-FRET assays can be developed that are completely homogeneous in nature, taking advantage of both the long lifetime of fluorescence and the efficient energy transfer characteristics of a long Förster radius. For instance, an antibody labeled with a europium chelate can be used along with another antibody labeled with an organic fluorescent label able to absorb energy from the lanthanide. If both antibodies recognize different epitopes on a target antigen, then a solution-phase assay can be designed wherein the FRET signal is observed only if both antibodies are bound to the

antigen. The excess labeled antibodies in solution still will be free to diffuse throughout the sample and thus not be held in enough proximity to undergo energy transfer. The result is low background interference, even though excess fluor is not washed away.

To make a luminescence resonance energy transfer (LRET) system work, the proper choice of acceptor fluor must be made for the lanthanide chelate. The acceptor must have an excitation band corresponding to or overlapping an emission band of the lanthanide label, so that excitation energy may be transferred. Although energy transfer is never 100% efficient as would be evident by a complete disappearance of the lanthanide emission band, the efficiency can be high. To maximize the yield of fluorescence transfer, the acceptor should also be an efficient absorber with a high extinction coefficient and should have bright fluorescent properties (high QY) to ensure good signal in the final assay application. In this regard, one of the best acceptor molecules for lanthanide luminescence is the phycobiliprotein allophycocyanin (APC). APC often is paired with europium chelates to create LRET assays. The protein's multiple fluorescent bilin groups enhance its ability to receive energy transfer from the luminescence of the donor europium. In a europium–APC system, excitation in the UV range with subsequent energy transfer results in emission in the red region of the spectrum, giving an effective Stokes shift of over 300 nm. Combine the FRET signal with a time-gated measurement and the result is a highly sensitive assay with virtually no interference from other biological or organic molecule fluorescence.



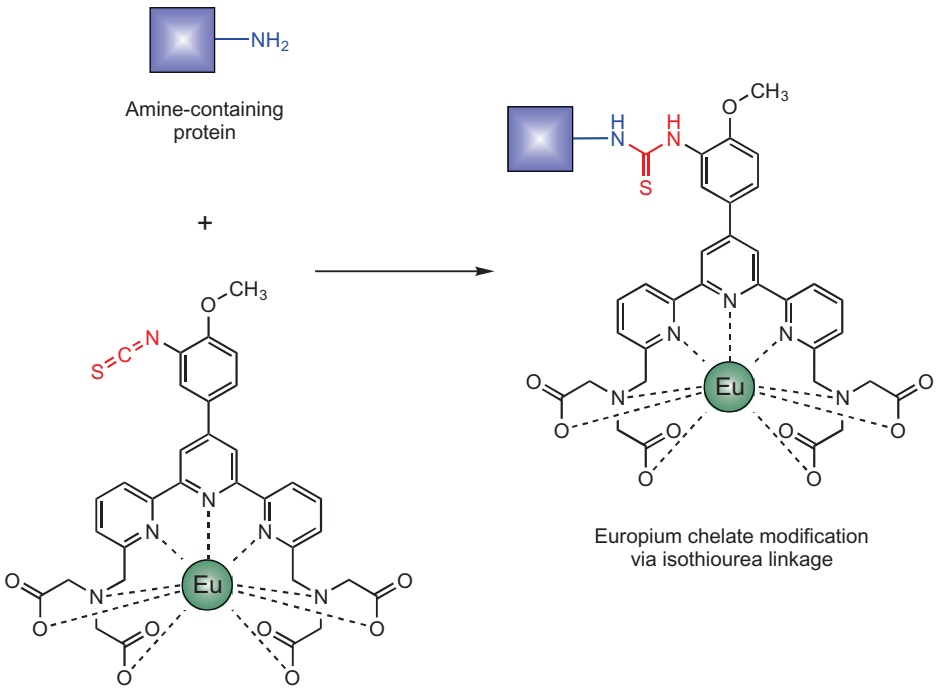
Organic fluorescent dyes with the appropriate spectral properties can also be paired with lanthanide chelates in FRET systems. For instance, many rhodamine dyes and the cyanine dye Cy5 have ideal excitation wavelengths for receiving energy from a nearby europium chelate. The LeadSeeker assay system from GE Healthcare incorporates various Cy5-labeled antibodies for developing specific analyte assays. In addition, when using a terbium chelate is used as the donor, a Cy3 fluorescent dye can be used in assays as the acceptor.

Antenna–chelator molecules for lanthanide luminescence typically have a reactive group to allow conjugation with targeting molecules to be useful for TR-FRET in biological applications. Some of the reactive groups that have been designed for polyaminocarboxylate chelates include the amine-reactive isothiocyanate derivatives (Li and Selvin, 1997), thiol-reactive maleimide groups, and pyridyl disulfide groups (Chen and Selvin, 1999). Alternatively, fluorescent lanthanide chelates can be embedded into nanoparticles at high density and form intensely bright particle-labeling agents for biomolecule detection (Ju *et al.*, 2011).

Two of the more common chelate structures are built from an EDTA or DTPA backbone (Chapter 12, Section 1). Depending on the method of antenna group addition, the DTPA chelate structure can have a maximum of eight coordination groups consisting of carboxylates and amines to hold the lanthanide atom. An EDTA chelating group can have up to six coordination groups per chelate molecule. The remaining coordination sites are taken up by water molecules in aqueous solution, which can potentially quench luminescence, because they are effective acceptors of excitation energy from the lanthanide. Both EDTA and DTPA chelating groups with antenna molecules do perform well in luminescent assays. However, it is better to have a chelating group that can coordinate with all or a majority of the nine coordination bonds on a lanthanide metal ion. This avoids the potential for quenching effects from other chelators in solution or from water itself. In this regard, reagents built from a DTPA chelating group are potentially better than those based on EDTA. For a review of stable lanthanide chelate constructs useful for luminescent assays, see Mathis and Basin (2011).

In some cases, the initial lanthanide chelating group may not have an antenna group built into its structure. One of the early commercial applications of europium luminescence in a TR-FRET-based assay system used an isothiocyanatophenyl–EDTA or an isothiocyanatophenyl–DTPA derivative to modify proteins (Delfia system from Wallac). This system uses an isothiocyanate chelate group to carry the lanthanide and attach it to antibodies and other molecules, but it does not have an antenna group. In an assay, this system requires the use of a secondary fluorescence enhancer to create the lanthanide fluorescence signal. This secondary reagent is typically β-naphthoyltrifluoroacetone, which when added in excess at the end of an assay extracts the lanthanide metal from the nonfluorescent chelate and forms another soluble chelate that is highly fluorescent.

More advanced designs incorporate efficient antenna groups directly into the chelating structure of the label. For instance, the terpyridine-*bis*(methylenamine) tetraacetic acid (TMT) chelator of europium developed by Toner *et al.* (1993) has multiple pyridine rings and two iminodiacetic acid groups on each side to create a chelator having nine coordination sites. The pyridine groups provide the antenna structure and also supply nitrogen atoms with unshared pairs of electrons to coordinate with the lanthanide metal ion. The result is a protected lanthanide that cannot be quenched easily by water or other matrix components. Complexed with europium, this label can be excited at 340 nm and provide sharp emission peaks at wavelengths of 589, 599, 618 (maximum emission), 623, 651, 689, 697, and 702 nm. The largest peaks in the >600 nm range can optimally excite Cy5 dyes, such as the hydrophilic DyLight 649 (Section 8), and create an effective TR-FRET system for homogeneous assay design.



Terpyridine-*bis*(methylenamine) tetraacetic acid (TMT) chelate of europium
MW 834.62

The TMT chelator containing an amine-reactive isothiocyanate group can be used to label antibodies, proteins, or other molecules using the following protocol (Figure 10.52).

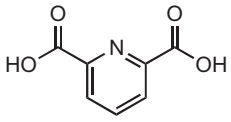
Protocol

1. In a fume hood, dissolve the TMT chelator in a 1:1 mixture of DMF:DMSO at a concentration of 10 mg/ml.
2. Dissolve a protein to be labeled in 0.1-*M* sodium bicarbonate, pH 9.0, at a concentration of 1 to 10 mg/ml.
3. With mixing, add a quantity of the TMT chelator to the protein solution to provide a 5- to 10-fold molar excess of reagent. Optimization may have to be done to determine the best ratio of chelator to protein for the intended application.
4. React at 4°C overnight with gentle mixing.
5. Purify the labeled protein by gel filtration or dialysis.

Activated TMT europium chelate

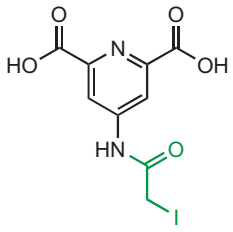
Europium chelate modification via isothiourea linkage

FIGURE 10.52 The isothiocyanate group of a TMT europium chelate can be used to label amine-containing proteins and other molecules to result in an isothiourea bond.



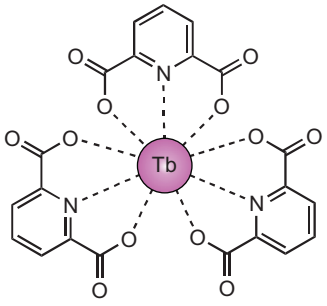
As in the structure of the TMT chelator group, pyridine derivatives have long been known to be enhancers of lanthanide luminescence (Thomas *et al.*, 1978). One such compound, dipicolinic acid (DPA), contains two carboxylates on both sides of a pyridine core, providing three coordination sites per molecule to complex with lanthanides. In solution, three DPA molecules can coordinate with one lanthanide ion to fully surround the metal and protect it from quenching by water or other molecules. Each DPA pyridine group can absorb energy in the UV region and transfer it to the central lanthanide, which results in strong emission at characteristic wavelengths.

Lamture and Wensel (1995) synthesized a unique modification of the basic DPA structure to make the chelator bifunctional and thus able to react with functional groups on other molecules. This reactive DPA reagent, 4-(iodoacetamido)-2,6-dimethylpyridine dicarboxylate, contains an iodoacetyl group on the C4 of the pyridine ring, thus making it particularly reactive with thiol groups and amines at higher pH. This derivative was used to create a large polymeric chelating structure from poly-L-lysine that contained 50 to 100 DPA units along its length. Loading this complex with Tb(III) ions resulted in highly intense luminescence. The remaining amines on poly-L-lysine finally were succinylated to create carboxylates for coupling to proteins via carbodiimide conjugation. Figure 10.53 shows DPA and iodoacetyl-DPA derivatives; Figure 10.54 shows the DPA-poly-L-lysine derivative succinylated.



Another antenna group that is particularly effective for lanthanide luminescence is the carbostyril derivatives (7-amino-4-methyl-2(1H)-quinolinone), which can be attached to many chelating compounds *via* amide bond formation with the 7-amino group to a carboxylate (Figure 10.55) (Hemmila and Laitala, 2011). A carbostyril–DTPA derivative has intense luminescence for use in TR-FRET-based assays for drug discovery. The 7-aminoquinolinone structure is a common choice for designing fluorescent lanthanide chelates (Soini and Lövgren, 1987; Sammes and Yanhioglu, 1996; Selvin, 2002; Selvin, 2003). The synthesis of various carbostyril derivatives is described in Ge and Selvin (2004). The 7-aminoquinolinone group first is put onto DTPA by reaction with one of the chelator's anhydride rings. Linking the chelator to proteins or other molecules is done through the anhydride on the opposite end by forming an amide-linked spacer arm. In some cases, sulfonate groups or other hydrophilic components on the carbostyril structure can provide increased hydrophilicity for modifying biomolecules.

When used with europium or terbium ions, a carbostyril-based lanthanide chelate can be excited at 340 nm and provide sharp characteristic emission bands for transfer of energy to the appropriate acceptor fluor. Similar to the TMT chelator described previously, luminescence from terbium FRET signals well with Cy3 dyes, and luminescence from europium can be used with APC or Cy5 dyes. Other fluorescent dyes that have similar excitation and emission ranges to these can also be used as acceptors in TR-FRET assays. For instance, terbium chelates can be used with fluorescein and tetramethyl rhodamine dyes, if the appropriate filters are used for measuring emission.



The potential for creating an expressed protein time-resolved luminescence system was realized in the

development of a novel lanthanide chelating complex derived from a metal-binding peptide sequence. This sequence, called a lanthanide binding tag (LBT), can be used as a fusion tag in recombinant protein expression (Franz *et al.*, 2003; Nitz *et al.*, 2003; Wöhnert *et al.*, 2003; Lim and Franklin, 2004; Goda *et al.*, 2007). To create this luminescent tag, a peptide sequence of about 15 to 20 amino acids representing the basic structural domain of a calcium-binding loop from calmodulin was mutated to tightly coordinate a terbium ion. Luminescence occurs through excitation in the UV of a nearby tryptophan residue with energy transfer to the chelated lanthanide. Recombinant mutagenesis of the original calcium-binding domain resulted in optimizing the dissociation constant for terbium to within the nanomolar range, thus the metal ion is tightly associated with the peptide tag (Martin *et al.*, 2005). Recombinant proteins containing this small fusion tag can be detected using time-resolved fluorescence techniques. Such *in vivo* expression of a luminescent lanthanide tag can be used to study protein interactions using LRET or track individual proteins within cells (Sculimbrene and Imperiali, 2006).

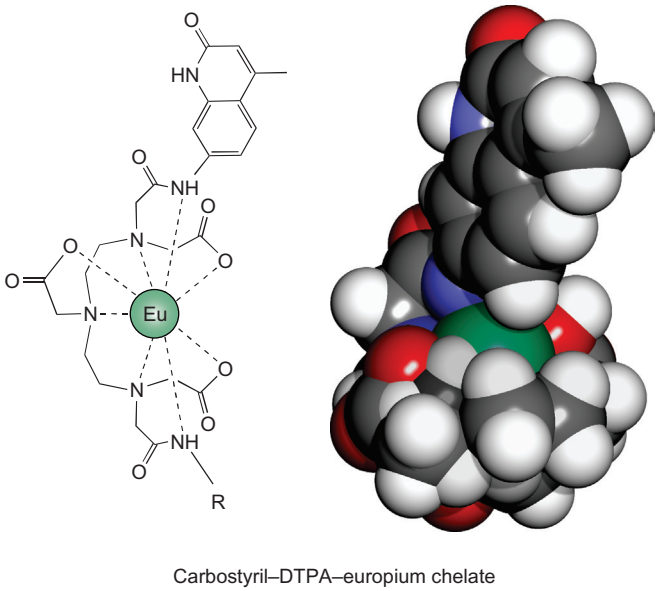

FIGURE 10.55 A carbostyril–DTPA–europium chelator is a strong enhancer of lanthanide luminescence. The chemical structure and three-dimensional structure of the chelator are shown. The metal ion is well protected at the center of the coordinating groups of the chelator.

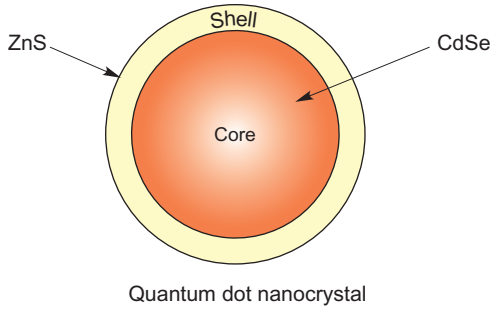

FIGURE 10.56 The structure of a typical QD nanocrystal includes a semiconductor alloy core surrounded by a shell consisting of a different alloy structure. Early QD compositions involved the use of a CdSe core capped with a ZnS shell, but many different alloy compositions have been used and are possible.

10. QUANTUM DOT NANOCRYSTALS

10.1. Properties of Quantum Dots

Quantum dots (QDs) are nanoparticles typically made of a semiconductor metal alloy arranged in a spherical crystalline core and capped with a shell consisting of a second metal alloy composition (Figure 10.56). The size of this raw core/shell construct is usually less than 10 nm in diameter or about the same size as many globular protein molecules. Upon exposure to light at the appropriate wavelength range, QDs are able to absorb a photon of energy, which results in the excitation of an electron within the core. The excited electron is confined within the nanocrystal, because its core diameter is less than the exciton Bohr radius, which thus leads to quantum confinement. The shell structure aids in this confinement and prevents the electron from tunneling out of the core and escaping into the outer medium or undergoing non-radiative deactivation. The size and shape of a QD govern the discrete energy levels that the excited state electron can attain within it, thus dots can be tuned to have desired electronic properties by careful adjustment of core diameter and composition. Upon return of the electron to its ground state, a radiative QD emits a photon of light, the wavelength of which is dependent on the alloy material type and its diameter (Alivisatos, 1996). QD size *versus* fluorescence is shown in Figure 10.57.

As a result of their unique optical and electronic properties, particularly their ability to fluoresce at discrete wavelengths directly proportional to their sizes and material compositions, QDs have found use in many fields, including electronics, biology, medicine, and even cosmetics. The first attempts to modify their surface characteristics to make them water soluble and biocompatible eventually led to their use as fluorescent labels for biomolecules in many applications (Rogach *et al.*, 1996; Bruchez *et al.*, 1998; Chan and Nie, 1998).

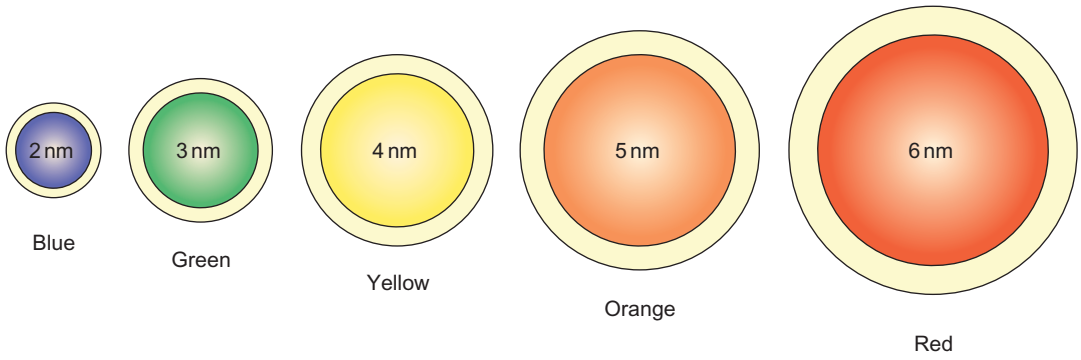

FIGURE 10.57 The size of a QD directly affects its emission wavelength. Careful control of nanocrystal diameter during the manufacturing process can result in discrete QD populations having emission properties ranging from the blue to the red region of the visible spectrum.

QDs have a number of advantages over other fluorescent molecules such as organic dyes, including: (1) resistance to photobleaching, which allows them to be imaged over long periods without loss of fluorescence; (2) narrow, nearly symmetrical emission peaks with no red-shift tail typical of organic fluors, thus creating a bright fluorescence signal at characteristic wavelengths (3) a broad absorbance band, which increases almost exponentially toward shorter wavelengths with extremely high extinction coefficients (10^5–$10^7\,M^{-1}\,cm^{-1}$); (4) the ability to excite at a single wavelength an entire family of QDs having different emission characteristics, thus providing multiplexed assay capability; (5) the capacity to design QDs with emission characteristics ranging from the low visible wavelengths to well within the IR region; and (6) the potential for relatively high quantum yields of fluorescence (0.65–0.95 for CdSe).

The emission properties of QDs can be adjusted based upon core diameter and nanoparticle composition. Nanoparticle diameters are typically carefully controlled during manufacture to be between 2 and 10 nm. In addition, the band-gap energy or energy of fluorescence emission is inversely proportional to the diameter of the QD particle. Thus, the smaller the particle, the more blue-shifted is its emission; the larger the QD, the more red-shifted is its emission bands. QDs also have an intrinsic color to their solutions that corresponds to the size of the particles and their fluorescence emission characteristics. However, to create a single particle population with a tight fluorescence emission pattern, the diameter of the particles must be controlled to well within a nanometer. The emission peak width is directly proportional to the size distribution of a particle population. This makes manufacturing reproducible QDs a constant challenge for most suppliers that rely on size to control fluorescence properties.

However, as opposed to the difficulty of tuning emission properties by particle diameter, QD alloy composition instead may be adjusted independent of size to control the wavelength of emission for a given particle population. In a QD having a concentration gradient composition, the concentration of an alloy of a first semiconductor gradually increases from the core to the surface of the particle, while the concentration of a second semiconductor gradually decreases from the core to the surface (Nie and Bailey, 2007). A third semiconductor type also may be added to further fine tune the emission properties. By careful adjustment of these semiconductor concentration gradients, QD populations can be made having discrete emission properties without changing the particle size. Therefore, tuning QD spectral characteristics can be done using a single particle size and by making selective changes to the alloy composition. This avoids the difficulty in manufacturing particles of uniform size, because all particle populations can have the same size but only vary in their relative semiconductor gradient concentrations to attain particles having discrete fluorescence character.

The material types making up the core of a quantum dot also affect the range of emission wavelengths that can be attained. For common material types, the ranges of emission wavelengths that can be achieved by adjustment of particle diameter or composition are: CdSe = ~470–660 nm, CdTe = ~520–750; InP = ~620–720 nm; PbS > 900 nm; and PbSe > 1000 nm.

Quantum dots have been made using a number of techniques. A common method to make bulk quantities of particles involves carrying out colloidal suspension synthesis in organic solvent with nucleation of semiconductor metals under high-temperature conditions (Murray *et al.*, 1993; Hines and Guyot-Sionnest, 1996; Dabbousi *et al.*, 1997). In one such process, a solvent such as octadecene is stirred at constant rate and heated to >300°C at which point solutions containing the semiconductor metals are injected. The metals at first decompose under high heat and then recombine to form alloys consisting of nanoparticle seeds, which grow to create the QDs. The reaction time determines the size of the nanoparticles and thus their spectral properties. Detergent molecules are often added to coat the resulting nanoparticles and prevent their aggregation during nucleation. Originally, the solvent and detergent molecule used for making QDs was TOPO (tri-*n*-octylphosphine oxide), which ends up coating the particles with the phosphine component interacting with the semiconductor surface and the alkyl chains pointing out into the organic solution (Figure 10.58). Other additives, such as stearic or oleic acid, function similarly. The raw particles thus prepared are hydrophobic and not dispersible in aqueous solution.

To use QDs in biological applications, the particles must be rendered biocompatible by coating with a hydrophilic layer that masks the surface, thus preventing aggregation and nonspecific binding. This is not a trivial problem, as the successful commercialization of QDs for biomolecule labeling took at least 5 years from the time the first two papers appeared in *Science* describing water soluble particles for bioconjugation (Bruchez *et al.*, 1998; Chan and Nie, 1998). The fact is, these early particles were not very soluble in aqueous environments and tended to clump together or bind nonspecifically with biomolecules.

The initial modifications carried out to covalently link molecules to QDs need to displace the TOPO or detergent coating on the raw nanocrystal surface with a new organic derivative imparting water solubility. The first attempts at making biocompatible QDs all involved the use of simple monothioacids, such as mercaptoacetic acid (thioglycolic acid), which can link to the shell through thiol dative bonding and provide a terminal

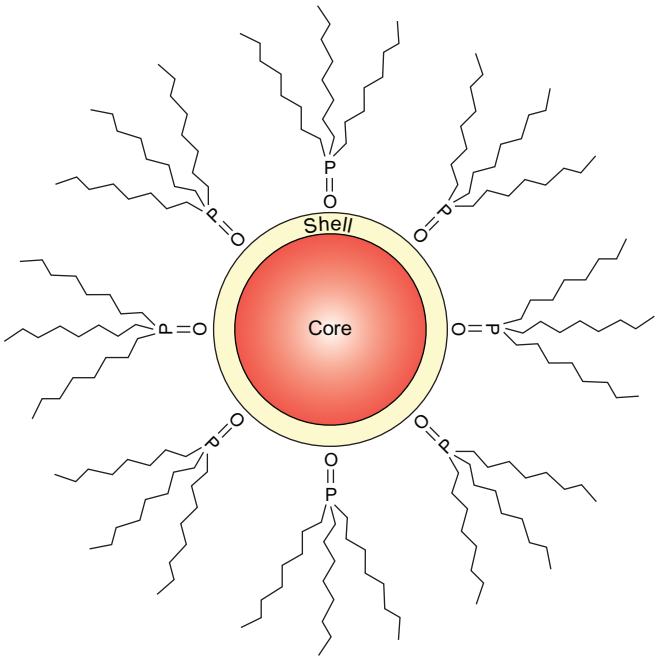

FIGURE 10.58 QDs made using the TOPO process typically have a layer of these molecules associated with their outer surface. The TOPO groups must be displaced and replaced by water soluble groups to provide biocompatibility for bioconjugation purposes.

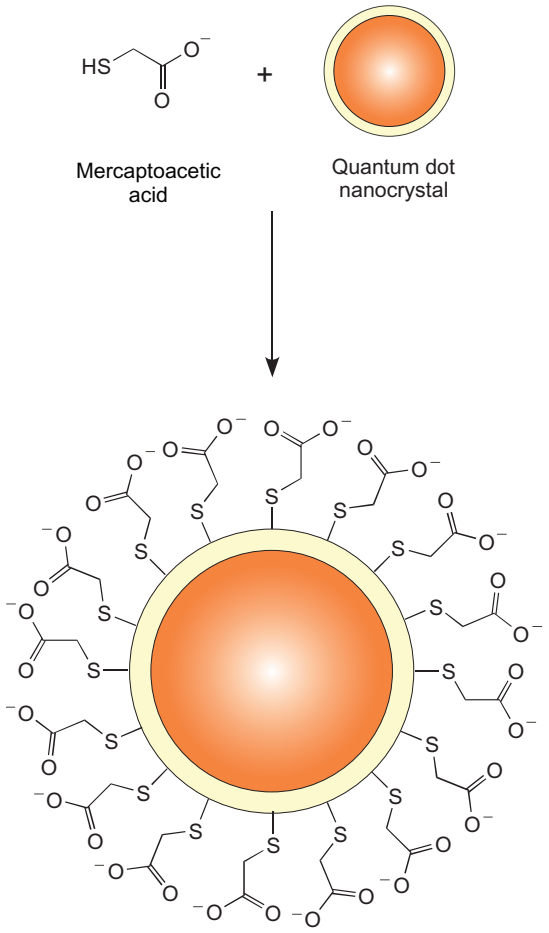

FIGURE 10.59 One of the first methods of preparing water-soluble QDs was to use mercaptoacetic acid modification of the nanocrystal surface. This resulted in a negative charge on the surface of each dot that provided like-charge repulsion of particles suspended in aqueous solution. The carboxylate group also could be used for conjugation with amine-containing molecules.

carboxylate for further conjugation (Figure 10.59). However, monothiol linkers can easily oxidize back off QDs and leave behind surface gaps, which become hydrophobic sites for particle clumping and nonspecific binding to biomolecules. A better approach is to use a dithiol compound, which forms two dative bonds per linker on the QD surface. This makes the linkage to the QD resistant to oxidation and prevents nonspecific surface gaps from forming. One such dithiol compound that is particularly useful is dihydrolipoic acid (DHLA), which contains a carboxylate group on the other end. QDs modified with DHLA can subsequently be modified with PEG groups to provide increased hydrophilicity of the surface or directly linked to proteins *via* electrostatic interactions or through an EDC-mediated reaction (Mattoussi *et al.*, 2000; Uyeda *et al.*, 2003; Medintz *et al.*, 2004; Anikeeva *et al.*, 2006; Clapp *et al.*, 2006). The functionalization of nanoparticles for bioimaging applications has been reviewed (Erathodiyil and Ying, 2011).

The negative charge character of DHLA-modified QDs has been used to link noncovalently positively charged proteins, such as avidin (Goldman *et al.*, 2002) or a recombinant protein containing a positively charged fusion peptide. In this regard, the highly positive leucine zipper peptide has been used as a fusion tag (Goldman *et al.*, 2002) as well as a penta-histidine peptide tag (Medintz *et al.*, 2003). Combinations of positively charged fusion proteins and avidin have also been used to control the resultant biotin-binding density on a DHLA-QD surface for use in live cell imaging (Jaiswal *et al.*, 2004).

One major advantage of DHLA modification is that the diameter of the QD remains as small as possible, while still creating a water soluble particle. QDs of <10-nm diameter have been created using this process and were successfully used to image intracellular proteins (Jaiswal *et al.*, 2003). The methods involved in conjugation of DHLA-QDs with peptides, proteins, and DNA have been reviewed (Prasuhn *et al.*, 2011).

Another type of simple surface modification involves noncovalent coating of the QDs with detergents or lipids. The hydrophobic tails of these molecules bind to the QD particle, while the hydrophilic portions interact with the aqueous phase and render the dots dispersible. Still other surface modification schemes use polymeric coatings containing multiple binding points

to the QD, thus eliminating the possibility for leaching. Coatings containing PEG spacers can also be used to create a highly hydrophilic layer on top of the semiconductor surface. All of these modification strategies provide QDs that are water soluble (or dispersible and stable in suspension) and that contain functional groups for covalent attachment of proteins or other affinity molecules.

Masking the surface of semiconductor QD particles can also be done by adding another inorganic layer to the outer shell alloy structure. This layer can take the form of a silica coating formed by the reaction of a silane derivative with the shell (Darbandi and Nann, 2005). For instance, a pure silica surface can be created by controlled polymerization of the raw nanocrystals with tetraethyl orthosilicate (TEOS), which forms a siliceous sphere with silanol groups on the outer surface. Another organosilane derivative that is appropriate for use with metallic particles is mercaptopropyl-tris-hydroxy-silane. The thiol groups on the silane compounds datively bind to the surface while the hydroxy-silane groups polymerize to form a new silica coating. The resultant silanol-containing surface can then be functionalized using other organosilane compounds containing functional groups or reactive groups for further conjugation with biomolecules (see Chapter 13 for organosilane reagents and protocols). The only disadvantage of this approach is the increasingly greater particle diameter that results from building successive layers on the initial QD core, which may inhibit their use for probing within cells or tissues (Figure 10.60).

Water soluble QDs are now available from a number of manufacturers (Invitrogen, Evident Technologies, and Crystalplex). Each supplier uses their own proprietary methods of surface pacification to create biocompatible particles. Even coated quantum dot clusters are available that contain hundreds of particles bound together in a polymer matrix (Crystalplex). These form intensely bright labels for biomolecules, because the nanocrystals do not quench when clustered together at high density.

Most QD surfaces for biological applications contain negatively charged carboxylates for conjugation with amine-containing molecules *via* a carbodiimide reaction with EDC and (sulfo)NHS (Chapter 4, Section 1). The negative charges on the QD surface prevent particle aggregation through like-charge repulsion. An alternative method of creating water-dispersible dots is to form a hydrophilic coating that carries along with it a layer of hydration consisting of hydrogen-bonded water molecules. This often is done using hydroxylic polymers or PEG modifications. This too prevents aggregation due to the high energy needed to remove the bound water layer.

QDs have been used successfully in many biological applications that exploit their best properties of brightness, photostability, and multiplex capability. There are many publications that use QDs for in-cell or whole-organism-based imaging, including tracking of targets within cells (Dahan *et al.*, 2003), gene localization within chromosomes (Xiao and Barker, 2004), embryo developmental monitoring (Dubertret *et al.*, 2002), tumor imaging *in vivo* (Gao *et al.*, 2004), and multiplexed imaging and assays (Medintz *et al.*, 2003; Wu *et al.*, 2003), including FRET signaling (Han *et al.*, 2001). For a review on the use of QDs for cancer imaging and treatment, see Cassette *et al.* (2012) and Vashist *et al.* (2006).

However, QD labels still are not without potential problems. Although the raw dots typically are less than 10 nm in diameter, the addition of thick surface layers for biocompatibility and conjugation can increase the hydrodynamic radius considerably. Most particles with polymer coatings are in the 20- to 50-nm range in diameter, which often limits their use for cell-based detection due to their inability to easily penetrate cells and diffuse freely to intracellular targets. Most cell imaging applications with this type of QD involve cell surface staining or transport within cells by endocytosis, which limits particle access to other areas within the cell. In addition, nonspecific binding still plagues some QD probes when used with complex biological samples.

Another potential deficiency of QDs is the toxic nature of their metallic composition. Most particles contain at least one known toxic metal (e.g., cadmium) or contain alloys with unknown toxilogical properties. Cadmium-based QDs exposed to UV light for long periods release cadmium ions, which are highly toxic to cells (Derfus *et al.*, 2004). The initial proposal that QDs would be ideal as fluorescent probes for *in vivo* diagnostic imaging may not be fully realized due to the potential for heavy metal toxicity in humans. Even the use of QDs for *in vitro* research purposes must be carried out with care, as the solutions should be regarded as hazardous waste and disposed of according to standards for handling heavy-metal-contaminated solutions.

Another potential difficulty with using quantum dots relates to their special spectral characteristics. Excitation of QDs optimally occurs in the low region of the spectrum, typically below 400 nm, while emission usually is measured in regions that can be hundreds of nanometers away from the excitation wavelength. Unfortunately, many instruments for imaging or fluorimetry still do not contain lasers and filter sets that exactly match QD excitation and emission patterns. Most instruments in use today were initially designed for organic fluors with matched filter sets for such common dye derivatives as fluorescein, rhodamine, and the cyanine dyes. Using QDs with these instruments may mean exciting at a non-optimal, higher wavelength than is recommended to obtain full brightness.

However, the most important issue with quantum dot fluorescence is their tendency to blink or to be

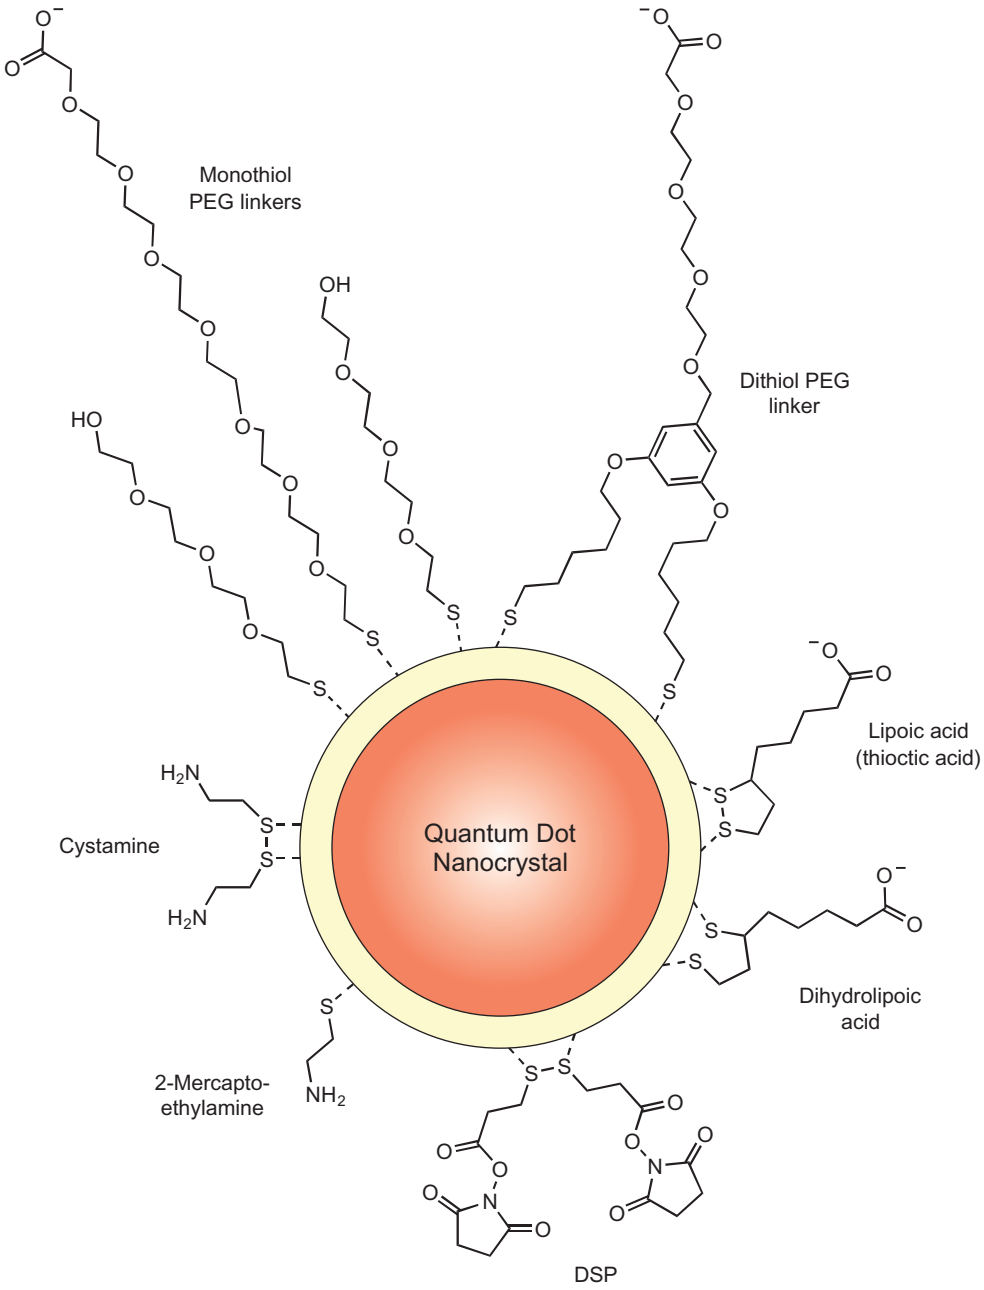

FIGURE 10.60 Many different thiol-containing linkers can be used to prepare water soluble QDs. The monothiol compounds suffer from the deficiency of being easily oxidized or displaced off the surface, thus creating holes for potential nonspecific binding. The dithiol linkers are superior in this regard, as they form highly stable dative bonds with the semiconductor metal surface that do not get displaced. The PEG-based linkers are especially effective at creating a biocompatible surface for conjugation with biomolecules.

completely dark and not fluoresce at all. Individual QDs can undergo an on/off cycle that results in a dark period of no light emission after a photon has been emitted (Nirmal *et al.*, 1996; Efros and Rosen, 1997). This blinking can be observed with a frequency on the order of milliseconds and can be problematic when imaging at the single-dot resolution or if using QDs for flow cytometry purposes is important. When imaging a larger population of QDs, the problem of blinking will be overcome by the fact that at any given moment many of the particles will be emitting light and thus contributing to the overall signal. Blinking will lower the apparent quantum yield for the combined QD population, but it will not eliminate signal entirely. In addition, certain solution additives used at relatively high concentration (i.e., 100-m*M* DTT or 2-mercaptoethanol) may serve to limit the blinking phenomena (Hohng and Ha, 2004).

A more severe issue with QDs, however, is the problem of dark or nonradiant dots in aqueous solution. Yao *et al.* (2005) documented that a significant fraction of commercially available QD particles in a population can be entirely dark. The nonradiant properties are probably due to defects in their nanocrystalline structure that occurred during manufacture. The percentage of dark dots varies for each sample, but they can represent 44 to 47% of all dots in a population. Thus, the use of QD conjugates for biomolecule imaging may mean that nearly half of all particles in an assay do not contribute to the resultant fluorescence signal.

10.2. Conjugation to Quantum Dots

Many antibodies, proteins, and other targeting or affinity ligands have been conjugated to QDs for biological applications. Antibodies to tumor markers have been used to image cancer cells *in vivo* (Tada *et al.*, 2007), fluoroimmunoassays have been developed using antibody-conjugated QDs (Goldman *et al.*, 2005; Tian *et al.*, 2012), peptide–QD conjugates have been made to target proteins *in vivo* (Ness *et al.*, 2003), antibody–QD conjugates containing tumor toxic agents have been designed to image and kill tumor cells (Gao *et al.*, 2004; Tavares *et al.*, 2011; Pöselt *et al.*, 2012), and sugar-QD conjugates have been made to detect carbohydrate binding proteins (Babu *et al.*, 2007).

The conjugation of proteins and other molecules to QDs involves standard coupling reactions with the added caveat related to the potential difficulties of working with particles. Many of the coupling strategies described in Chapter 14 for dealing with nanoparticles and microparticles are valid for use with QDs, but it is best when using commercially available particles to pay close attention to the manufacturer's suggested protocols.

When designing a protein–QD conjugate, it is also important to consider the optimal number of proteins to be coupled per particle. In some applications, a low ratio of protein-to-QD may result in the highest signal for fluorescence detection. This is often the case for antibody–QD conjugates where two to three antibodies coupled per particle are sufficient to target antigens. However, other applications may require a high density of protein on the QD surface. For instance, as a result of investigations into the interaction of CD8 with HLA A2 complexes, it was found to be important to create multiple contacts between the HLA molecules and the CD8 molecules on cell surface membranes. Therefore, up to 12 HLA A2 complexes per QD were coupled (the maximal possible to fit on the particle surface) to ensure the greatest interaction potential with cells (Anikeeva *et al.*, 2006). Additionally, when preparing (strept)avidin–QD conjugates, it may be desirable to maximize the biotin-binding ability of the complex to interact with as many biotinylated molecules as possible. Commercial streptavidin–QD conjugates typically have at least 5 to 10 proteins coupled per particle. Since each QD conjugate will have its own unique use, the conjugation process should be optimized to perform best in its intended application.

As is the case with most nanoparticles, buffer and salt compatibility should be taken into account when working with QDs. Small charged particles maintain colloidal stability by like-charge repulsion, which prevents aggregation by van der Waals or hydrophobic attraction. Any salt or buffer constituents that neutralize or eliminate the surface charge on the QDs will cause clumping or precipitation. Some buffer additives will also cause loss of fluorescence intensity and should be avoided in concentrations above a certain level. Consult the supplier's guidelines for buffer suggestions to maintain particle stability.

The following methods are based on those cited in the literature or in company instruction manuals for coupling molecules to fluorescent nanoparticles. The coupling of unique proteins or other molecules to QD surfaces may need further optimization of reactant ratios as well as time and temperature to obtain the best conjugates.

10.3. Conjugation of Proteins to Quantum Dots using EDC

Carbodiimide coupling to carboxylate-containing QDs usually involves the use of EDC in a single-step or two-step process to form an amide bond. If a one-step reaction is done, the QD is activated with EDC in the presence of an amine-containing molecule, such as a protein. Many protocols use this method, but it can result in protein polymerization in addition to coupling, because proteins contain both carboxylates and amines. A two-step protocol results in better control of the reaction (Figure 10.61). In the first step, EDC is used in the presence of sulfo-NHS to activate the carboxylates on the particles to intermediate sulfo-NHS esters. After a quick separation step to remove excess reactants, the activated QDs are added to the protein solution to be coupled. This then results in amide bond formation without polymerization of the protein in solution. See Chapter 4, Section 1, and Chapter 14, Section 4.2, for additional information on this process.

The following protocol describes the coupling of amine-containing proteins to carboxylated QDs using a single-step EDC reaction, as recommended by several manufacturers.

Protocol

1. Prepare a carboxylated QD solution in 10-m*M* sodium borate, pH 7.4 (reaction buffer), at a concentration of 1 µ*M*. The supplier of QDs usually will provide the reagent concentration as a molar

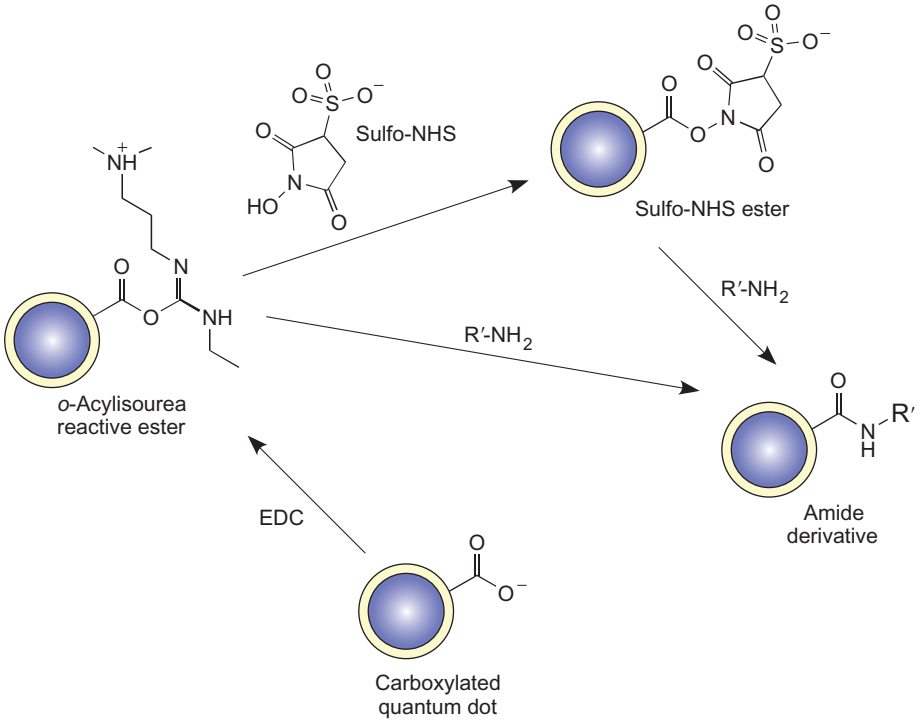

FIGURE 10.61 QDs containing carboxylate groups can be coupled to amine-containing proteins or other molecules using the EDC/sulfo-NHS reaction to form amide bond linkages. The intermediate sulfo-NHS ester is negatively charged and will help maintain particle stability due to like charge repulsion between particles.

quantity, which treats each particle as though it was a single molecule. A typical QD solution as obtained from a manufacturer may be about 8 µ*M* starting concentration.

2. Dissolve the protein to be conjugated to the QD in reaction buffer at a concentration of 1 to 10 mg/ml.
3. Add a quantity of the protein solution to the QD solution with mixing to obtain the desired molar excess of protein over the concentration of nanoparticles. Using a 1- to 20-fold molar excess typically works well, but optimization should be carried out to determine the best ratio for a particular application.
4. Prepare a solution of EDC in water at a concentration of 10 mg/ml. Immediately add 57 µl of this solution to the protein/QD solution. Mix well.
5. React for 2 h at room temperature with gentle mixing.
6. Filter the solution through a 0.2-µm filter (low protein binding type) to remove any precipitated protein or particles.
7. Separate excess protein from the protein–QD conjugate by use of ultrafiltration spin columns using an exclusion limit appropriate for allowing passage of the unconjugated protein, but retention of the protein–QD conjugate. For proteins of molecular weight below 100 kD, a membrane of this cutoff will work well.

QD nanoparticles containing carboxylate groups also may be reacted in a two-step EDC/sulfo-NHS reaction to couple proteins and other molecules containing both amines and carboxylates. This type of reaction is designed to remove excess EDC activating agent before addition of protein, so protein polymerization cannot occur.

Protocol

1. Prepare a QD solution in 25-m*M* PIPES buffer, pH 7.0 (reaction buffer), at a concentration of 100 µg/ml.
2. Prepare a protein solution in reaction buffer at a concentration of 1 mg/ml.
3. Prepare a solution of 20-m*M* EDC, 50-m*M* sulfo-NHS in water immediately before use.
4. To each milliliter of QD solution, add 50 µl of the EDC/sulfo-NHS stock solution. Maintain the pH at 7.0 by the addition of base, if necessary. Small volume reactions may be controlled using a pH stat.
5. React for 10 min at room temperature with gentle mixing.
6. Add 1.4 µl of 2-mercaptoethanol to each milliliter of the reaction mixture to quench excess EDC. Sonicate the QD solution several times to maintain particle dispersion.
7. Add 5 µl of the protein solution to each 100 µg quantity of activated QDs.

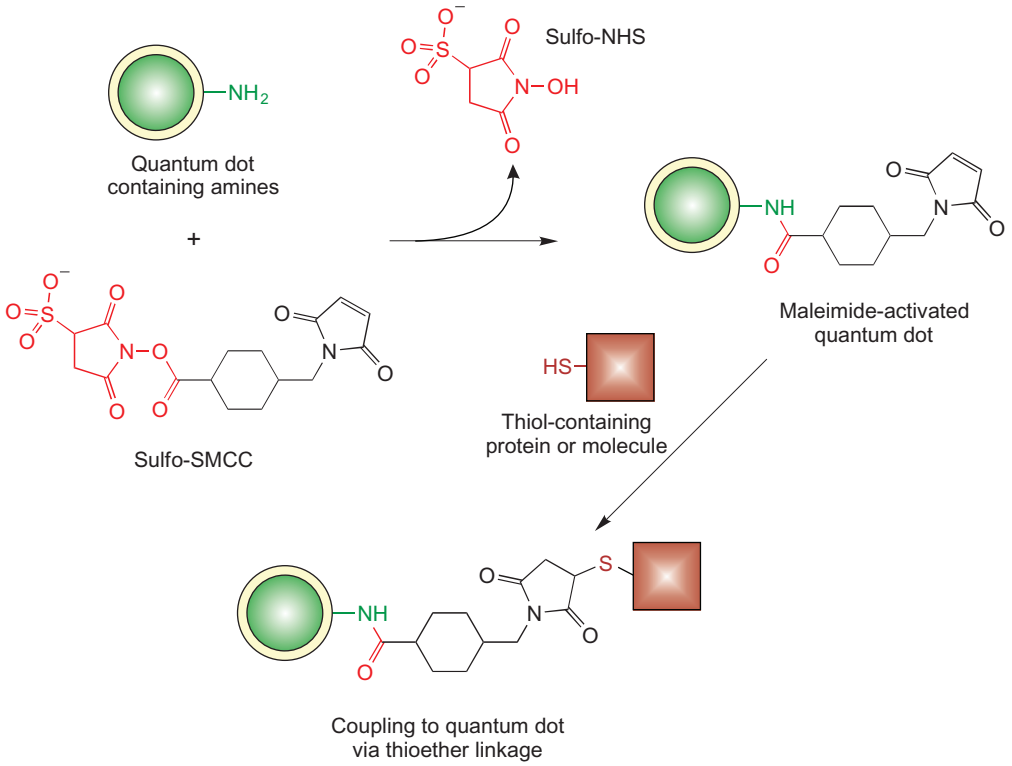

FIGURE 10.62 Sulfo-SMCC can be used to conjugate amine-containing QDs with thiol-containing proteins or other molecules using a two-step coupling procedure.

8. React for 60 min at room temperature with mixing.
9. Remove excess reactants and block remaining sulfo-NHS ester sites by dialysis against 50-m*M* Tris, pH 7.4. Use a membrane cutoff appropriate to allow passage of the protein being coupled, but retention of the protein–QD conjugate.

10.4. Conjugation to Quantum Dots Using Sulfo-SMCC

Sulfo-SMCC is a heterobifunctional crosslinking agent containing an amine-reactive NHS ester on one end and a thiol-reactive maleimide group on the other end (Chapter 6, Section 1.3). Amine-containing QDs may be activated with sulfo-SMCC to contain sulfhydryl-reactive maleimides for conjugation with thiol-containing proteins or other molecules (Figure 10.62).

An alternative to the use of an aliphatic crosslinker like sulfo-SMCC is to use a hydrophilic PEG-based one, which displays greater biocompatibility and lower nonspecific binding character. Particularly, the NHS–PEG$_n$–maleimide crosslinkers described in Chapter 18 may be a superior choice in designing QD conjugates of low background and high sensitivity for biomolecule-detection purposes.

The following protocol illustrates the process of activating an amine-containing QD with sulfo-SMCC and coupling a thiol-containing molecule in a second step.

Protocol

1. Prepare a 200-µl solution of amine-containing QDs at a concentration of 2.5 µ*M* in 50-m*M* sodium phosphate, pH 7.4 (reaction buffer). This represents 0.5 n*M* of QD in 200 µl buffer.
2. Add 1 mg of sulfo-SMCC to the QD solution with mixing to dissolve the crosslinker.
3. React for 60 min at room temperature with mixing.
4. Remove excess crosslinker and reaction by products by gel filtration on a desalting resin. The QD fraction is identified by its characteristic fluorescence. This operation should be done quickly to limit the degree of maleimide hydrolysis. The resulting particles contain reactive maleimide groups for coupling to a thiol-containing protein or other molecule.
5. Prepare a protein or antibody containing an available thiol group in reaction buffer at a concentration of 1 to 10 mg/ml. Add a quantity of this protein solution to the purified nanoparticle suspension to attain the desired molar excess of protein over the concentration of activated QDs. Typically, a 1- to 20-fold molar excess of protein over the QD concentration works well. The optimal amount of protein to be added should be determined experimentally by considering the best performance of the fluorescent conjugate in its intended application. Tada *et al.* (2007) created a monoclonal anti-HER2 antibody–QD conjugate at a

level of three antibodies per nanoparticle to target tumors in mice. Creating thiol groups on proteins or peptides may be done from disulfides by reduction. Alternatively, a thiolation reagent may be used to add thiols to the protein surface for coupling (see the protocols in Chapter 2, Section 4.1).

6. React with mixing for 2 h at room temperature. At the completion of the reaction, cysteine may be added at 50-m*M* to block excess maleimide reactive sites.
7. Purify the QD conjugate using gel filtration or ultrafiltration using a micro-spin device. The use of a molecular weight cutoff for gel filtration that will accommodate both the conjugate and the not-coupled protein is appropriate (e.g., Superdex-200 resin). For ultrafiltration, use a membrane cutoff that will retain the conjugate but permit the not-coupled protein to pass through.

CHAPTER

11

(Strept)avidin–Biotin Systems

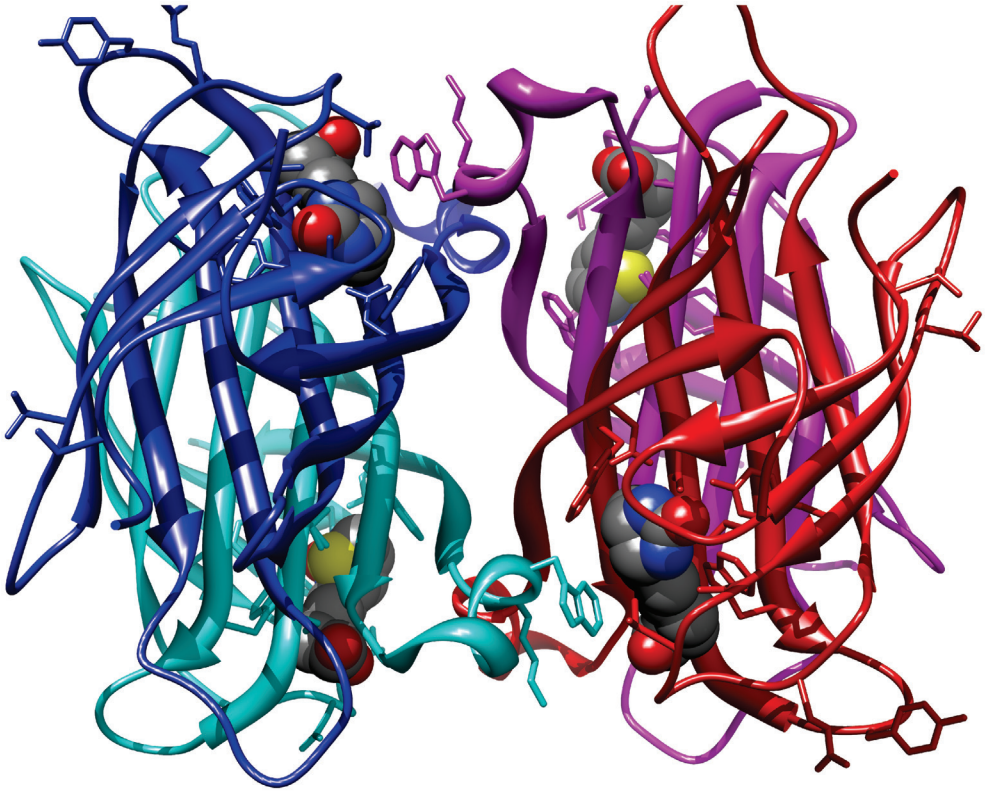
One of the most popular methods of noncovalent conjugation is to make use of the natural strong binding of (strept)avidin for the small molecule biotin. The strength of the (strept)avidin–biotin interaction has made it a useful tool in specific targeting applications and assay design. Since each (strept)avidin molecule contains a maximum of four biotin-binding sites, the interaction can be used to enhance the signal strength in immunoassay systems.

Modification reagents that can add a functional biotin group to proteins, nucleic acids, and other molecules now come in many shapes and reactivities (Section 6, this chapter, and Chapter 18, Section 1.3). Depending on the functionality present on the biotinylation compound, specific reactive groups on antibodies or other proteins may be modified to create a (strept)avidin binding site. Amines, carboxylates, sulfhydryls, and carbohydrate groups can be specifically targeted for biotinylation through the appropriate choice of biotin derivative. In addition, photoreactive biotinylation reagents (Section 6.5, this chapter) are used to add nonselectively a biotin group to molecules containing no convenient functional groups for modification. In this manner, oligonucleotide probes often are modified for detection with (strept)avidin conjugates (Chapter 23, Section 2.3).

The following sections discuss the concept and use of the (strept)avidin–biotin interaction in bioconjugate techniques. Preparation of biotinylated molecules and (strept)avidin conjugates also are reviewed with suggested protocols. For a discussion of the major biotinylation reagents, see Section 6, this chapter, and Chapter 18, Section 1.3.

1. THE (STREPT)AVIDIN–BIOTIN INTERACTION

Avidin is a glycoprotein found in egg-whites that contains four identical subunits of 16,400 Daltons each, giving an intact molecular weight of approximately 66,000 (Green, 1975). Each subunit contains one binding site for biotin, or vitamin H, and one oligosaccharide modification (Asn-linked). The tetrameric protein is highly basic, having a pI of about 10. The biotin interaction with avidin is among the strongest noncovalent affinities known, exhibiting a dissociation constant of about 1.3×10^{-15} M. Tryptophan and lysine residues in each subunit are known to be involved in forming the binding pocket (Gitlin *et al.*, 1987, 1988).



The tetrameric native structure of avidin is resistant to denaturation under extreme chaotropic conditions. Even in 8-*M* urea or 3-*M* guanidine hydrochloride the protein maintains structural integrity and activity (Green, 1963). When biotin is bound to avidin, the interaction promotes even greater stability to the complex. An avidin–biotin complex (ABC) is resistant to breakdown in the presence of up to 8-*M* guanidine at pH 5.2. A minimum of 6- to 8-*M* guanidine at pH 1.5 is required for inducing complete dissociation of the avidin–biotin interaction complex (Cuatrecasas and Wilchek, 1968; Bodanszky and Bodanszky, 1970). Since the subunits in avidin are not held together by disulfide bonds, conditions that cause denaturation also result in subunit disassociation.

The strength of the noncovalent avidin–biotin interaction along with its resistance to breakdown makes it extraordinarily useful in bioconjugate chemistry. Biotinylated molecules and avidin conjugates can "find" each other under the most extreme conditions to bind and complex together. The biospecificity of the interaction is similar to antibody–antigen or receptor–ligand recognition, but on a much higher level with respect to affinity constants. Variations in buffer salt, pH, the presence of denaturants or detergents, and extremes of temperature will not prevent the interaction from occurring (Ross *et al.*, 1986).

The only disadvantage to the use of avidin is its tendency to bind nonspecifically with components other than biotin due to its high pI and carbohydrate content. The strong positive charge on the protein causes ionic interactions with more negatively charged molecules, especially cell surfaces. In addition, carbohydrate

binding proteins on cells can interact with the polysaccharide portions on the avidin molecule to bind them in regions devoid of targeted biotinylated molecules. These nonspecific interactions can lead to elevated background signals in some assays, preventing the full potential of the avidin–biotin amplification process to be realized.

Streptavidin is a biotin-binding protein similar to avidin, but it is of bacterial origin and originates from *Streptomyces avidinii*. Due to streptavidin's structural differences, however, it can overcome some of the nonspecific binding deficiencies of avidin (Chaiet and Wolf, 1964). Similar to avidin, streptavidin contains four subunits, each with a single biotin-binding site. After some postsecretory modifications, the intact tetrameric protein has a molecular mass of about 60,000 Daltons, slightly less than that of avidin (Bayer *et al.*, 1986, 1989).

The primary structure of streptavidin is considerably different than that of avidin, despite the fact that they both bind biotin with similar avidity. The molecular model illustrates the four identical subunits of streptavidin as colored ribbons with four biotins shown as space-filling molecules bound deep within the binding pockets of each polypeptide chain (Le Trong *et al.*, 2011) (PDB structure 3RY1). The variation in the amino acid sequence from avidin results in a much lower isoelectric point for streptavidin (pI 5–6) compared to the highly basic pI of 10 for the egg-white protein. Moderation in the overall charge of streptavidin substantially reduces the amount of nonspecific binding due to ionic interaction with other molecules. Of additional significance is the fact that streptavidin is not a glycoprotein, thus there is no potential for binding to carbohydrate receptors. These factors lead to better signal-to-noise ratios in assays using streptavidin–biotin interactions than those employing avidin–biotin.

Both avidin and streptavidin can be conjugated to other proteins or labeled with various detection reagents without loss of biotin-binding activity. The biotin-binding proteins can also be immobilized onto surfaces, chromatography supports, microparticles, and nanoparticles for use in coupling biotinylated molecules (Xie *et al.*, 2011; Williams *et al.*, 2012; Yu *et al.*, 2012). Streptavidin is slightly less soluble in water than avidin, but both are extremely robust proteins that can tolerate a wide range of buffer conditions, pH values, and chemical modification processes. Bioconjugate techniques can utilize the ε- or N-terminal amines on these proteins for direct conjugation or employ modification reagents to transform their existing functional groups into other reactive groups (Chapter 2, Section 4).

In this chapter and throughout this book, the use of the term "(strept)avidin" is meant to infer that either avidin or streptavidin can be used in the associated protocols, conjugates, and applications. However, due to its enhanced properties, streptavidin has effectively replaced native avidin in most capture or detection

methods designed for use with biomolecules. There are some chemically modified avidin preparations, such as NeutrAvidin (Thermo Fisher), that have eliminated its negative properties through deglycosylation and reducing its pI through covalent modification of charged residues. These modified avidin preparations perform much better than native avidin and for certain applications even perform better than streptavidin.

2. USE OF (STREPT)AVIDIN–BIOTIN INTERACTIONS IN ASSAY SYSTEMS

The specificity of biotin binding to (strept)avidin provides the basis for developing assay systems to detect or quantify analytes. Biotinylated molecules can be targeted in complex mixtures by using the appropriate (strept)avidin conjugates. If the biotinylated component has affinity for binding a particular antigen, then the antigen can be located through the use of a (strept)avidin conjugate containing a detectable molecule. A series of (strept)avidin–biotin interactions can be built upon each other—utilizing the multivalent nature of each tetrameric (strept)avidin molecule—to further enhance the detection capability for the target. Immunoassays built on the layering of (strept)avidin–biotin interactions can result in amplified sensitivities and lower limits of detection than assays using antibodies directly targeting an analyte (He *et al.*, 2012).

A common application for (strept)avidin–biotin chemistry is in immunoassays. The specificity of antibody molecules provides the targeting capability to recognize and bind particular antigen molecules. If there are biotin labels on the antibody, it creates multiple sites for the binding of (strept)avidin. If (strept)avidin is in turn labeled with an enzyme, fluorophore, etc., then a very sensitive antigen-detection system is created. The potential for more than one labeled (strept)avidin to become attached to each antibody through its multiple biotinylation sites is the key to dramatic increases in assay sensitivity over that obtained through the use of antibodies directly labeled with a detectable tag.

There are several basic immunoassay designs that make use of the enhanced sensitivity afforded by the (strept)avidin–biotin interaction. Most of these assays use conjugates of (strept)avidin with enzymes, such as horseradish peroxidase (HRP) or alkaline phosphatase, although other labels (such as fluorophores) can be used as well. In the simplest assay design, called the labeled avidin–biotin (LAB) system (Figure 11.1), a biotinylated antibody is allowed to incubate and bind with its target antigen. Next, a (strept)avidin–enzyme conjugate is introduced and allowed to interact with the available biotin sites on the bound antibody. Just as in other enzyme-linked immunosorbent assay (ELISA) tests, substrate development then provides the chemical detectability necessary to quantify the antigen (Guesdon *et al.*, 1979).

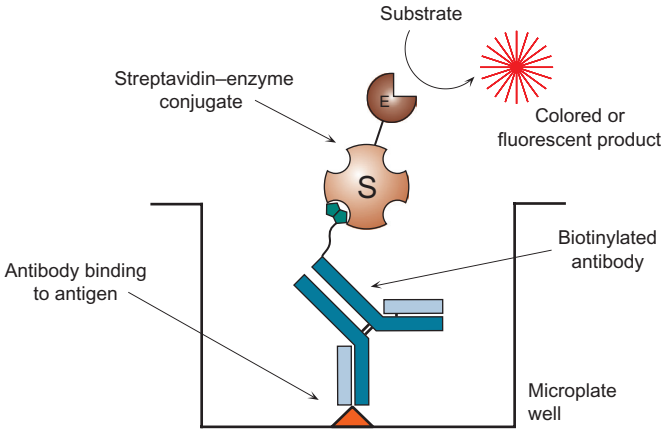

FIGURE 11.1 The basic design of the labeled avidin–biotin (LAB) assay system.

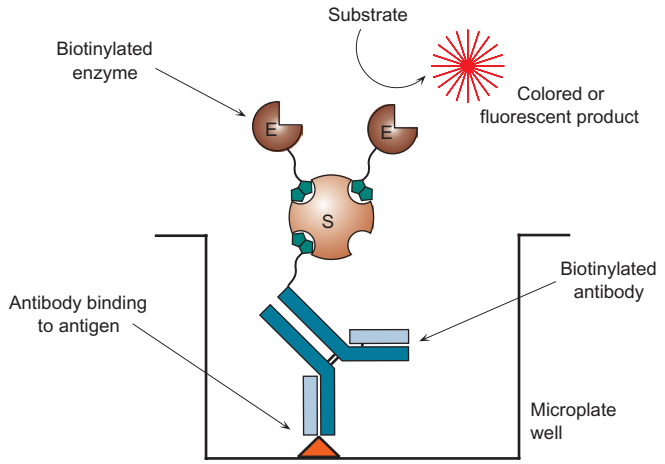

FIGURE 11.2 The basic design of the bridged avidin–biotin (BRAB) assay system.

In a slightly more complex design, the bridged avidin–biotin (BRAB) system uses (strept)avidin's multiple biotin-binding sites to create an assay of potentially higher sensitivity than that of the LAB assay. Again the biotinylated antibody is allowed to bind to its target, but in the next step an unmodified (strept)avidin is introduced to bind with the biotin binding sites on the antibody. Finally, a biotinylated enzyme is added to provide a detection vehicle (Figure 11.2). Since the bound (strept)avidin still has additional biotin-binding sites available, the potential exists for more than one biotinylated enzyme to interact with each bound (strept)avidin. In some cases, sensitivity can be increased over that of the LAB technique by using this bridging ability of (strept)avidin (Seydack, 2008; Jedrychowski *et al.*, 2009).

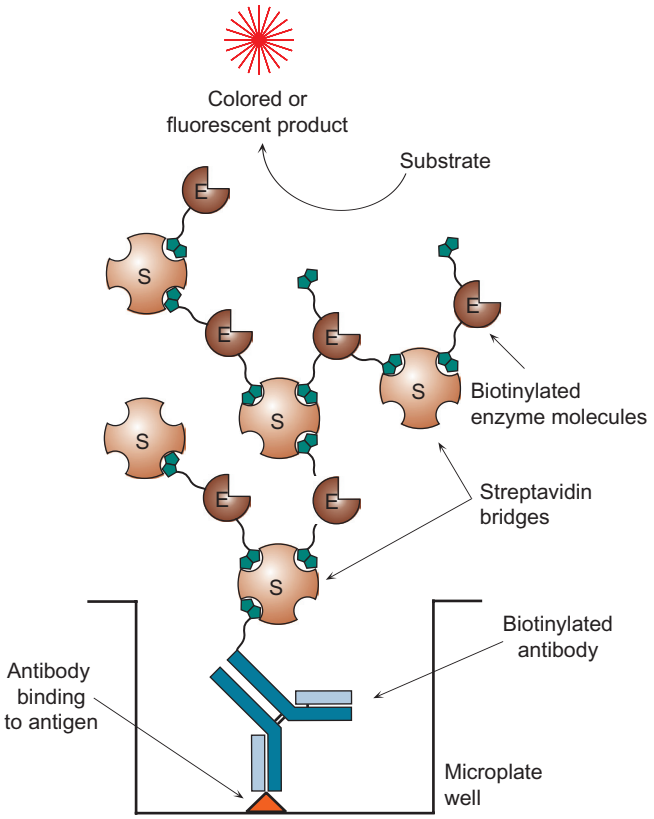

FIGURE 11.3 The assay design of the avidin–biotin complex (ABC) system.

A modification on this theme can be used to produce one of the most sensitive enzyme-linked assay systems known. The ABC system (for avidin–biotin complex) increases the detectability of antigen beyond that possible with either the LAB or BRAB designs by forming a polymer of biotinylated enzyme and (strept)avidin before its addition to an antigen-bound, biotinylated antibody (Bayer *et al.*, 1988). When (strept)avidin and a biotinylated enzyme are mixed together in solution in the proper proportion, the multiple binding sites on (strept)avidin create a linking matrix to form a high-molecular-weight complex. If the biotinylated enzyme is not in large enough excess to block all the binding sites on (strept)avidin, then additional sites will still be available on this complex to bind a biotinylated antibody which is bound to its complementary antigen. The large complex provides multiple enzyme molecules to enhance the sensitivity of detecting antigen (Figure 11.3). Thus, the ABC procedure is currently among the highest-sensitivity methods available for immunoassay work. It is a common assay technique used for microplate-based ELISA assays and for immunohistochemistry (IHC) procedures (Hadisaputri *et al.*, 2011; Inouye *et al.*, 2012; Li *et al.*, 2012).

Similar techniques can be used to devise (strept) avidin–biotin assay systems for detection of nucleic acid hybridization. DNA probes labeled with biotin can be detected after they bind their complementary DNA target through the use of (strept)avidin-labeled complexes (Bugawan *et al.*, 1990; Lloyd *et al.*, 1990). Direct detection of hybridized probes can be accomplished, similar to the LAB method, by incubating with a (strept)avidin–enzyme conjugate followed by substrate development. BRAB-like and ABC-like assays can also be utilized to further enhance a DNA probe signal (Chapter 23, Section 2.3).

Non-enzyme assay systems can be designed with the (strept)avidin–biotin interaction, as well. Fluorescently labeled (strept)avidin molecules can be used to detect a biotinylated molecule after it has bound its target. In fact, a single preparation of a fluorescent (strept)avidin derivative can be used as a universal detection reagent for any biotinylated targeting molecule. The main application of this technique is in cytochemical staining wherein the fluorescence signal is used to localize antigen or receptor molecules in cells and tissue sections. In addition, detection of analytes on arrays is commonly carried out using fluorescently labeled (strept)avidin conjugates to bind to biotinylated primary antibodies interacting with specific targets on the array surface.

Other tags or probes can be coupled to (strept)avidin and used in a similar fashion. For instance, radiolabeled (strept)avidin can be employed as a universal detection reagent in radioimmunoassay designs (Wojchowski and Sytkowski, 1986) (Chapter 12, Section 2). (Strept) avidin labeled with ^{125}I can be used to localize biotinylated monoclonal antibodies directed against tumor cells *in vivo* for imaging purposes (Paganelli *et al.*, 1988). Chemical tags such as in hydrazide–(strept)avidin derivatives can be made to site-direct (strept)avidin's interaction toward oxidized carbohydrate residues for specific detection of glycoconjugates (Section 5, this chapter). Colloidal gold-labeled (strept)avidin can be used as highly sensitive detection reagents for microscopy techniques (Cubie and Norval, 1989; Krager *et al.*, 2012) (Chapter 14, Section 6.6). Finally, cytotoxic substances coupled to (strept)avidin can be used to direct cell-killing activity toward a tumor-cell-bound, biotinylated monoclonal antibody (or other targeting molecule) for cancer therapy (Hashimoto *et al.*, 1984; Haugland and Bhalgat, 2008) (Chapter 20, Section 3).

Universal detection reagents can also be constructed through biotinylation techniques. Modification of immunoglobulin-binding proteins with biotin tags, for instance, creates a reagent useful for the general assay of antibody molecules. In this sense, biotinylated protein A or biotinylated protein G can be used to detect the binding of any primary IgG to its antigen target

(provided there is no other antibody molecule presence to cause nonspecific binding of the protein A component). Subsequent addition of a labeled (strept)avidin molecule binds to the biotinylated protein A, completing the formation of a detection complex (Jagannath and Sehgal, 1989).

To develop assay systems using the (strept)avidin–biotin interaction, it is first necessary to produce the associated (strept)avidin conjugates and/or biotinylated components. When the LAB technique is employed, the (strept)avidin conjugate is made using crosslinking agents, not biotinylation reagents, in order to maintain the binding capacity of the (strept)avidin tetramer toward other biotinylated molecules. In the BRAB assay system, (strept)avidin is left unconjugated and acts merely as the multivalent bridging molecule, while both the targeting molecule and the detection molecule are biotinylated. The components for the ABC assay are identical to the BRAB system.

The following sections discuss the main techniques used to make (strept)avidin conjugates and various biotinylated components. Section 6 of this chapter and Chapter 18, Section 1.3, should be consulted for a complete overview of biotinylation reagents.

3. PREPARATION OF (STREPT)AVIDIN CONJUGATES

Conjugates of (strept)avidin with other protein molecules must be prepared to design systems using the LAB assay technique. Suitable protein molecules attached to (strept)avidin either possess indigenous detectability, such as in the case of ferritin or phycobiliproteins, or possess catalytic activity (enzymatic) that can be utilized to produce a detectable substrate product. The majority of conjugation procedures for making (strept)avidin–protein conjugates use the amines, sulfhydryls, or carbohydrates on each protein as functional groups for crosslinking.

Perhaps the most common conjugates of (strept)avidin involve attaching enzyme molecules for use in ELISA systems. As in the case of antibody–enzyme conjugation schemes (Chapter 20, Section 1), by far the most commonly used enzymes for this purpose are horseradish peroxidase and alkaline phosphatase. Other enzymes such as β-galactosidase and glucose oxidase are used less often, especially with regard to assay tests for clinically important analytes (Chapter 22).

Other proteins commonly crosslinked to (strept)avidin are chromogenic or fluorescent molecules, such as ferritin or phycobiliproteins (Chapter 10, Section 7). These conjugates can be used in microscopy techniques to stain and localize certain antigens or receptors in cells or tissue sections.

The following sections discuss three main methods for preparing these types of (strept)avidin–protein conjugates: (1) the use of an *N*-hydroxysuccinimide (NHS) ester–maleimide heterobifunctional crosslinker, (2) the use of the carbohydrate on glycoproteins for reductive amination coupling, and (3) employing the old technique of homobifunctional crosslinking with glutaraldehyde.

3.1. NHS Ester–Maleimide-Mediated Conjugation Protocols

Heterobifunctional crosslinking agents can be used to control the degree of protein conjugation, thus limiting polymerization and controlling the molar ratio of each component in the final complex (Chapter 6). Particularly useful heterobifunctionals include the amine- and sulfhydryl-reactive NHS ester–maleimide crosslinkers discussed in Chapter 6, Section 1. Chief among these is succinimidyl-4-(*N*-maleimidomethyl)cyclohexane-1-carboxylate (SMCC) or sulfo-SMCC (Chapter 6, Section 1.3), which contains a reasonably long spacer and a relatively stable maleimide group due to the adjacent cyclohexane ring in its cross-bridge.

Conjugations carried out with SMCC usually involve up to three steps. In the first stage, one of the proteins is modified at its amine groups *via* the NHS ester end of the crosslinker to form amide linkages, which upon modification then create derivatives that terminate in reactive maleimide groups. If the other protein to be conjugated does not contain sulfhydryl residues necessary to react with the maleimide-activated protein, it must be modified to contain them (Chapter 2, Section 4.1). Finally, the two reactive components are mixed together in the proper ratio to effect the conjugation reaction (Shuvaev *et al.*, 2011; Lillich *et al.*, 2012).

For the preparation of (strept)avidin–enzyme conjugates, either protein may first be modified with SMCC and the other one modified to contain –SH groups. Since (strept)avidin does not possess any free sulfhydryls—and the disulfides present in (strept)avidin are inaccessible to easy reduction—it must be modified with either a crosslinker or with a thiolation agent before conjugation. If the enzyme employed contains free sulfhydryls in its native state, such as β-galactosidase, then it is convenient to activate (strept)avidin with SMCC and simply add the sulfhydryl-containing protein to it for conjugation. If the enzyme does not contain free sulfhydryls (as is the case with alkaline phosphatase or horseradish peroxidase), then the choice of which component gets maleimide-activated and which gets thiolated is up to the individual.

The following protocol describes the activation of (strept)avidin with sulfo-SMCC and its subsequent

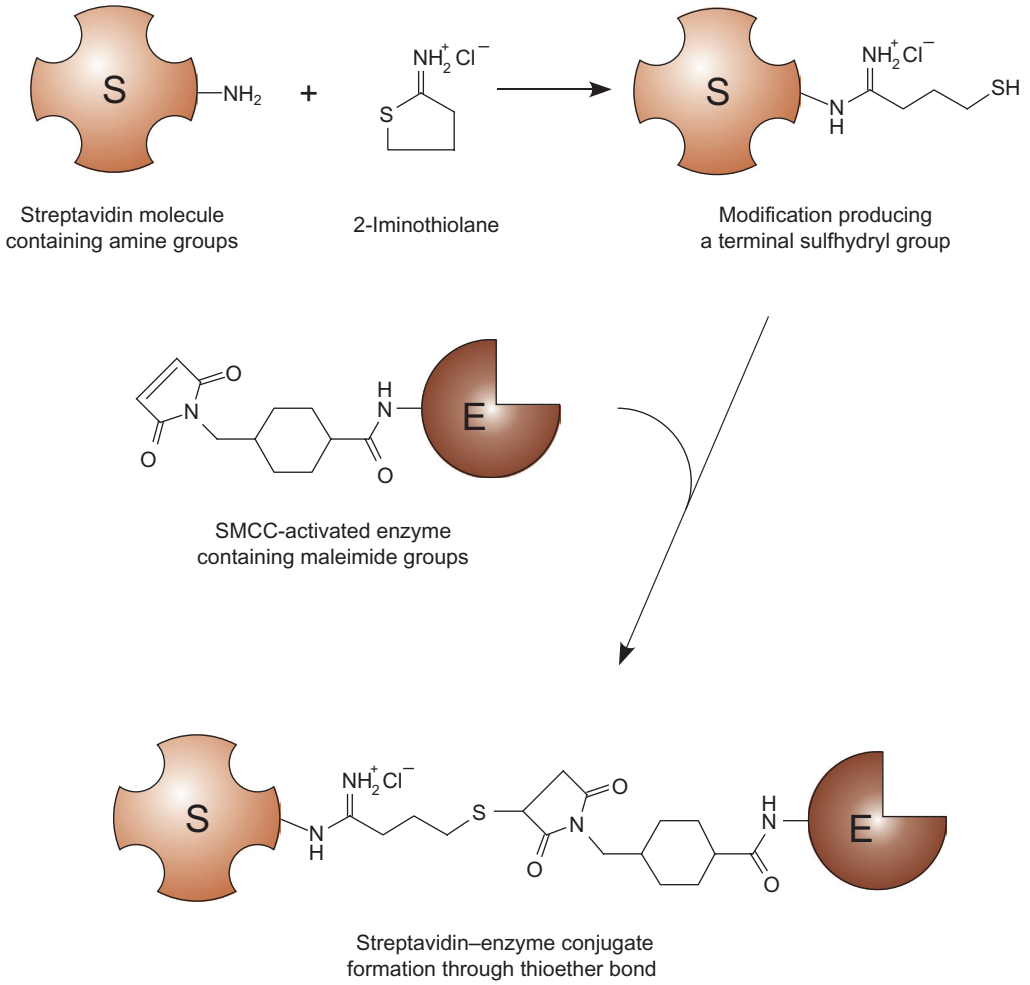

FIGURE 11.4 Streptavidin can be modified with 2-iminothiolane (Traut's reagent) to produce sulfhydryl groups. Subsequent reaction with a maleimide-activated enzyme produces a thioether-linked conjugate.

conjugation with an enzyme modified to contain sulfhydryls using *N*-succinimidyl-*S*-acetylthioacetate (SATA) (Chapter 2, Section 4.1). A method for the opposite approach, wherein the enzyme is activated with SMCC and the (strept)avidin component is thiolated, is presented immediately after this protocol. This strategy may be the most common approach to forming these conjugates (Figure 11.4). In addition, since there are enzymes commercially available that are activated with SMCC (Thermo Fisher), their use may be the easiest solution to forming conjugates.

Protocol for the Conjugation of SMCC-Activated (Strept)avidin with Thiolated Enzyme

ACTIVATION OF (STREPT)AVIDIN WITH SMCC

1. Dissolve (strept)avidin (Thermo Fisher) in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 10 mg/ml.
2. Add 1.0 mg of sulfo-SMCC (Thermo Fisher) to each ml of (strept)avidin solution. Mix to dissolve.
3. React for 30 to 60 min at room temperature. Since maleimide groups are labile in aqueous solution, extended reaction times should be avoided.
4. Immediately purify the maleimide-activated (strept)avidin away from excess crosslinker and reaction byproducts by gel filtration on a desalting resin. A spin column will facilitate the most rapid purification. Use 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, as the chromatography buffer. Pool the fractions containing protein (the first peak eluting from the column). After elution, adjust the protein concentration to 10 mg/ml for the conjugation reaction (centrifugal concentrators work well for this step). At this point, the maleimide-activated (strept)avidin may be frozen and lyophilized to preserve its maleimide activity. The modified protein is stable for at least 1 year in a

freeze-dried state. If kept in solution, the maleimide-activated (strept)avidin is labile and should be used immediately to conjugate with a thiolated enzyme following the procedure described below.

MODIFICATION OF ENZYME WITH SATA

If β-galactosidase is used to conjugate with an SMCC-activated (strept)avidin, then there is no need to thiolate the enzyme, since it contains sulfhydryls in its native state (Fujiwara, 1988; Sivakoff and Janes, 1988). For conjugations using horseradish peroxidase, alkaline phosphatase, or glucose oxidase, however, thiolation is necessary to add the necessary sulfhydryls.

1. Dissolve the enzyme to be modified in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 10 mg/ml.
2. Prepare a stock solution of SATA (Thermo Fisher) by dissolving it in DMSO at a concentration of 13 mg/ml. Use a fume hood to handle the organic solvent.
3. Add 25 µl of the SATA stock solution to each ml of 10 mg/ml enzyme solution. For different concentrations of enzyme in the reaction medium, proportionally adjust the amount of SATA addition; however, do not exceed 10% DMSO in the aqueous reaction medium.
4. React for 30 min at room temperature.
5. To purify the SATA-modified enzyme perform a gel filtration separation using a desalting resin or dialyze against 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA. Purification is not absolutely required, since the following deprotection step is carried out using hydroxylamine at a significant molar excess over the initial amount of SATA added. Whether a purification step is carried out or not, at this point, the derivative is stable and may be stored under conditions which favor long-term enzyme activity.
6. Deprotect the acetylated sulfhydryl groups on the SATA-modified enzyme according to the following protocol:
   a. Prepare a 0.5-*M* hydroxylamine solution in 0.1-*M* sodium phosphate, pH 7.2, containing 10-m*M* EDTA.
   b. Add 100 µl of the hydroxylamine stock solution to each ml of the SATA-modified enzyme. Final concentration of hydroxylamine in the enzyme solution is 50-m*M*.
   c. React for 2 h at room temperature.
   d. Purify the thiolated enzyme by gel filtration on a desalting resin using 0.1-*M* sodium phosphate, 0.1-*M* NaCl, pH 7.2, containing 10-m*M* EDTA as the chromatography buffer. To obtain efficient separation between the thiolated protein and excess hydroxylamine and reaction byproducts, the sample size applied to the column should be at a ratio of no more than 5% sample volume to the total column volume. Collect 0.5-ml fractions. Pool the fractions containing protein by measuring the absorbance of each fraction at 280 nm.

PRODUCTION OF CONJUGATE

1. Immediately mix the thiolated enzyme with an amount of maleimide-activated (strept)avidin to obtain the desired molar ratio of enzyme-to-(strept)avidin in the conjugate. Use of a 4:1 (enzyme:avidin) molar ratio in the conjugation reaction usually results in high-activity conjugates suitable for use in many enzyme-linked immunoassay procedures employing the LAB approach.
2. React for 30 to 60 min at 37°C or 2 h at room temperature. The conjugation reaction may also be carried out at 4°C overnight.

A variation of the above method can be used, wherein the enzyme is first activated with SMCC and conjugated to a thiolated (strept)avidin molecule. This approach is probably the most common way of preparing (strept)avidin–enzyme conjugates, and since the activated enzymes are readily available (Thermo Fisher) it may also be the easiest.

Protocol for the Conjugation of SMCC-Activated Enzymes with Thiolated (Strept)avidin

ACTIVATION OF ENZYME WITH SULFO-SMCC

The following protocol describes the activation of horseradish peroxidase (HRP) with sulfo-SMCC. Other enzymes may be activated in a similar manner. The activated enzyme possesses maleimide groups that are relatively unstable in aqueous solution. Therefore, the thiolation reaction should be coordinated with the activation process so that the final conjugation can be carried out immediately. Note: If activated enzymes are obtained (Thermo Fisher), this step may be eliminated.

1. Dissolve HRP in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 10 mg/ml.
2. Add 3.3 mg of sulfo-SMCC (Thermo Fisher) to each ml of the HRP solution. Mix to dissolve and react for 30 min at room temperature. Alternatively, two equal additions of crosslinker may be carried out—the second one after 15 min of incubation—to obtain even more efficient modification.
3. Immediately purify the maleimide-activated HRP away from excess crosslinker and reaction byproducts by gel filtration on a desalting column. Use 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, as the chromatography buffer. HRP can be

observed visually as it flows through the column due to the color of its heme ring. Pool the fractions containing the HRP peak. After elution, adjust the HRP concentration to 10 mg/ml for the conjugation reaction. At this point, the maleimide-activated enzyme may be frozen and lyophilized to preserve its maleimide activity. The modified enzyme is stable for at least one year in a freeze-dried state. If kept in solution, the maleimide-activated HRP should be used immediately to conjugate with thiolated (strept) avidin following the protocols outlined below.

THIOLATION OF (STREPT)AVIDIN

1. Dissolve (strept)avidin in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 10 mg/ml.
2. Prepare a stock solution of SATA by dissolving it in DMSO at a concentration of 13 mg/ml. Use a fume hood to handle the organic solvent.
3. Add 25 µl of the SATA stock solution to each ml of 10 mg/ml (strept)avidin solution. For different concentrations of protein in the reaction medium, proportionally adjust the amount of SATA addition; however, do not exceed 10% DMSO in the aqueous reaction medium.
4. React for 30 min at room temperature.
5. To purify the SATA-modified (strept)avidin use gel filtration on a desalting column or dialyze against 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, containing 10-m*M* EDTA. At this point, the derivative is stable and may be stored under conditions which favor long-term (strept)avidin activity.
6. Deprotect the acetylated sulfhydryl groups on the SATA-modified protein according to the following protocol:
   a. Prepare a 0.5-*M* hydroxylamine solution in 0.1-*M* sodium phosphate, pH 7.2, containing 10-m*M* EDTA.
   b. Add 100 µl of the hydroxylamine stock solution to each ml of the SATA-modified (strept)avidin. Final concentration of hydroxylamine in the solution is 50-m*M*.
   c. React for 2 h at room temperature.
   d. Purify the thiolated protein by gel filtration on Sephadex G-25 using 0.1-*M* sodium phosphate, 0.1-*M* NaCl, pH 7.2, containing 10-m*M* EDTA as the chromatography buffer.

CONJUGATION OF SMCC-ACTIVATED ENZYME WITH THIOLATED (STREPT)AVIDIN

7. Immediately mix the SMCC-activated enzyme with an amount of thiolated (strept)avidin to obtain the desired molar ratio of enzyme-to-(strept)avidin in the conjugate. Use of a 4:1 (enzyme:avidin) molar ratio in the conjugation reaction usually results in high-activity conjugates suitable for use in many enzyme-linked immunoassay procedures employing the LAB approach.
8. React for 30 to 60 min at 37°C or 2 h at room temperature. The conjugation reaction also may be done at 4°C overnight.

3.2. Conjugation Using Periodate Oxidation/ Reductive Amination

Glycoproteins may be conjugated with another amine-containing protein through the process of periodate oxidation and reductive amination. Periodate oxidation of polysaccharide components on the glycoprotein results in the formation of reactive aldehyde residues by cleavage of carbon–carbon bonds and oxidation of the associated adjacent hydroxyls (Chapter 2, Section 4.4). Conjugation with another protein may be achieved by reacting the aldehydes with amines to form intermediate Schiff bases with subsequent reduction using sodium cyanoborohydride to create stable secondary amine bonds.

This method of conjugation is particularly well-suited for coupling HRP or ferritin with (strept)avidin (Dhar *et al.*, 2012). Both HRP and (strept)avidin are glycoproteins that can be oxidized with sodium periodate to generate aldehydes. Thus, HRP–(strept)avidin and ferritin–(strept)avidin may be prepared by reductive amination. Ferritin is a large, complex protein of molecular weight 750,000. Its structure is comprised of a protein shell of diameter approximately 12 nm that surrounds a micelle core consisting of ferric hydroxide of about 6-nm diameter. This core contains more than 2000 iron atoms, making the protein extremely electron dense and thus perfect for electron microscopy applications. The properties of HRP are described in Chapter 22, Section 1.

The following protocol is adapted from Bayer *et al.* (1976).

Protocol for the Conjugation of (Strept)avidin with Ferritin Using Reductive Amination

1. Dissolve (strept)avidin in 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 4.5, at a concentration of 3 mg/ml.
2. Dissolve ferritin in 0.1-*M* sodium acetate, 0.15-*M* NaCl, pH 4.5, at a concentration of 100 mg/ml.
3. Add 1 ml of ferritin solution to every 5 ml of (strept) avidin solution. Chill on ice.
4. Dissolve sodium periodate in water at a concentration of 100-m*M*. Prepare fresh and protect from light.
5. Add 110 µl of sodium periodate solution to each ml of (strept)avidin/ferritin solution.
6. React for 3 h on ice with periodic mixing. Protect from light.

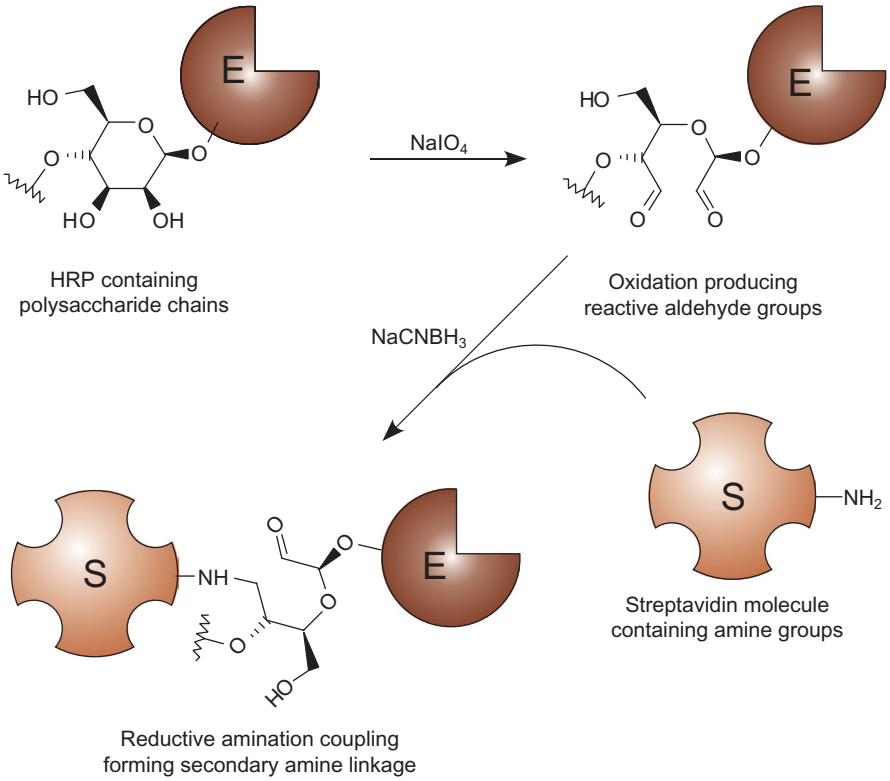

FIGURE 11.5 Oxidation of the polysaccharide components of HRP produces reactive aldehyde groups. Conjugation to streptavidin may then be achieved by reductive amination.

7. Remove excess periodate by gel filtration on a column of Sephadex G-25 or by overnight dialysis against 50-m*M* sodium borate, 0.15-*M* NaCl, pH 8.5.
8. Dissolve 10 mg of sodium borohydride in 1 ml of 10-m*M* NaOH. Prepare fresh. Add 83 µl of this reducing solution to each ml of (strept)avidin/ferritin solution.
9. React for 1 h on ice.
10. Remove excess reductant by gel filtration using a column of Sephadex G-25 or by extensive dialysis against 20-m*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4.

Conjugation of HRP by reductive amination can be achieved by oxidizing the carbohydrate on the enzyme and subsequently coupling to the amines on (strept)avidin (Figure 11.5).

Protocol for the Preparation of (Strept)avidin–HRP by Reductive Amination

OXIDATION OF HRP WITH SODIUM PERIODATE

1. Dissolve HRP in water or 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2, at a concentration of 10 to 20 mg/ml.
2. Dissolve sodium periodate in water at a concentration of 0.088-*M*. Protect from light.
3. Immediately add 100 µl of the sodium periodate solution to each ml of the HRP solution. This results in an 8-m*M* periodate concentration in the reaction mixture. Mix to dissolve. Protect from light.
4. React in the dark for 15 min at room temperature. A color change will be apparent as the reaction proceeds—changing from the brownish/gold color of concentrated HRP to green. Longer reaction times will result in a decrease in HRP enzymatic activity.
5. Immediately purify the oxidized enzyme by gel filtration using a column of Sephadex G-25. The chromatography buffer is 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. Collect 0.5-ml fractions and monitor for protein at 280 nm. HRP may also be detected by its absorbance at 403 nm. In oxidizing large quantities of HRP, the fraction collection process may be done visually by pooling the colored HRP peak as it comes off the column.
6. Pool the fractions containing protein. Adjust the enzyme concentration to 10 mg/ml for the conjugation step. The periodate-activated HRP may be stored frozen or freeze-dried for extended periods without loss of activity. However, do not store the preparation in solution at room temperature or 4°C, since precipitation will occur over time due to self-polymerization.

CONJUGATION OF PERIODATE-OXIDIZED HRP WITH (STREPT)AVIDIN

1. Dissolve (strept)avidin at a concentration of 10 mg/ml in 0.2-*M* sodium bicarbonate, pH 9.6, at room temperature. The high pH buffer will result in very efficient Schiff base formation and conjugation

with the highest possible incorporation of enzyme molecules per (strept)avidin molecule. To produce lower molecular weight conjugates (using less efficient Schiff base formation conditions), dissolve the proteins at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2.

2. The periodate-oxidized HRP (prepared above) is finally purified using 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2. For conjugation using the lower-pH-buffered environment, this HRP preparation can be used directly at 10 mg/ml concentration. For conjugation using the higher pH carbonate buffer, dialyze the HRP solution against 0.2-*M* sodium carbonate, pH 9.6 for 2 h at room temperature prior to use.
3. Mix the (strept)avidin solution with the enzyme solution at a ratio of 1 : 6.6 (v/v). Since (strept)avidin has a molecular weight of about 66,000 and HRP's molecular weight is 40,000, this ratio of volumes will result in a molar ratio of HRP:(strept)avidin equal to 4 : 1. For conjugates consisting of greater enzyme-to-(strept)avidin ratios, proportionally increase the amount of enzyme solution as required. Typically, molar ratios of 2 : 1 to 10 : 1 (enzyme:avidin) give acceptable conjugates useful in a variety of ELISA techniques.
4. React for 2 h at room temperature to form the initial Schiff base interactions.
5. In a fume hood, add 10 µl of 5-*M* sodium cyanoborohydride (Sigma) per ml of reaction solution. Caution: Cyanoborohydride is extremely toxic. All operations should be carried out with care in a fume hood. Also, avoid any contact with the reagent, as the 5-*M* solution is prepared in 1-*N* NaOH.
6. React for 30 min at room temperature (in a fume hood).
7. Block unreacted aldehyde sites by addition of 50 µl of 1-*M* ethanolamine, pH 9.6, per ml of conjugation solution. Approximately 1-*M* ethanolamine solution may be prepared by addition of 300 µl ethanolamine to 5 ml of deionized water. Adjust the pH of the ethanolamine solution by addition of concentrated HCl, keeping the solution cool on ice.
8. React for 30 min at room temperature.
9. Purify the conjugate from excess reactants by dialysis or gel filtration using Sephadex G-25. Use 0.01-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.0, as the buffer for either operation. Use a fume hood, since cyanoborohydride will be present in some of the fractions.

3.3. Glutaraldehyde Conjugation Protocol

Glutaraldehyde is one of the oldest homobifunctional reagents used for protein conjugation. It reacts with amine groups to create crosslinks by one of several routes (Chapter 5, Section 6.2, and Chapter 15, Section 2.1). In aqueous solution, the molecule undergoes a number of transformations through hemiacetal and aldol products to create a variety of reactive intermediates. Although glutaraldehyde is a bifunctional aldehyde molecule, it doesn't react at both ends as one might expect through aldehyde–amine Schiff base formation and reductive amination. The complex activation and conjugation reactions described in Chapter 15 for the use of glutaraldehyde to immobilize affinity ligands onto chromatography supports can be referenced as a basis for the conjugation reactions that can occur for bioconjugation in solution. The reagent is highly efficient at protein conjugation, but it also has a tendency to form high-molecular-weight polymers due to its bifunctional or multifunctional nature. Single-step protocols using glutaraldehyde are particularly notorious at resulting in some degree of insoluble protein oligomers (Porstmann *et al.*, 1985). Two-step methods somewhat alleviate this problem, but the potential for conjugate precipitation is still present.

Preparation of (strept)avidin conjugates with other proteins can be accomplished using either a one- or two-step glutaraldehyde procedure. Both methods may result in some degree of oligomer formation; however, the two-step protocol may keep insoluble material to a minimum. Although the following procedures are described using particular proteins, they may be used as a general guide for coupling enzymes, ferritin, phycobiliproteins, or other detectable proteins to (strept)avidin. Some optimization may be necessary to obtain the best yield of active conjugate.

Protocol for the One-Step Glutaraldehyde Conjugation of Ferritin to (Strept)avidin

This protocol is adapted from Bayer and Wilchek (1980).

1. Prepare a solution containing 5 mg/ml (strept)avidin and 25 mg/ml ferritin in 0.02-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, at room temperature. Note: For the coupling of other proteins to (strept)avidin, their concentration may be reduced from the 25 mg/ml stated for ferritin.
2. In a fume hood, add 10 µl of 25% glutaraldehyde per ml of (strept)avidin/ferritin solution. Mix well.
3. React for 1 h at room temperature.
4. To reduce the resultant Schiff bases and any excess aldehydes, add sodium borohydride to a final concentration of 10 mg/ml.

Note: Some protocols do not call for a reduction step. The addition of borohydride at this level may result in disulfide bond cleavage and loss of protein

activity in some cases. As an alternative to reduction, add 50 µl of 0.2-*M* lysine in 0.5-*M* sodium carbonate, pH 9.5, to each ml of the conjugation reaction to block excess reactive sites. Block for 2 h at room temperature. Other amine-containing small molecules may be substituted for lysine—such as glycine, Tris buffer, or ethanolamine.

5. Reduce for 1 h at 4°C.
6. To remove any insoluble polymers that may have formed, centrifuge the conjugate or filter it through a 0.45-µm filter. Purify the conjugate by gel filtration or dialysis using PBS, pH 7.4.

A two-step glutaraldehyde protocol may result in lower molecular weight conjugates, thus limiting the degree of insoluble material formed during the cross-linking process. The following protocol is adapted from Avrameas (1969).

Protocol for the Two-Step Glutaraldehyde Conjugation of Enzymes to (Strept)avidin

1. Dissolve the enzyme at a concentration of 10 mg/ml in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.8.
2. Add glutaraldehyde to a final concentration of 1.25%.
3. React overnight at room temperature.
4. Purify the activated enzyme from excess glutaraldehyde by gel filtration (using Sephadex G-25) or by dialysis against PBS, pH 6.8.
5. Dissolve (strept)avidin at a concentration of 10 mg/ml in 0.5-*M* sodium carbonate, pH 9.5. Mix the activated enzyme with the (strept)avidin solution at the desired molar ratio to effect the conjugation. Mixing the equivalent of 1 to 2 moles of enzyme per mole of (strept)avidin usually results in acceptable conjugates.
6. React overnight at 4°C.
7. To reduce the resultant Schiff bases and any excess aldehydes, add sodium borohydride to a final concentration of 10 mg/ml.

Note: Some protocols avoid a reduction step, as it can lead to disulfide bond cleavage and detrimental effects on protein activity. As an alternative to reduction, add 50 µl of 0.2-*M* lysine in 0.5-*M* sodium carbonate, pH 9.5, to each ml of the conjugation reaction to block excess reactive sites. Block for 2 h at room temperature. Other amine-containing small molecules may be substituted for lysine—such as glycine, Tris buffer, or ethanolamine.

8. Reduce for 1 h at 4°C.
9. To remove any insoluble polymers that may have formed, centrifuge the conjugate or filter it through a 0.45-µm filter. Purify the conjugate by gel filtration or dialysis using PBS, pH 7.4.

4. PREPARATION OF FLUORESCENTLY LABELED (STREPT)AVIDIN

Fluorophore modification of (strept)avidin creates a reagent system that can be used to detect and localize biotinylated targeting molecules. The application of such reagents in immunohistochemical staining techniques is significant (Bonnard *et al.*, 1984). A biotinylated antibody directed against a particular tissue antigen can be allowed to bind its target *in situ*, and then a fluorescently tagged (strept)avidin may be added to bind and visualize the antibody-bound antigenic sites by luminescence. Individual cellular structures can be labeled in similar assay strategies and detected by fluorescent microscopy or cell sorting techniques (Sternberger, 1986; Abou-Samra *et al.*, 1990). Biotinylated targeting molecules like antibodies can have some nonspecific binding potential due to the presence of a hydrophobic biotin tag. However, if hydrophilic biotinylation compounds are used in the modification reaction (such as those containing a PEG spacer; see Chapter 18, Section 1.3), then the degree of nonspecific binding in the conjugate can be kept to a minimum. The multivalent nature of (strept)avidin's biotin-binding sites combined with the potential of more than one biotin tag per antibody creates a system of much greater potential sensitivity than when using fluorescently modified antibodies alone. The complex formed from the (strept)avidin–biotin interaction amplifies the fluorescent signal beyond that capable in directly labeled antibody techniques.

Double labeling systems can also be developed using the (strept)avidin–biotin interaction. If two primary antibodies directed against separate antigenic determinants are labeled, one with biotin and the other with another detection component (such as a fluorophore, enzyme, gold particles, etc.), then both may be used to simultaneously localize different antigens in tissue sections. The biotinylated antibody may subsequently be detected by the addition of a fluorescently labeled (strept)avidin reagent. An example of a double label (strept)avidin–biotin detection system is that of Feller *et al.* (1983). A pair of tonsil antigens was visualized using two monoclonal antibodies, one fluorescein-labeled, and the other biotinylated. The biotinylated antibody was detected by using a phycoerythrin-labeled (strept)avidin conjugate (Section 4.4, this chapter, and Chapter 10, Section 7). Even triple-labeling systems may be developed using this strategy (van Dongen *et al.*, 1985).

The following sections present suggested protocols for labeling (strept)avidin with selected fluorophores. Other fluorescent probes may be constructed using the reagents and methods discussed in Chapter 10.

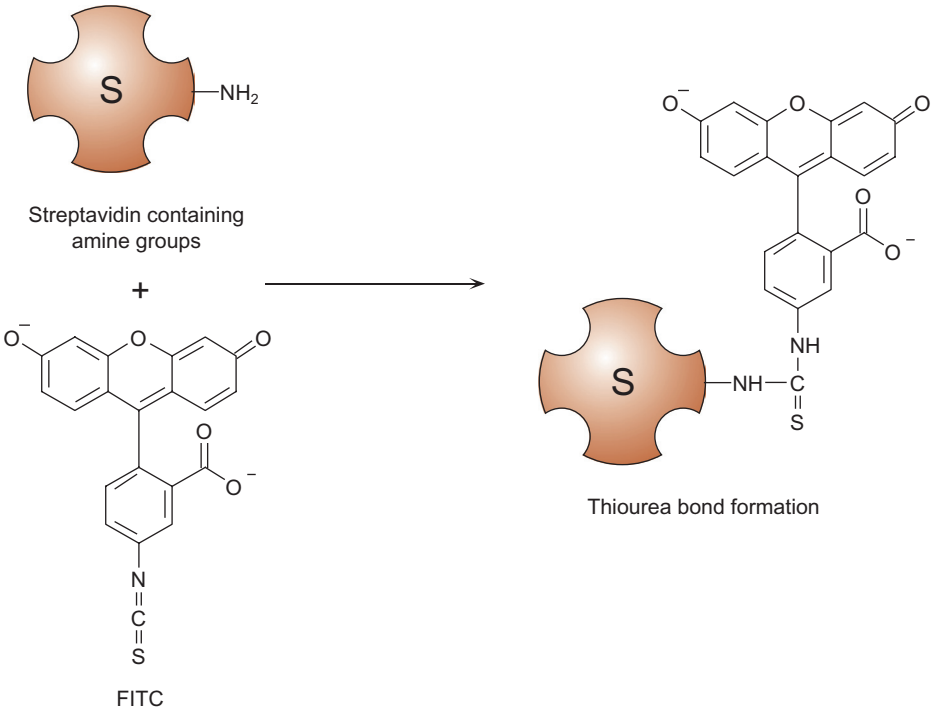

FIGURE 11.6 The reaction of FITC with streptavidin produces a fluorescent probe *via* isothiourea bonds.

4.1. Modification with FITC

Fluorescein isothiocyanate (FITC) has been one of the most common fluorescent labels used to modify proteins and other biomolecules (Chapter 10, Section 1). The isothiocyanate group reacts with amines in protein molecules to form a stable thiourea linkage (Figure 11.6). (Strept)avidin may be tagged with this reagent to yield highly fluorescent derivatives useful both in single-staining and double-staining techniques (Bayer and Wilchek, 1980; Bakkus *et al.*, 1989; Szabo *et al.*, 1989). Optimal modification levels for fluorescein are in the range of 3 to 8 fluorophores per (strept)avidin molecule. Lower incorporation levels will result in low luminescence and poor sensitivity. Higher levels may cause fluorescein–fluorescein quenching effects, resulting in decreased fluorescence. Too high a modification level may also result in nonspecific binding of the derivatized proteins to non-targeted components in assay systems or even result in precipitation of the modified protein due to hydrophobic aggregation of the dyes.

Although FITC and other reactive fluorescein derivatives are still widely used to label (strept)avidin and other proteins, better fluorescence yield and stability will be obtained if one of the newer hydrophilic fluorescein dyes is used, such as DyLight 488 (Thermo Fisher). See Chapter 10, Section 1, for additional details on labeling proteins with fluorescein.

Protocol

1. Dissolve (strept)avidin in 0.1-*M* sodium carbonate, pH 9.5, at a concentration of 2 to 4 mg/ml.
2. Dissolve FITC in DMF at a concentration of 2 mg/ml. Protect from light.
3. Add 50 to 100 µl of the FITC solution to each ml of the (strept)avidin solution.

Note: The optimal level of fluorescein modification should be determined experimentally to obtain a bright conjugate without the tendency to precipitate or fluorescently quench due to over-labeling. For relatively hydrophobic dyes such as FITC, this may mean reacting the (strept)avidin with no more than a 5-fold mole excess of dye to obtain about two to three fluorescent labels per molecule. Excessive labeling also causes nonspecific binding of dye-labeled conjugates in assays and detection applications.

4. React overnight at 4°C in the dark.
5. Remove excess fluorescein by gel filtration using a column of Sephadex G-25.

4.2. Modification with Lissamine Rhodamine B Sulfonyl Chloride

Rhodamine derivatives are popular probes to use in tandem with fluorescein labels. The Lissamine derivatives of rhodamine (Chapter 10, Section 2) are intensely

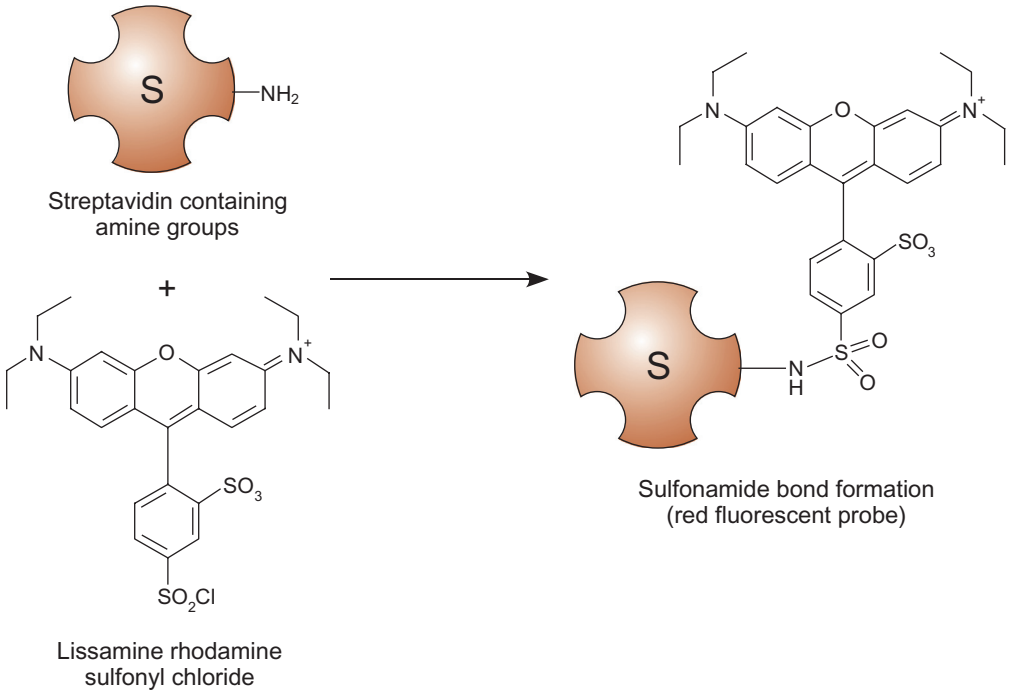

FIGURE 11.7 Streptavidin can be labeled with Lissamine rhodamine sulfonyl chloride to form a fluorescent probe.

fluorescent, strongly emitting in the red region of the spectrum. The red luminescence of Lissamine rhodamine contrasts sharply with the green emission of fluorescein derivatives. Lissamine rhodamine B sulfonyl chloride can be used to modify proteins at their ε- and N-terminal amine functional groups. The resultant derivatives are linked through stable sulfonamide bonds, resulting in rhodamine's fluorescent character being incorporated into the modified molecules. (Strept)avidin derivatives of this fluorophore are particularly popular for use in fluorescent assay systems (Figure 11.7).

Protocol

1. Dissolve (strept)avidin in 0.1-*M* sodium carbonate/bicarbonate buffer, pH 9.0, at a concentration of 1 to 5 mg/ml.
2. Dissolve Lissamine rhodamine B sulfonyl chloride in DMF at a concentration of 1 to 2 mg/ml. Protect from light and use immediately. Do not use DMSO as the solvent, as sulfonyl chlorides react with it.
3. In a darkened lab and with gentle mixing, slowly add 50 to 100 µl of the fluorophore solution to each ml of the (strept)avidin solution.

Note: Determine the optimal level of dye labeling experimentally to avoid over-labeling, which can cause fluorescent quenching, nonspecific binding in assays, or even precipitation of the conjugate. For hydrophobic dyes, a reaction including no more than about a 5-fold mole excess of dye over the amount of (strept)avidin in solution may result in the best performing conjugate.

4. React for 1 h at room temperature in the dark.
5. Remove excess fluorophore by gel filtration using a column of Sephadex G-25 or by dialysis.

Modification of (strept)avidin with Texas Red sulfonyl chloride may be done similarly, except the fluorophore is first dissolved in acetonitrile prior to addition to the aqueous reaction mixture.

4.3. Modification with AMCA–NHS

AMCA derivatives possess fluorescent properties within the blue region of the visible spectrum (Chapter 10, Section 3). Their emission range is well removed from other common fluorophores, making them excellent choices for use in double-labeling techniques, for example with fluorescein-labeled molecules. Coumarin-based fluorescent probes are very good donors for excited-state energy transfer to fluorescein dye derivatives. AMCA–NHS reacts with amine-containing molecules to result in stable amide-bond derivatives (Figure 11.8). (Strept)avidin may be labeled with this reagent to give probes useful for immunohistochemical staining of biotinylated targeting molecules. AMCA-labeled proteins are fairly stable to photoquenching and exhibit a large Stokes shift, allowing sensitive measurements to be made without interference from scattered excitation light.

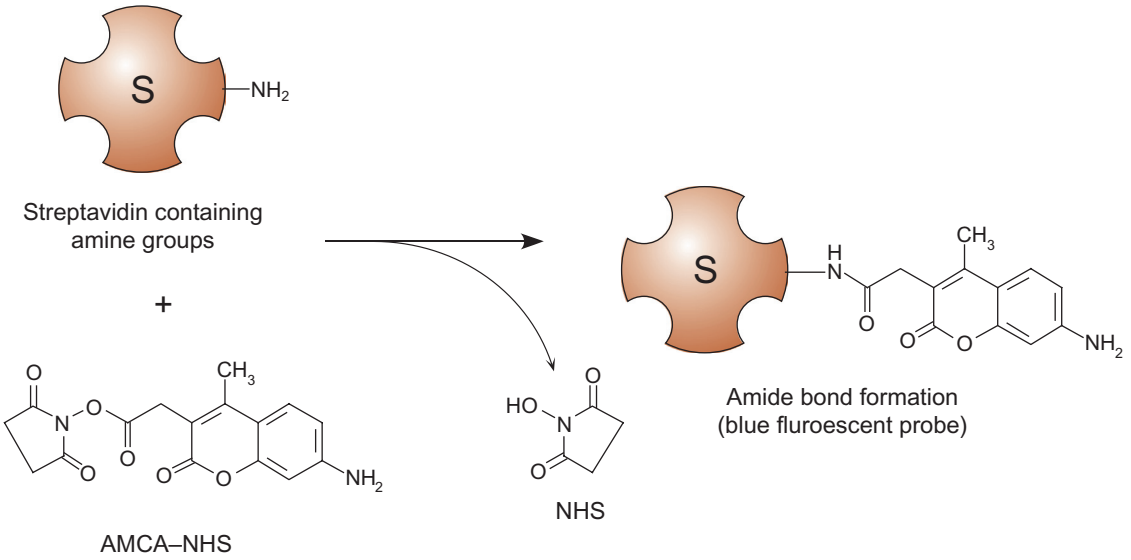

FIGURE 11.8 AMCA–NHS reacts with the amine groups of streptavidin to produce amide bonds.

Protocol

1. Dissolve (strept)avidin) in 50-m*M* sodium borate, pH 8.5, at a concentration of 10 mg/ml. Other buffers may be used for an NHS ester reaction, including 0.1-*M* sodium phosphate, pH 7.5 (Chapter 3, Section 1.4).
2. Dissolve AMCA–NHS (Thermo Fisher) in DMSO at a concentration of 2.6 mg/ml. Protect from light.
3. In subdued lighting conditions, slowly add 50–100 µl of the AMCA–NHS stock solution to each ml of the (strept)avidin solution, with gentle mixing.

Note: The optimal level of fluorescent labeling should be determined experimentally to obtain the best conjugate in the intended application. Avoid over-labeling as this may cause conjugate precipitation or nonspecific binding in assays. Relatively hydrophobic dyes may perform best if the substitution level of the conjugate is not greater than about three to five dyes per (strept)avidin molecule.

4. React for 1 h at room temperature in the dark.
5. Remove excess reagent and reaction byproducts by gel filtration using a column of Sephadex G-25 or by dialysis.

4.4. Conjugation with Phycobiliproteins

Phycobiliproteins are incredibly fluorescent due to their multiple chromophoric bilin prosthetic groups, conferring extremely high absorbance coefficients to each protein molecule (Chapter 10, Section 7). Conjugates of these biliproteins with targeting molecules form extraordinarily luminescent probes. Labeling with phycobiliprotein derivatives can provide absorption coefficients 30-fold higher than labeling with small, synthetic fluorophores. Their ability to be monitored by fluorescing in the red region of the spectrum decreases potential interferences from indigenous biological fluorescence. Phycoerythrin-labeled (strept)avidin probes can be used in double-staining procedures with a fluorescein-labeled antibody, detecting two antigens in the same tissue section simultaneously by excitation at 488 nm (Feller *et al.*, 1983; Agata *et al.*, 2012).

The bilin content of these fluorescent proteins ranges from a low of 4 prosthetic groups in C-phycocyanin to the 34 groups of B- and R-phycoerythrin. Phycoerythrin derivatives, therefore, can be used to create the most intensely fluorescent probes possible using these proteins. (Strept)avidin–phycoerythrin conjugates, for example, have been used to detect as few as 100 biotinylated antibodies bound to receptor proteins per cell (Zola *et al.*, 1990).

Conjugates of (strept)avidin with these fluorescent probes may be prepared by activation of the phycobiliprotein with SPDP to create a sulfhydryl-reactive derivative, followed by modification of (strept)avidin with 2-iminothiolane or SATA (Chapter 2, Section 4.1) to create the free sulfhydryl groups necessary for conjugation. The protocol for SATA modification of (strept) avidin can be found in Section 3.1, this chapter. The procedure for SPDP activation of phycobiliproteins can be found in Chapter 10, Section 7. Reacting the SPDP-activated phycobiliprotein with thiol-labeled (strept) avidin at a molar ratio of 2:1 will result in highly fluorescent biotin-binding probes.

Other fluorescent probes may also be used to label (strept)avidin molecules for detection of biotinylated

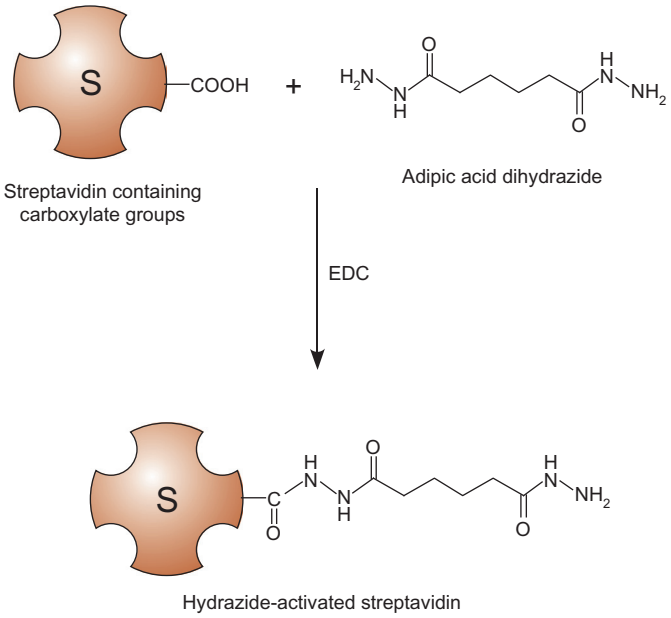

FIGURE 11.9 Reaction of adipic acid dihydrazide with streptavidin produces a hydrazide derivative that is highly reactive toward periodate-oxidized polysaccharides.

targeting molecules. Chapter 10 reviews many additional fluorescent labels, such as quantum dots, lanthanide chelates, and cyanine dye derivatives, all of which may be used in similar protocols to create detection conjugates for (strept)avidin–biotin-based assays.

5. PREPARATION OF HYDRAZIDE ACTIVATED (STREPT)AVIDIN

Hydrazide groups can react with aldehydes or ketones to form hydrazone linkages (Chapter 3, Section 5.1). Proteins may be labeled with hydrazide residues by reaction of their indigenous carboxylate groups with *bis*-hydrazine compounds such as adipic acid dihydrazide or carbohydrazide (Chapter 5, Section 8). A carbodiimide-mediated reaction between the protein and the *bis*-hydrazine reagent forms diimide-bond derivatives terminating in hydrazide groups (Figure 11.9). (Strept)avidin labeled with adipic acid dihydrazide can form the basis of a carbohydrate detection system using the (strept)avidin–biotin interaction (Bayer *et al.*, 1987, 1990; Bayer and Wilchek, 1990). Glycoconjugates in tissue sections, cells, or blots may be treated with sodium periodate or galactose oxidase to create aldehyde groups on the associated sugar components. Introduction of hydrazide-activated (strept)avidin causes hydrazone bonds to form between the hydrazides and aldehydes, thus specifically targeting glycoproteins and other carbohydrate-containing molecules. Subsequent detection with a biotinylated enzyme allows precise localization of glycoconjugates. Detection in a single step using this strategy is possible using preformed complexes of hydrazide-activated (strept)avidin and a biotinylated enzyme (Figure 11.10).

The activation of (strept)avidin with adipic dihydrazide may be done using the method of Bayer *et al.* (1987). A summary of this protocol is given below.

Protocol

1. Dissolve 160 mg of adipic acid dihydrazide (Aldrich) in 5 ml of 0.1-*M* sodium phosphate, pH 6.0. Some heating of the tube under a hot-water tap may be required to help solubilize the compound. Cool to room temperature.
2. Dissolve 50 mg of (strept)avidin in the adipic acid dihydrazide solution.
3. Add 160 mg of the water soluble carbodiimide EDC (Thermo Fisher) (Chapter 4, Section 1.1) to the solution, and mix to dissolve.
4. React for 4 h at room temperature.
5. Dialyze against PBS, pH 7.2, to remove excess reagent and reaction byproducts.

Hydrazide-activated (strept)avidin may be stored as a freeze-dried preparation without loss of activity.

6. BIOTINYLATION TECHNIQUES

The highly specific interaction of (strept)avidin with the small vitamin biotin can be a useful tool in designing assay, detection, and targeting systems for biological analytes (see Sections 1 and 2). The extraordinary affinity of (strept)avidin's interaction with biotin allows biotin-containing molecules in complex mixtures to be discretely bound with (strept)avidin conjugates. If the (strept)avidin–biotin complex contains detection components, then the targeted analytes can be located or quantified. This assay concept is made possible through the ability of biotin to be covalently attached to other targeting molecules, such as antibodies. In this sense, biotin derivatives may be prepared which contain reactive portions able to couple with particular functional groups in proteins and other molecules. Biotin modification of secondary molecules, called *biotinylation*, results in covalent derivatives containing one or more bicyclic biotin rings extending from the parent structure. These biotinylation sites are still capable of binding avidin or streptavidin with the specificity and nearly the same avidity of free biotin in solution. Since the biotin components are relatively small, macromolecules can be modified with these reagents without significantly affecting their physical or chemical properties (Della-Penna *et al.*, 1986). Proteins, carbohydrates, lipid molecules, and nucleic acids can be modified to

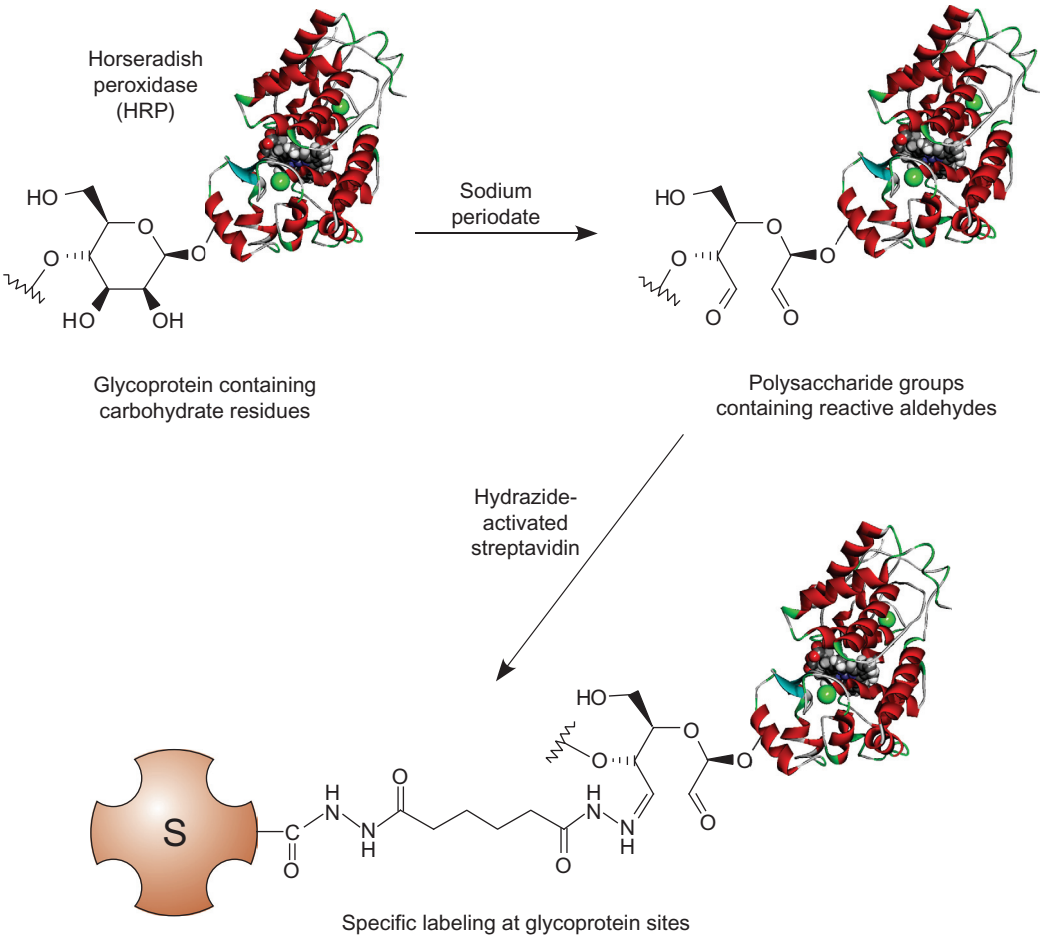

FIGURE 11.10 Glycoproteins can be oxidized with sodium periodate to generate aldehyde residues. These may be specifically labeled using a hydrazide–streptavidin derivative through hydrazone bond formation. Subsequent detection may be done using biotinylated enzymes.

contain one or more biotins able to strongly interact with (strept)avidin. The technique of biotinylation is made easier through the commercial availability of a range of different biotin derivatives having a number of important reactivity and property characteristics useful in (strept)avidin–biotin chemistry.

The basic design of a biotin labeling compound is illustrated in Figure 11.11. Common to all such modification reagents is the presence of the bicyclic biotin ring at one end of the structure and a reactive group at the other end that can be used to couple with other molecules. Biotinylation reagents also possess various cross-bridges or spacer groups built off the valeric acid side chain of the molecule. Since the binding sites for biotin on avidin and streptavidin are pockets buried about 9 Å beneath the surface of the proteins, spacers can affect the accessibility of biotinylated compounds for efficiently binding avidin or streptavidin conjugates (Green *et al.*, 1971). In some applications, the use of a long spacer arm in the biotinylation reagent will result in the greatest potential assay sensitivity. The rate of binding

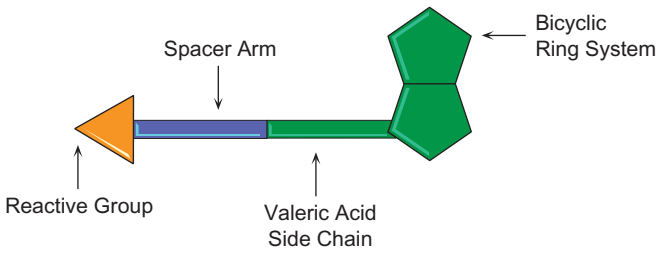

FIGURE 11.11 The basic design of a biotinylation reagent includes the bicyclic rings and valeric acid side chain of D-biotin at one end and a reactive group to couple with target groups at the other end. Spacer groups may be included in the design to extend the biotin group away from modified molecules, thus ensuring better interaction capability with avidin or streptavidin probes.

of an avidin or streptavidin probe to a biotinylated molecule is also affected by the length of spacer in the biotinylation reagent. When longer spacers are utilized to make biotinylated macromolecules, it can potentially result in a 5-fold greater rate of streptavidin interaction (Bonnard *et al.*, 1984).

Biotinylation reagents containing spacers can be subdivided into several categories: (1) aliphatic spacers, (2) PEG-based spacers, and (3) cleavable or noncleavable. The aliphatic spacer arms typically consist of hydrocarbon chains, which may be substituted with amide bonds or disulfide linkages. These spacers increase the length of the biotin group from a modified protein, but they may also confer considerable hydrophobicity to the biotinylation agent and molecules labeled with them. In fact, many biotinylated proteins may have a tendency to aggregate in solution or even precipitate due to the overall increased hydrophobicity of the biotin modifications. By contrast, biotinylation compounds built using hydrophilic PEG-based spacers have excellent water-solubility properties and have little or no tendency to aggregate or precipitate in solution. When using biotinylation agents having aliphatic spacers, such as the popular NHS–LC-biotin, it is therefore advantageous to keep the level of biotin modification at a minimum to avoid nonspecific binding, aggregation, or precipitation caused by the reagent. Antibodies biotinylated using such biotin compounds often do well if there are only one to three biotin groups per antibody molecule; however, higher modification levels can quickly cause stability problems as well as nonspecific binding in assays. This problem is circumvented by use of the hydrophilic biotin compounds containing a PEG spacer arm. Even over-biotinylation of an antibody with a PEG-based reagent usually won't result in precipitation, especially if the length of the PEG spacer is at least PEG_4 or greater. These hydrophilic biotins are discussed in detail in Chapter 18, Section 1.3.

Another variable to consider in choosing biotinylation reagents is the use of a biotin analog such as iminobiotin that has a moderated affinity constant in its binding of avidin or streptavidin (Section 6.2, this chapter). Analogs may be useful if release of the (strept)avidin–biotin bond is important for isolating a targeted analyte. Using native biotin, the interaction with avidin is so strong that up to 6- to 8-*M* guanidine at pH 1.5 is required to break the bond, possibly causing extensive denaturation of any other complexed molecules. By contrast, iminobiotinylated molecules can be released simply by adjusting the pH down to 4.

The following sections discuss some of the more common biotinylation reagents available for modification of proteins and other biomolecules. Each biotin derivative contains a reactive portion (or can be made to contain a reactive group) that is specific for coupling to a particular functional group on another molecule. Careful choice of the correct biotinylation reagent can result in directed modification away from active centers or binding sites, and thus preserve the activity of the modified molecule.

6.1. Determination of the Level of Biotinylation

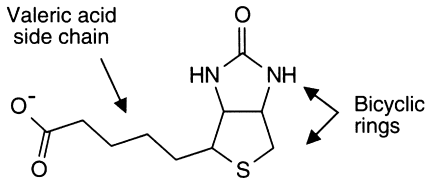
It is often important to determine the extent of biotin modification after a biotinylation reaction is complete. Measuring biotin incorporation into macromolecules can aid in optimizing a particular (strept)avidin–biotin assay system. It can also be used to ensure reproducibility in the biotinylation process. The most common method of measuring the degree of biotinylation makes use of the HABA dye assay (Green, 1965). HABA is 4′-hydroxyazobenzene-2-carboxylic acid. In the absence of biotin, the dye is capable of specifically forming noncovalent complexes with (strept)avidin at its biotin-binding sites. Upon binding to (strept)avidin in aqueous solution, HABA exhibits a characteristic absorption band at 500 nm ($\varepsilon = 35{,}500\,M^{-1}cm^{-1}$, expressed as per mole of HABA bound). The addition of biotin to this complex results in displacement of HABA from the binding site, since the affinity constant of the (strept)avidin–biotin interaction ($1.3 \times 10^{15}\,M^{-1}$) is much greater than that for (strept)avidin–HABA ($6 \times 10^{6}\,M^{-1}$). As HABA is displaced, the absorbance of the complex decreases proportionally. Thus, the amount of biotin present in the solution can be determined by plotting the (strept)avidin–HABA absorbance at 500 nm *versus* the absorbance modulation with increasing concentrations of added biotin. Comparing an unknown biotin-containing sample to this standard response curve, can result in the determination of the biotin concentration in the sample.

Since a biotinylated molecule potentially is able to interact with (strept)avidin at its biotin-binding sites just as strongly as biotin in solution, the degree of biotinylation may be determined using the HABA method as well. Comparison of the response of a biotinylated protein, for example, with a standard curve of various biotin concentrations allows calculation of the molar ratio of biotin incorporation.

Two variations of the HABA–dye assay for biotinylated proteins are possible. In one approach, the biotinylated protein is digested using the enzyme pronase prior to doing the assay. The digestion process breaks the protein into small fragments, some of which possess biotin modifications. The digestion is done to eliminate any sterically hindered biotinylation sites from not being able to interact with (strept)avidin. The second approach merely uses the intact biotinylated protein in the assay, assuming that the HABA assay results will then provide a truer picture of the level of *accessible* biotin sites on the molecule. Pronase addition obviously is not necessary for assessing biotinylated molecules which are not proteins.

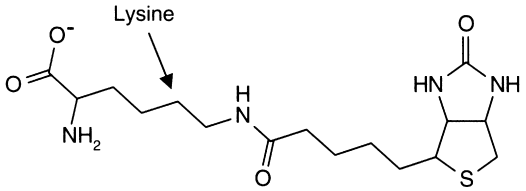
The following protocol describes both of these HABA-based tests for determining the level of biotinylation.

Protocol



1. Dissolve (strept)avidin in 0.05-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.0, at a concentration of 0.5 mg/ml. A total of 3 ml of the (strept)avidin solution is required to create a standard curve using known concentrations of biotin and an additional 3 ml is needed for each sample determination.
2. Dissolve the HABA dye (Sigma) in 10-m*M* NaOH at a concentration of 2.42 mg/ml (10-m*M*). Prepare about 100 µl of the HABA solution for each 3-ml portion of (strept)avidin solution required.
3. Dissolve the biotinylated protein to be measured in 0.05-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.0, at a concentration of 10 to 20 mg/ml. The amount required is about 100 µl of sample per determination.
4. Dissolve D-biotin in 0.05-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.0, at a concentration of 0.5-m*M*.
5. For the proteolytic digestion procedure, dissolve pronase in water at a concentration of 1% (w/v).
6. If pronase digestion of the biotinylated protein is to be carried out, heat 100 µl of the sample at 56°C for 10 min, then add 10 µl of the pronase solution. Allow the sample to digest enzymatically at room temperature overnight. If no pronase digestion is desired, simply use the biotinylated protein solution prepared in step three without further treatment.
7. To construct a standard curve of various biotin concentrations, first zero a spectrophotometer at an absorbance setting of 500 nm with sample and reference cuvettes filled with 0.05-*M* sodium phosphate, 0.15-*M* NaCl, pH 6.0. Remove the buffer solution from the sample cuvette and add 3 ml of the (strept)avidin solution plus 75 µl of the HABA dye solution. Mix well and measure the absorbance of the solution at 500 nm. Next add 2-µl aliquots of the biotin solution to this (strept)avidin–HABA solution, mix well after each addition, and measure and record the resultant absorbance change at 500 nm. With each addition of biotin, the absorbance of the (strept) avidin–HABA complex at 500 nm decreases. The absorbance readings are plotted against the amount of biotin added to construct the standard curve.
8. To measure the response of the biotinylated protein sample, add 3 ml of the (strept)avidin solution plus 75 µl of the HABA dye to a cuvette. Mix well and measure the absorbance of the solution at 500 nm. Next, add a small amount of sample to this solution and mix. Record the absorbance at 500 nm. If the change in absorbance due to sample addition was not sufficient to obtain a significant difference from the initial (strept)avidin–HABA solution, add another portion of sample and measure again. Determine the amount of biotin present in the protein sample by using the standard curve. The number of moles of biotin divided by the moles of protein present gives the number of biotin modifications on each protein molecule.

6.2. Amine-Reactive Biotinylation Agents



Amine-reactive biotinylation reagents contain reactive groups off biotin's valeric acid side chain that are able to form covalent bonds with primary amines in proteins and other molecules. Two basic types are commonly available: NHS esters and carboxylates. NHS esters spontaneously react with amines to form amide linkages (Chapter 3, Section 1.4), whereas carboxylate-containing biotin compounds can be coupled to amines *via* a carbodiimide-mediated reaction using EDC (Chapter 4, Section 1.1).

D-Biotin and Biocytin

D-Biotin (hexahydro-2-oxo-1 H-thieno[3,4-d]imidazole-4-pentanoic acid) is a naturally occurring growth factor present in small amounts within every cell. It is a key component in numerous processes involving carboxylation reactions, wherein it functions as a cofactor and transporter of CO_2 (coenzyme R). Biotin is mainly found covalently attached to lysine ε-amine groups of proteins *via* its valeric acid side chain. The compound was originally discovered through symptoms of deficiency caused by eating too many raw egg-whites. Biotin (or vitamin H) was found to be complexed and inactivated by the egg-white protein avidin (Boas, 1927; du Vigneaud, 1940). Treatment with additional vitamin H alleviated the symptoms.

D-Biotin
MW 244.31

Biocytin
MW 372.48

The interaction of biotin with the proteins avidin and streptavidin is among the strongest noncovalent affinities known (Ka = $10^{15} M^{-1}$). The binding occurs between the bicyclic ring of biotin and a pocket within each of the four subunits of the proteins. The valeric acid portion is not directly involved with the interaction with avidin (Green, 1975; Wilchek and Bayer, 1988), but elimination of its carboxylate group or changing the amide linkage in biotinylation compounds can affect its affinity for (strept)avidin. Amide derivatives of biotin's valeric acid group, however, can be made without interfering with its high-affinity interactions. This characteristic allows modification of the valeric acid side chain without affecting the binding potential toward avidin or streptavidin.

D-Biotin is thus the basic building block for constructing biotinylation reagents. The molecule may be attached directly to a protein *via* its valeric acid side chain or derivatized at this carboxylate with other organic components to create spacer arms and various reactive groups. Reaction of biotin with primary amine groups on proteins can be done using the water soluble carbodiimide EDC (Chapter 4, Section 1.1). EDC activates the carboxylate to create a highly reactive, intermediate ester. This ester can then couple to amines to form stable amide bond derivatives (Figure 11.12). Biotinylated molecules thus formed retain the ability to bind avidin or streptavidin with high affinity.

The only potential deficiency in using D-biotin to directly modify a protein is the relatively short spacer arm afforded by the indigenous valeric acid group. Some applications may require longer spacers to maintain good binding potential toward avidin or streptavidin.

Biocytin is ε-*N*-biotinyl-L-lysine, a derivative of D-biotin containing a lysine group coupled at its ε-amino side chain to the valeric acid carboxylate. It is a naturally occurring complex of biotin that is typically found in serum and urine, and probably represents breakdown products of recycling biotinylated proteins. The enzyme biotinidase specifically cleaves the lysine residue and releases the biotin component from biocytin (Ebrahim and Dakshinamurti, 1986, 1987).

Biocytin has been used extensively as a labeling reagent for intracellular components within neurons (Horikawa and Armstrong, 1988; King *et al.*, 1989; Izzo, 1991; Granata and Kitai, 1992). It is particularly good for anterograde tracing studies in the central nervous system, since it can be easily injected into neurons using micropipettes. Subsequent visualization of biocytin locations may be achieved using a (strept)avidin–enzyme conjugate (Section 3, this chapter).

Biocytin should not be used in a carbodiimide reaction to modify proteins or other molecules, since it contains both a carboxylate and an amine group. A carbodiimide-mediated reaction, as suggested for D-biotin previously, would cause self-conjugation and polymerization of this reagent.

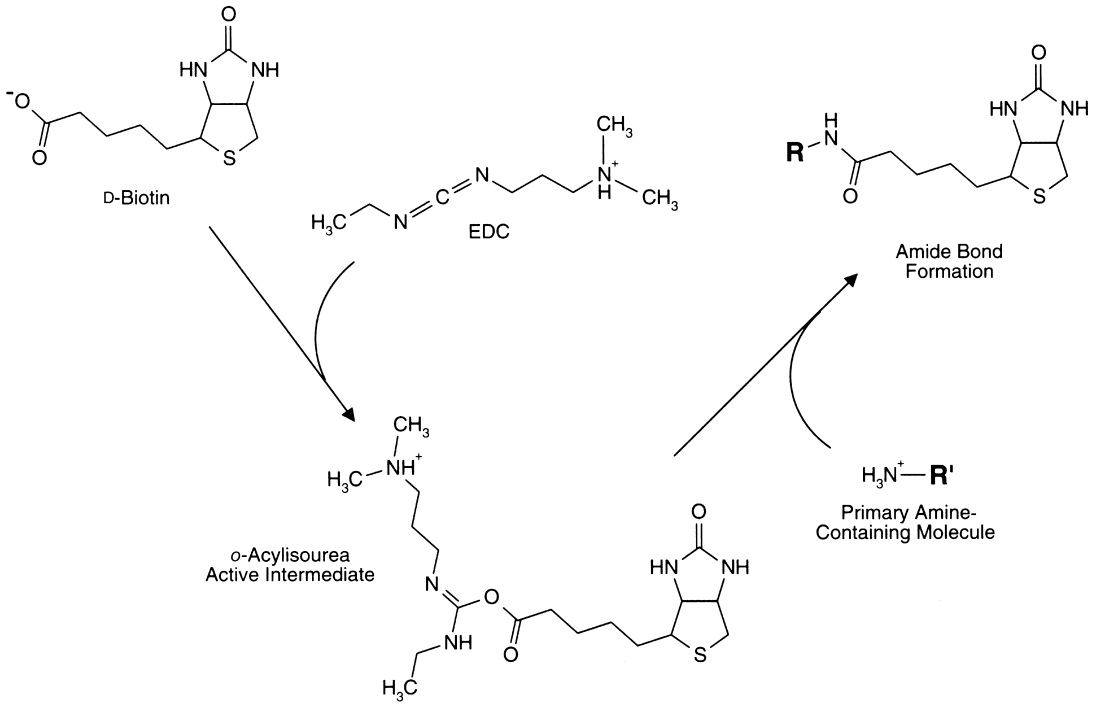


FIGURE 11.12 D-Biotin can be directly coupled to amine-containing molecules using the water soluble carbodiimide EDC to form an amide bond linkage.

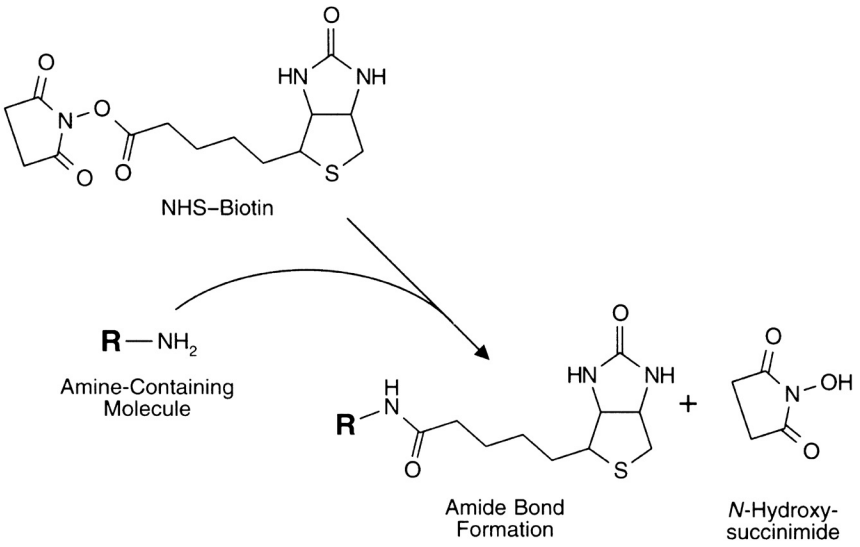

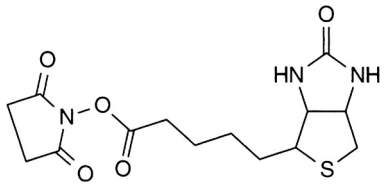

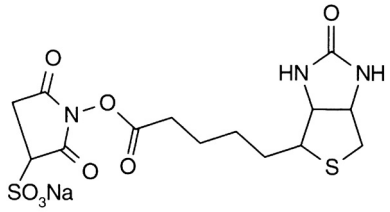

FIGURE 11.13 The active ester group of NHS–biotin reacts with amine-containing compounds to form amide bond linkages.

Biocytin, however, can form the basis for constructing trifunctional crosslinking reagents (Chapter 7). The lysine component of the molecule contains a free carboxylate and an α-amine group that can be used to build spacers and reactive groups for crosslinking purposes. The biotin component is the third arm of the trifunctional system, retaining its ability to bind (strept)avidin probes after conjugation has occurred at its other two ends. Such a trifunctional derivative has been used to study the hormone binding site of the insulin receptor (Wedekind *et al.*, 1989). This compound, 4-azido-2-nitrophenyl-biocytin-4-nitrophenyl ester, contains an amine-reactive group and a photoreactive phenyl azide functionality (Chapter 7, Section 1). The nitrophenyl ester reacts with amines on proteins and other molecules to from stable amide linkages. Once a molecule is modified in this manner, it contains both a photosensitive group and a biotin handle for conjugation and detection, respectively. Interaction of the modified protein with another protein followed by subsequent photolysis with UV light will result in covalent crosslinking. Localization and detection of the crosslinked molecules can then be done using an avidin or streptavidin conjugate. Another trifunctional compound, sulfo-SBED (or sulfosuccinimidyl-2-[6-(biotinamido)-2-(pazidobenzamido) hexanoamido] ethyl-1,39-dithiopropionate), is also based on a biocytin core (Chapter 7, Section 2). Additional information on the properties and use of these trifunctional biotin compounds based upon biocytin is described in Chapter 7 and in Chapter 24, Section 3, related to the study of protein interactions.

NHS–Biotin and Sulfo-NHS–Biotin

The valeric acid carboxylate of D-biotin may be activated to an NHS ester for direct modification of amine groups in proteins and other molecules. NHS esters react by nucleophilic attack of an amine on the carbonyl group, releasing the NHS group and forming a stable amide linkage (Chapter 3, Section 1.4) (Figure 11.13). NHS–biotin is the simplest biotinylation reagent available. Modification reactions are carried out under mildly alkaline conditions, and they usually result in a high efficiency of biotin incorporation.

NHS–biotin is insoluble in aqueous environments. It must be dissolved first in organic solvent as a concentrated stock solution and an aliquot added to an aqueous reaction medium to facilitate dissolution. Organic solvents such as dimethylformamide (DMF) or dimethyl sulfoxide (DMSO) are suitable for this

purpose. Addition of an NHS–biotin solution to a reaction should not exceed a level of about 10% organic solvent in the buffer to avoid protein precipitation problems or precipitation of the buffer salt itself. Once added to the reaction medium, NHS–biotin may appear as a cloudy or hazy suspension, indicating incomplete solubility. However, such micro-dispersions are still effective at modification, often driving the bulk of the reagent into solution as the NHS ester reacts. Biotinylation of peptides or other molecules that are water insoluble may be carried out completely in organic solvent. For example, insulin can be biotinylated with NHS–biotin in an organic medium (Hofmann *et al.*, 1977).

A water soluble analog of NHS–biotin containing a negatively charged sulfonate group on its NHS ring structure is also available. Sulfo-NHS–biotin may be added directly to aqueous reactions without the need for organic solvent dissolution. A concentrated stock solution may be prepared in water to facilitate the addition of a small quantity to a reaction, but hydrolysis of the NHS ester will occur at a rapid rate, so the solution must be used immediately. This reagent is widely used to biotinylate antibodies and proteins for subsequent detection using streptavidin-based conjugates or for capture on immobilized streptavidin resins, especially in pull-down assays (Lei *et al.*, 2012; Wu *et al.*, 2012) (Chapter 15).

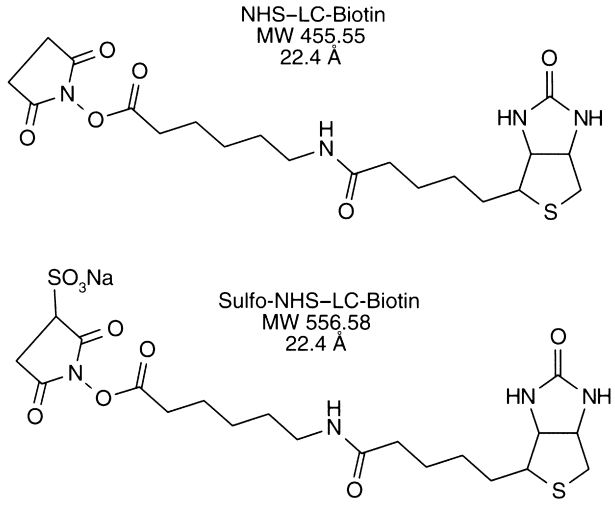
The only disadvantage to the use of NHS–biotin or sulfo-NHS–biotin is the lack of a long spacer group off the valeric acid side chain. Since the binding site for biotin on avidin and streptavidin is somewhat below the surface of the proteins, some biotinylated molecules may not interact as efficiently with (strept)avidin as when longer cross-bridges are used (Green *et al.*, 1971; Bonnard *et al.*, 1984).

NHS esters of D-biotin have been used in many applications, including the biotinylation of rat IgE to study receptors on murine lymphocytes (Lee and Conrad, 1984), in the development of an immunochemical assay for a post-synaptic protein and its receptor (LaRochelle and Froehner, 1986), in the study of plasma membrane domains by biotinylation of cell surface proteins in *Dictyostelium disoideum* amoebas (Ingalls *et al.*, 1986), and for the detection of blotted proteins on nitrocellulose membranes after transfer from polyacrylamide electrophoresis gels (LaRochelle and Froehner, 1986b).

The following protocol is a generalized method for the biotinylation of a protein using sulfo-NHS–biotin.

Protocol

1. Dissolve the protein to be biotinylated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 to 7.5, at a concentration of 1 to 10 mg/ml.
2. Immediately before use, dissolve sulfo-NHS–biotin (Thermo Fisher) in water at a concentration of 20 mg/ml. Alternatively, the compound may be dissolved in organic solvent to prevent hydrolysis prior to a reaction (i.e., dry DMF or DMSO). Adjust the concentration and quantity of this stock solution to be prepared according to the amount of reagent needed to biotinylate the desired amount of protein. If prepared in water, the sulfo-NHS–biotin stock solution must be used immediately, since the NHS ester is subject to hydrolysis in aqueous environments.
3. With mixing, add a quantity of the sulfo-NHS–biotin solution to the protein solution to obtain a 5- to 10-fold molar excess of biotinylation reagent over the quantity of protein present. For instance, for an immunoglobulin (MW 150,000) at a concentration of 10 mg/ml, 10 µl of a sulfo-NHS–biotin solution (containing 8×10^{-4} mmoles) should be added per ml of antibody solution to obtain a 6-fold molar excess. For more dilute protein solutions (e.g., 1–2 mg/ml), an increased amount of biotinylation reagent may be required (e.g., >10-fold molar excess) to obtain similar incorporation yields as when using more concentrated protein solutions.



Note: To obtain biotinylation densities in the range of one to five biotins per protein, use no more than a 5-fold mole excess of biotinylation reagent over the concentration of protein present in the reaction. Some optimization may have to be done to obtain the best biotinylation level for use in the anticipated application.

4. React for 30 to 60 min at room temperature.
5. Purify the biotinylated protein from excess reagent and reaction byproducts by gel filtration using a desalting resin or by dialysis against PBS.

Determination of the degree of biotinylation can be done using the HABA assay (Section 6.1, this chapter).

NHS–LC-Biotin and Sulfo-NHS–LC-Biotin

NHS–LC-biotin is a derivative of D-biotin containing a spacer arm off the valeric acid side chain, terminating in an NHS ester. The compound is also known as succinimidyl-6-(biotinamido)hexanoate or NHS-X-biotin. The 6-aminocaproic acid spacer provides greater length between a covalently modified molecule and the bicyclic biotin rings. The total distance from an attached molecule to the biotin component is about 22.4 Å, significantly greater than the 13.5-Å length of NHS–biotin without a spacer arm. This increased distance can result in better binding potential for avidin or streptavidin probes, because the binding sites on these proteins are buried relatively deep inside the surface plane.

The NHS ester end of NHS–LC-biotin reacts with amine groups in proteins and other molecules to form stable amide-bond derivatives (Figure 11.14). Optimal reaction conditions are at a pH of 7 to 9, but the higher the pH the greater will be the hydrolysis rate of the ester. Avoid amine-containing buffers that will compete in the acylation reaction. NHS–LC-biotin is insoluble in aqueous reaction conditions and must be solubilized in organic solvent prior to the addition of a small quantity to a buffered reaction. Preparation of concentrated stock solutions may be carried out in DMF or DMSO. Nonaqueous reactions may also be carried out with this reagent for the modification of molecules insoluble in water. The molar ratio of NHS–LC-biotin to a protein in a reaction can be from about 2:1 to about 50:1, with higher levels resulting in better incorporation yields (Gretch *et al.*, 1987).

In a study comparing NHS–LC-biotin with two other derivatives of biotin, NHS–SS-biotin (Section 6.2, this chapter) and biotin hydrazide (Section 6.4, this chapter), it was found that modification through amines on monoclonal antibodies resulted in 2.5 times more activity in binding a streptavidin–agarose affinity column than when modification of carbohydrate residues using hydrazide conjugation chemistry was done (Gretch *et al.*, 1987). This was probably due to the greater abundance of amino groups over polysaccharide residues on these antibodies or the limited accessibility of the glycan between the heavy chains in the Fc region.

NHS–LC-biotin can be used to add a biotin tag to monoclonal antibodies directed at certain tumor antigens. The biotinylated monoclonals are allowed to bind to the tumor cell surfaces *in vivo*, and subsequent administration of an avidin or streptavidin conjugate can form the basis for inducing cytotoxic effects or creating traceable complexes for use in imaging techniques (Hnatowich *et al.*, 1987).

The reagent has also been used in a unique tRNA-mediated method of labeling proteins with biotin for nonradioactive detection of cell-free translation products (Kurzchalia *et al.*, 1988), in creating one- and two-step noncompetitive avidin–biotin immunoassays (Vilja, 1991), for immobilizing streptavidin onto solid surfaces using biotinylated carriers with subsequent use in a protein avidin–biotin capture system (Suter and Butler, 1986), and for the detection of DNA on nitrocellulose blots (Leary *et al.*, 1983).

Sulfo-NHS–LC-biotin, a water soluble analog of NHS–LC-biotin, is also available (Thermo Fisher), which contains a negatively charged sulfonate group on its NHS ring structure. The presence of the negative

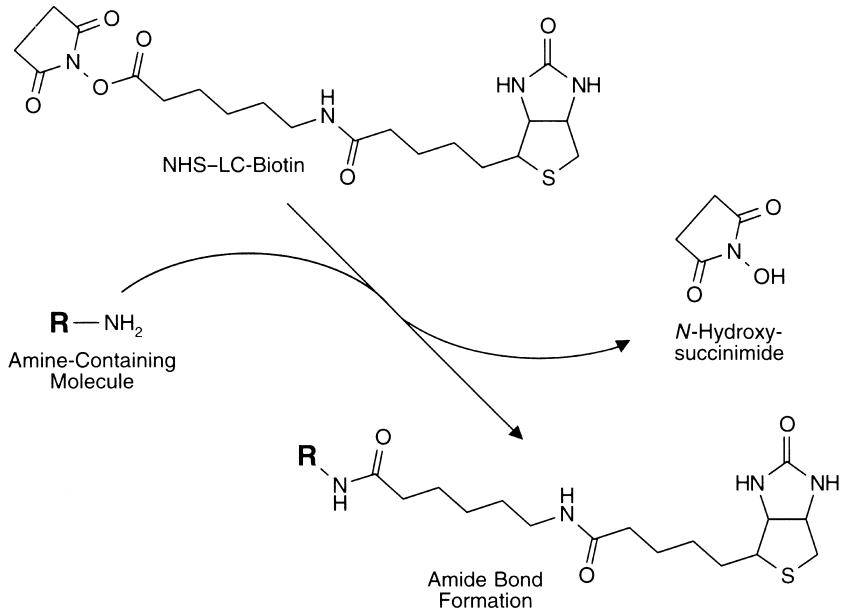


FIGURE 11.14 NHS–LC-biotin provides an extended spacer arm to allow greater distance between the biotin rings and a modified molecule. Reaction with amines forms amide linkages.

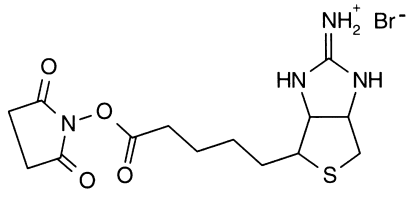
charge creates enough polarity within the molecule to allow direct solubility in aqueous reaction mediums. All other properties of the sulfonated version of the reagent are the same as those of NHS–LC-biotin. Sulfo-NHS–LC-biotin has been used to develop a dual-labeling method for virus imaging (Liu *et al.*, 2012), as a biotinylation agent having reduced membrane permeability for cell labeling (Strassberger *et al.*, 2011), and to develop a pull-down assay to investigate pore opening in ion channels (Tolino *et al.*, 2011).

Although NHS–LC-biotin and sulfo-NHS–LC-biotin are very popular reagents for biotinylation, they both result in hydrophobic aliphatic biotin modifications on proteins and antibodies. Unfortunately, these groups have a tendency to aggregate in aqueous solution and may cause protein precipitation or loss of activity over time, even when using low amounts of biotin substitution. Many commercial applications of biotinylated antibodies, for instance, use a low substitution level of biotin to avoid the aggregation issue as much as possible. As an alternative, the use of more hydrophilic PEG-based biotin compounds of approximately the same spacer length are a better choice for maintaining water solubility of modified proteins (Chapter 18, Section 1.3).

The following protocol is a suggested method for the biotinylation of proteins with either NHS–LC-biotin or sulfo-NHS–LC-biotin.

Protocol



1. Dissolve the protein to be biotinylated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 to 7.5, at a concentration of 10 mg/ml.
2. Dissolve NHS–LC-biotin (Thermo Fisher) in dry DMF at a concentration of 40 mg/ml. This stock solution is stable for reasonable periods, although long-term storage is not recommended. For use of the water soluble sulfo-NHS–LC-biotin, a stock solution may be prepared in either organic solvent or water. If a solution in water is made to facilitate the addition of a small quantity of reagent to a reaction, then the solution should be prepared quickly and used immediately to prevent hydrolysis of the NHS ester. Sulfo-NHS–LC-biotin may be dissolved in water at a concentration of 20 mg/ml.
3. Add 50 µl of the NHS–LC-biotin solution in DMF to each ml of the protein solution in two aliquots apportioned 10 min apart. Alternatively, add a quantity of the sulfo-NHS–biotin solution prepared in water to the protein solution to obtain a 5- to 10-fold molar excess of biotinylation reagent over the quantity of protein present. For instance, for an immunoglobulin (MW 150,000) at a concentration of 10 mg/ml, 10 µl of the sulfo-NHS–biotin solution (8×10^{-4} mmoles) should be added per ml of antibody solution to obtain a 6-fold molar excess.

Note: To obtain a lower level of biotinylation (better to maintain solubility and avoid aggregation of biotinylated proteins), react the biotin compound at a level of no more than a 5-fold mole excess over the amount of protein present in the reaction medium.

4. React for a total of 30 to 60 min at room temperature or several hours at 4°C.
5. Remove unreacted biotinylation reagent and reaction byproducts by gel filtration using a desalting resin or dialysis against PBS.
6. Assay for the level of biotin incorporation using the HABA dye procedure (Section 6.1, this chapter).

NHS–Iminobiotin

NHS–iminobiotin is *N*-hydroxysuccinimido-2-iminobiotin, the guanidino analog of NHS–biotin that has a lower affinity constant for binding avidin or streptavidin. Iminobiotin replaces the 2-oxo-imidazole upper ring structure of D-biotin with a 2-imino-imidazole structure, causing moderated interaction with the avidin or streptavidin binding sites. This biotin analog can be used in situations requiring mild dissociation of the (strept)avidin-biotin complex. Normally, breaking the (strept)avidin–biotin interaction requires 6- to 8-*M* guanidine hydrochloride at a pH of 1.5, an environment too severe for most proteins to maintain native structure or recover activity. Iminobiotin, by contrast, can be bound to avidin or streptavidin at a pH wherein the guanidino group is unprotonated and thus uncharged. Binding occurs at pH values above 9.5 (typically done with good affinity at pH 11), and elution can be accomplished simply by changing the pH to 4.0—an environment that protonates the 2-imino group and creates a positive charge, thus effectively dissociating the interaction (Figure 11.15).

NHS–Iminobiotin
N-Hydroxysuccinimido-iminobiotin hydrobromide
MW 421.32
13.5 Å

NHS–iminobiotin can be used to label amine-containing molecules with an iminobiotin tag, providing reversible binding potential with avidin or streptavidin. The NHS ester reacts with proteins and other amine-containing molecules to create stable

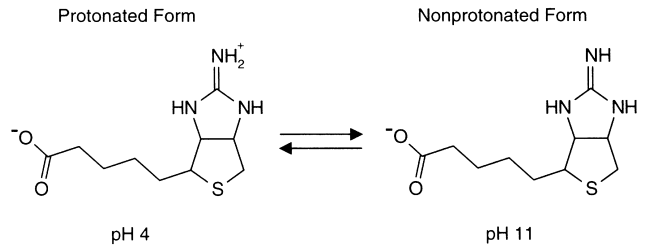


FIGURE 11.15 At pH 4, the protonated form of iminobiotin does not interact with the binding sites on avidin or streptavidin. At pH 11, the imino group is unprotonated and regains binding capability toward these proteins.

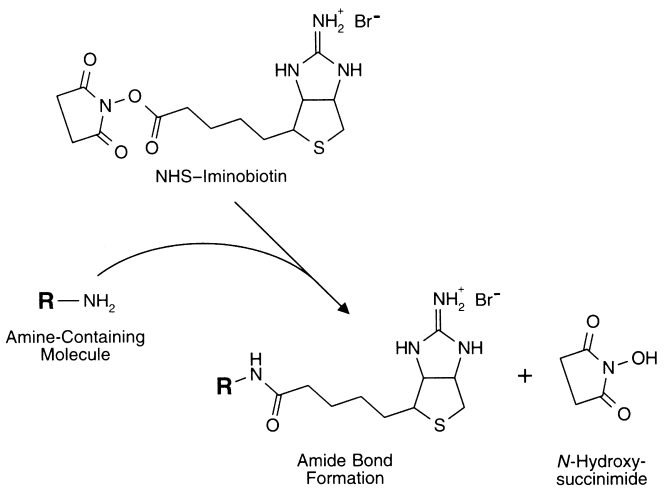

FIGURE 11.16 NHS–iminobiotin can be used to label amine-containing molecules, creating amide linkages.

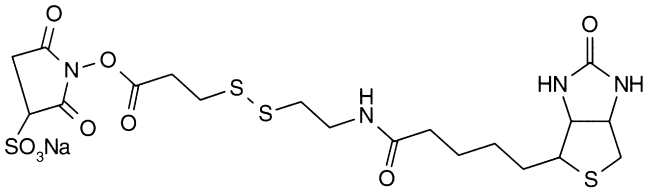
amide bond derivatives (Figure 11.16). An iminobiotinylated molecule can then be used to target and purify other components in biological samples. For instance, a targeting molecule, such as an antibody, can be iminobiotinylated and allowed to bind its target in complex mixtures (such as tissue sections, cell extracts, or homogenates). The antibody–antigen complex subsequently can be purified using an affinity column of immobilized avidin with binding at pH 10 to 11 and simple elution at pH 4 (Orr, 1981; Zeheb *et al.*, 1983). The relatively mild elution condition allows recovery of the bound antigen without exposure to severely denaturing conditions.

The iminobiotin–avidin interaction can also be utilized in the opposite approach. Immobilized iminobiotin affinity columns can be used to purify avidin- or streptavidin-containing complexes under mild elution conditions (Hofmann *et al.*, 1980).

NHS–iminobiotin is insoluble in aqueous solution. It can be dissolved in organic solvent (DMF) prior to addition of a small aliquot to a buffered reaction medium. Do not exceed 10% DMF in the reaction to avoid protein precipitation problems. Optimal conditions for protein derivatization include non-amine-containing buffers at a pH of 7 to 9. The following protocol is a suggested method for labeling antibodies with NHS–iminobiotin. Some optimization may have to be carried out for particular derivatization needs.

Protocol

1. Dissolve the antibody to be modified in 50-m*M* sodium borate, pH 8.0, at a concentration of 5 mg/ml.
2. Dissolve NHS–iminobiotin in DMF at a concentration of 1 mg/ml. Prepare fresh.
3. Add 100 µl of the NHS–iminobiotin solution to each ml of the antibody solution. Mix well to dissolve.



Note: In the beginning, some turbidity may be present in the reaction due to incomplete dissolution of the NHS–iminobiotin. The solution may look cloudy or have a micro-particulate suspension present. This is normal for many water-insoluble reagents when added to an aqueous solution in an organic solvent. As the reaction takes place, the NHS–iminobiotin will be driven into solution, both by coupling to the protein and by hydrolysis of the NHS ester.

Note: The level of biotinylation of the protein to be modified should be controlled to prevent over-labeling, which can result in precipitation of the conjugate and nonspecific binding in the intended application. Reacting at a mole excess of no more than about 5-fold over the amount of protein present may result in the best performing biotinylated proteins, especially when using relatively hydrophobic biotin compounds. Some experimentation may be necessary to determine the optimal conjugate for a particular application.

4. React for 30 to 60 min at room temperature or for 3 h at 4°C.
5. Remove unreacted NHS-iminobiotin and reaction byproducts by dialysis or gel filtration using a desalting resin.

Sulfo-NHS–SS-Biotin

Sulfo-NHS–SS-biotin (also known as NHS–SS-biotin) is sulfosuccinimidyl-2-(biotinamido)ethyl-1,3-dithiopropionate, a long-chain cleavable biotinylation reagent that can be used to modify amine-containing proteins and other molecules (Thermo Fisher). The cross-bridge of the compound provides a 24.3-Å spacer arm that creates plenty of distance between the modified molecule and the biotin end. Using a long-chain biotinylation reagent can increase the efficiency of biotinylated molecules to bind avidin or streptavidin conjugates, thus enhancing the potential sensitivity of assay systems.

Sulfo-NHS–SS-Biotin
Sulfosuccinimidyl-2-(biotinamido)-ethyl-1,3-dithiopropionate
MW 606.7
24.3 Å

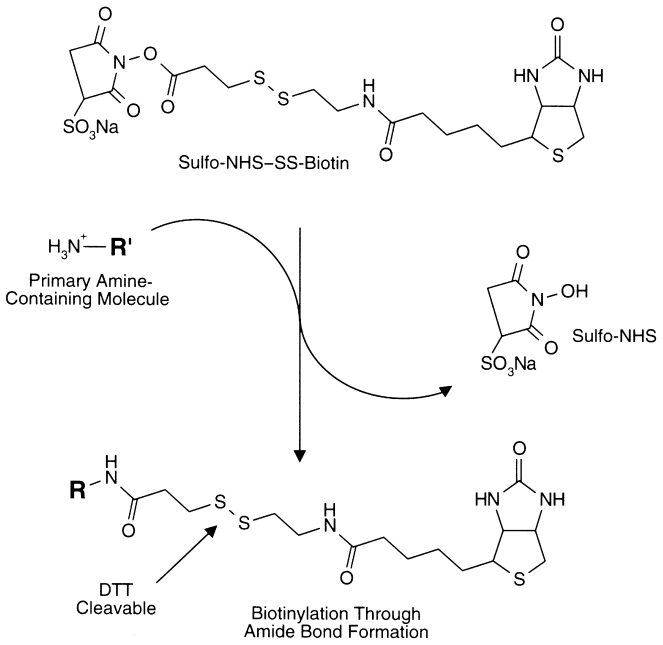


FIGURE 11.17 Sulfo-NHS–SS-biotin reacts with amine groups to form amide bonds. The biotin group can be later cleaved off the modified molecule by reduction of its internal disulfide linkage.

After molecules modified with sulfo-NHS–SS-biotin are allowed to interact with avidin or streptavidin probes, the complexes can be cleaved at the disulfide bridge by treatment with 50-m*M* DTT. Reduction releases the biotinylated molecule from the avidin or streptavidin capture reagent without breaking the (strept)avidin interaction. The use of disulfide biotinylation reagents thus provides much gentler conditions to break the complex than would be required if the avidin–biotin interaction itself were disrupted (which dissociates only at 6- to 8-*M* guanidine, pH 1.5).

The use of a cleavable biotinylation reagent also provides a means to purify targeted molecules using affinity chromatography on a column of immobilized avidin or streptavidin. For instance, an antibody modified with sulfo-NHS–SS-biotin can be allowed to bind its target in complex mixtures (such as tissue sections, cell extracts, or homogenates). The antibody–antigen complex subsequently can be isolated using an affinity column of immobilized avidin or streptavidin in a "pull-down assay" (Knezevic *et al.*, 2011; Hayashi, 2012). Elution from the column with DTT breaks the disulfide bonds, releasing the antibody and its bound antigen. The isolation of herpes virus proteins (Gretch *et al.*, 1987) and the recovery of DNA binding proteins (Shimkus *et al.*, 1985) were both carried out using this approach. Other methods of immunoprecipitation using non-cleavable biotinylation agents result in the inability to recover the captured proteins except under severely denaturing conditions.

Due to the presence of the negatively charged sulfonate group, sulfo-NHS–SS-biotin is a water soluble biotinylation reagent that may be added directly to aqueous reactions without prior dissolution in organic solvent. For the addition of small quantities of reagent, the compound may be dissolved in water and an aliquot transferred to the reaction medium. If an aqueous stock solution of sulfo-NHS–SS-biotin is prepared, it must be dissolved rapidly and used immediately to prevent hydrolysis of the active ester. The NHS ester reaction forms stable amide linkages with amine-containing proteins and other molecules (Figure 11.17). Optimal conditions for the NHS ester reaction include a pH of 7 to 9, avoidance of any amine-containing buffers or other components that may compete in the reaction (including imidazole buffers which catalyze hydrolysis of these esters), and avoidance of reducing agents that could cleave the disulfide bridge.

The following protocol is a suggested method for biotinylating antibody molecules with sulfo-NHS–SS-biotin. Some optimization may have to be done with each application to ensure good biotin incorporation with retention of antigen binding activity. Other proteins and amine-containing molecules may be biotinylated using similar conditions.

Protocol

1. Dissolve the antibody to be biotinylated in 50-m*M* sodium bicarbonate, pH 8.5, at a concentration of 10 mg/ml. Other buffers and pH conditions between pH 7 and 9 can be used as long as no amine-containing buffers like Tris are present. Avoid also the presence of disulfide reducing agents that can cleave the disulfide group of the biotinylation reagent.
2. Add 0.3 mg of sulfo-NHS–SS-biotin (Thermo Fisher) to each ml of the antibody solution. To measure out small amounts of the biotinylation reagent, it may first be dissolved in water (or DMF) at a concentration of at least 1 mg/ml. Immediately transfer the appropriate amount to the antibody solution.

Note: This level of sulfo-NHS–SS-biotin addition represents about an 8-fold molar excess over the amount of antibody present. This should result in a molar incorporation of approximately two to four biotins per immunoglobulin molecule. Some optimization of the biotinylation level may have to be carried out to obtain the best performing conjugate for a particular application.

3. React for 30 to 60 min at room temperature or for 2 to 4 h at 4°C.
4. Remove unreacted biotinylation reagent and reaction byproducts by dialysis or gel filtration using a desalting resin.

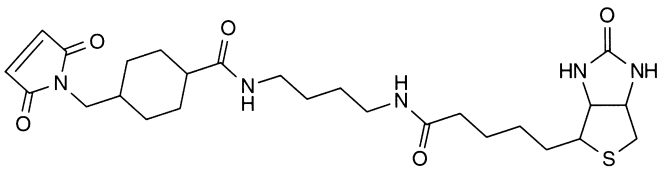
Sulfo-NHS–SS-biotin can also be used to label cell surface proteins for subsequent detection or isolation using (strept)avidin reagents. The negative charge character of the compound prior to its reaction with an amine on a protein prevents it from penetrating the cell membrane bilayer. Thus, proteins on the outer surface of the cell can be specifically tagged with a biotin group. The disulfide cross-bridge of sulfo-NHS–SS-biotin allows recovery of labeled proteins after capture on an immobilized (strept) avidin support. Reduction of the disulfide using DTT or TCEP releases the proteins without the severe denaturing conditions usually required to break the (strept)avidin–biotin interaction. This allows isolation of cell surface proteins under non-denaturing conditions for subsequent analysis (Schuberth *et al.*, 1996; DeBlaquiere and Burgess, 1999; Ellerbroek *et al.*, 2001; Jang and Hanash, 2003).

The following protocol is based on the method of Thermo Fisher, as found in the instructions for the cell surface biotinylation kit.

Protocol

1. Grow cells in four T75-cm^2 flasks until they are 90 to 95% confluent.
2. Remove the media and wash the cells twice with 8 ml of cold 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.2 (PBS). Note: This buffer contains a high buffer salt content to stabilize the pH during the biotinylation reaction. Do not allow the cells to remain in contact with it for more than 5 s to prevent detachment from the flask surface.
3. Dissolve 12 mg of sulfo-NHS–SS-biotin in 48 ml of cold PBS and immediately add 10 ml of the solution to each flask containing the washed cells.
4. React with gentle rocking for 30 min at 4°C.
5. Quench the reaction by the addition of 1 ml of 1-*M* Tris, pH 7.2.
6. Scrape the cells from each flask and transfer them into a 50-ml tube. Wash each flask using a single 10-ml portion of 0.025-*M* Tris, 0.15-*M* NaCl, pH 7.2, and add the solution to the scraped cells.
7. The isolated cells may be lysed using standard mechanical or detergent methods and the biotinylated cell surface proteins analyzed or isolated using (strept)avidin reagents.

6.3. Sulfhydryl-Reactive Biotinylation Agents



Sulfhydryl-reactive biotinylation reagents allow modification at cysteine –SH groups or at sites of specific thiolation within proteins and other molecules. Targeting sulfhydryls for modification, as opposed to amines, usually results in more limited derivatization, often away from active centers or binding sites. Directed coupling of biotin in this manner can aid in preserving activity. For instance, antibodies may be treated by reduction of their disulfide groups (mainly in the hinge region), which forms free sulfhydryls that are removed from the antigen-binding sites (Chapter 20, Section 1.1). Biotinylation at these sites produces a derivative that can bind efficiently to both antigen and (strept)avidin probes without steric hindrance.

Sulfhydryl groups also can be added to 5′-phosphate end of DNA probes (Chapter 23, Section 2.2). Biotinylation at these sites avoids disruption of base pairing with complementary DNA targets, since the point of modification is restricted to a single end position on the oligonucleotide.

The following sections discuss three sulfhydryl-reactive biotinylation reagents that utilize maleimide-, pyridyl disulfide-, and iodoacetyl-reactive groups, respectively. The maleimide and iodoacetyl options produce nonreversible, covalent thioether linkages with target –SH groups. The pyridyl disulfide chemistry results in disulfide bonds that are reversible through cleavage with a reducing agent.

Biotin–BMCC

Biotin–BMCC is 1-biotinamido-4-[4′-(maleimidomethyl) cyclohexane-carboxamido]butane, a biotinylation reagent containing a maleimide group at the end of an extended spacer arm (Thermo Fisher). The maleimide end reacts with sulfhydryl groups in proteins and other molecules to form stable thioether linkages (Figure 11.18). The reaction is highly specific for –SH groups in the range of pH 6.5 to 7.5. The long spacer arm (32.6 Å) provides more than enough distance between modified molecules and the bicyclic biotin end to allow efficient binding of avidin or streptavidin probes.

Biotin–BMCC
1-Biotinamido-4-[4'-(maleimidomethyl)-
cyclohexane-carboxamido]butane
MW 533.69
32.6 Å

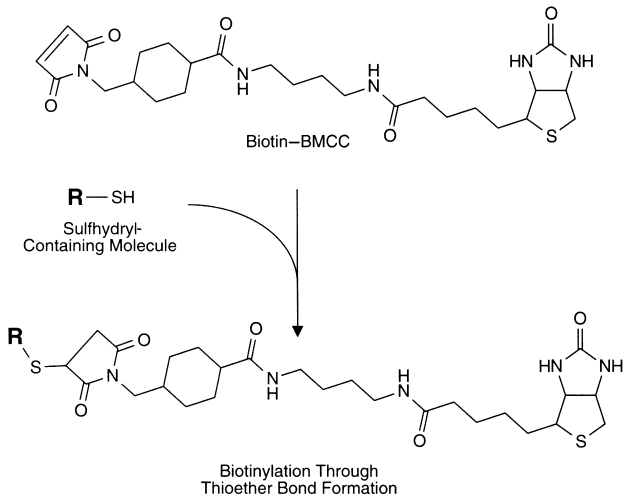


FIGURE 11.18 Biotin–BMCC provides sulfhydryl reactivity through its terminal maleimide group. The reaction creates a stable thioether linkage.

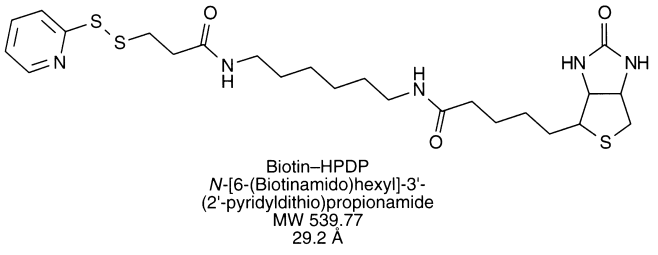
The reagent is similar to another maleimide-containing biotinylation reagent, 3-(*N*-maleimidopropionyl) biocytin, a compound used to detect sulfhydryl-containing molecules on nitrocellulose blots after SDS–electrophoresis separation (Bayer *et al.*, 1987). Biotin–BMCC should be useful in similar detection procedures.

Biotin–BMCC is insoluble in water and must be dissolved in an organic solvent prior to addition to an aqueous reaction mixture. Preparing a concentrated stock solution in DMF or DMSO allows transfer of a small aliquot to a buffer reaction. The upper limit of biotin–BMCC solubility in DMSO is approximately 33-m*M* or 17 mg/ml. In DMF, it is only soluble to a level of about 7-m*M* (4 mg/ml). Upon addition of an organic solution of the reagent to an aqueous environment (do not exceed 10% organic solvent in the aqueous medium to prevent protein precipitation), biotin–BMCC may form a micro-emulsion. This is normal, and during the course of the reaction the remainder of the compound will be driven into solution as it couples or hydrolyzes.

The required sulfhydryl groups for biotin–BMCC modification may be indigenous in molecules, formed through reduction of disulfides or created by the use of thiolation reagents (Chapter 2, Section 4.1). At physiological pH, the rate of the maleimide reaction toward sulfhydryls is almost 1000-fold faster than its reaction toward amines. However, at higher pH values the maleimide will couple to amines quite readily (Wu *et al.*, 1976; Ishi and Lehrer, 1986). Maleimides can also undergo a ring-opening hydrolysis reaction which increases in rate with pH, effectively inactivating the reactive group for thiol coupling.

Biotin–BMCC has been used to investigate palmitoylation (Fairbank, 2012), to study the heat-shock response in yeast (Wang *et al.*, 2012), and to study *S*-nitrosylation of proteins (Cheng *et al.*, 2012).



The following protocol is a suggested method for modifying sulfhydryl-containing proteins with biotin–BMCC. Some optimization of biotinylation levels may have to be carried out for particular applications.

Protocol

1. Dissolve the protein to be biotinylated (containing one or more free sulfhydryls) in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 6.5 to 7.5, at a concentration of 2.5 mg/ml.
2. Dissolve biotin–BMCC (Thermo Fisher) in DMSO at a concentration of 5 mg/ml.
3. Add 100 µl of the biotin–BMCC solution to each ml of the protein solution. Mix well.
4. React for at least 2 h at room temperature.
5. Remove excess biotinylation reagent and reaction byproducts by dialysis or gel filtration using a desalting resin.

Biotin–HPDP

Biotin–HPDP is *N*-[6-(biotinamido)hexyl]-3′-(2′-pyridyldithio)propionamide (Thermo Fisher). The reagent contains a 1,6-diaminohexane spacer group which is attached to biotin's valeric acid side chain. The terminal amino group of the spacer is further modified *via* an amide linkage with the acid precursor of SPDP (Chapter 6, Section 1.1) to create a terminal, sulfhydryl-reactive group. The pyridyl disulfide end of biotin–HPDP can react with free thiol groups in proteins and other molecules to form a disulfide bond with loss of pyridine-2-thione (Figure 11.19). This leaving group may be monitored by its characteristic absorbance at 343 nm to assess the level of biotinylation. However, since its extinction coefficient is rather low (about $8 \times 103\,M^{-1}\,cm^{-1}$), small-scale biotinylation reactions may not be quantifiable using this technique.

Modifications carried out with biotin–HPDP produce biotinylated compounds with long spacer arms (29.2 Å), which typically provide good binding efficiency with avidin or streptavidin probes. After coupling to sulfhydryl-containing molecules, the biotin–HPDP component can be cleaved back off by treatment with

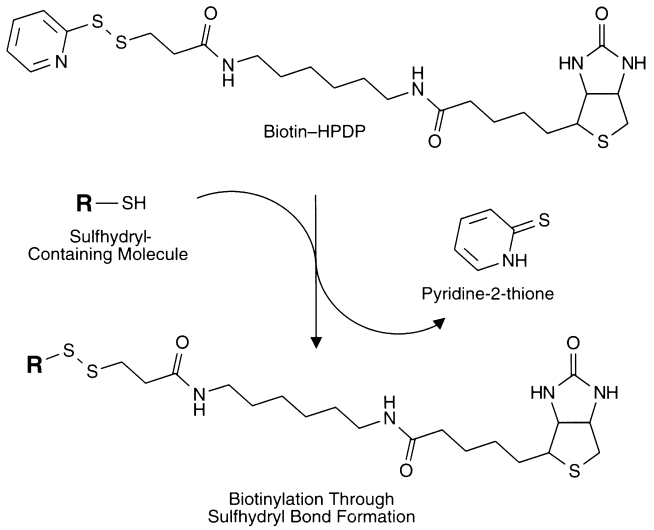


FIGURE 11.19 Biotin–HPDP reacts with sulfhydryl-containing molecules through its pyridyl disulfide group, forming reversible disulfide bonds. The biotin group may be released from modified molecules by reduction with DTT.

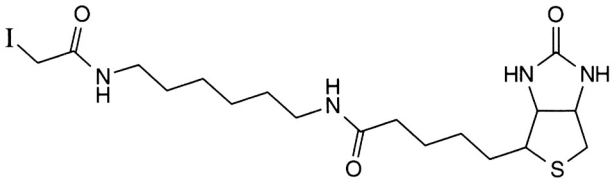
disulfide reducing agents, such as DTT. Breaking this bond releases the biotin modifications and regenerates the original sulfhydryl-containing molecule. This cleavability also provides a means of recovering target complexes after purification of the biotinylated molecules by affinity chromatography on immobilized avidin or streptavidin. Thus, biotin–HPDP-modified antibodies directed against some specific cellular antigen can be used to aid in the isolation of targeted components using affinity chromatography (immunoprecipitation) followed by elution with a disulfide reductant.

Using a similar approach, C1q has been modified with biotin–HPDP and allowed to interact with its specific receptor. Subsequent purification of the C1q receptor was accomplished through binding to immobilized streptavidin (Chapter 15) and subsequent cleavage of the disulfide bridge of the biotinylation reagent using DTT (Ghebrehiwet *et al.*, 1988). Similar pull-down assays continue to be done with biotin–HPDP to study protein interactions in cells (Seth and Stamler, 2011) or to analyze post-translational modifications (Lee *et al.*, 2011).

Biotin–HPDP is water insoluble and therefore must be dissolved in an organic solvent prior to addition to an aqueous reaction medium. Suitable solvents include DMSO and DMF. Concentrated stock solutions may be prepared in DMSO and a small aliquot transferred to a buffered reaction solution. Do not add more than 10% organic solvent to the aqueous reaction to prevent precipitation or denaturation of biological molecules. After addition, a micro-emulsion may result. This is normal for many water-insoluble reagents. The solution usually will become clearer during the course of the reaction. Optimal conditions for the disulfide interchange reaction include a pH range of 6 to 9 in buffer systems that do not contain any extraneous sulfhydryl compounds or reducing agents such as DTT, 2-mercaptoethanol, or TCEP. If reducing agents are used to create sulfhydryls in the protein to be biotinylated, these must be completely removed by dialysis or gel filtration before reacting with biotin-HPDP.



A suggested protocol for the use of biotin–HPDP in the modification of sulfhydryl-containing proteins follows. Similar procedures may be used when biotinylating other molecules containing thiols.

Protocol

1. Dissolve the sulfhydryl-containing protein to be biotinylated in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, 10-m*M* EDTA, pH 7.2, at a concentration of at least 2 mg/ml.
2. Dissolve biotin–HPDP (Thermo Fisher) in DMSO at a concentration of 4-m*M* (2.1 mg/ml).
3. Add 100 µl of the biotin–HPDP stock solution to each ml of the protein solution. Mix well.
4. React for 90 min at room temperature.
5. Purify the biotinylated protein by gel filtration using a desalting resin or by dialysis. The PBS/EDTA buffer described in step 1 is suitable for either operation.

Iodoacetyl–LC-Biotin

Iodoacetyl–LC-biotin is *N*-iodoacetyl-*N*-biotinylhexylenediamine, a sulfhydryl-reactive biotinylation agent (Thermo Fisher). The reagent contains a 1,6-diaminohexane spacer group that is attached to biotin's valeric acid side chain. The terminal amino group of the spacer is further modified *via* an amide linkage with an iodoacetyl group to provide the sulfhydryl reactivity. Coupling to sulfhydryl-containing proteins or other molecules creates nonreversible thioether bonds (Figure 11.20). Modifications carried out with iodoacetyl–LC-biotin produce biotinylated compounds with sufficiently long spacer arms (27.1 Å), which help to ensure excellent binding potential with avidin or streptavidin probes.

Iodoacetyl–LC-biotin is water insoluble and therefore must be dissolved in an organic solvent prior to

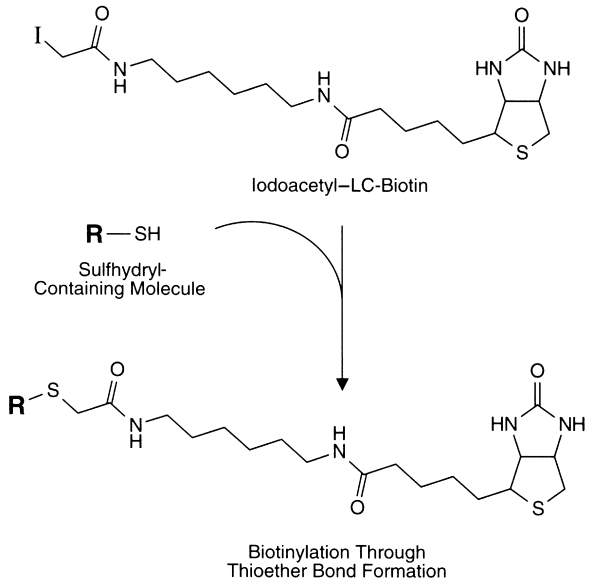


FIGURE 11.20 This biotinylation reagent reacts with sulfhydryl groups through its iodoacetamide end to form thioether bonds.

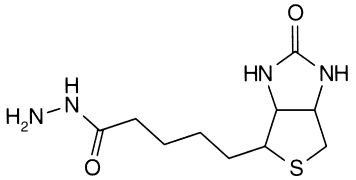
addition to an aqueous reaction medium. Suitable solvents include DMSO and DMF. Concentrated stock solutions may be prepared in DMSO and a small aliquot transferred to a buffered reaction solution. Do not add more than 10% organic solvent to the aqueous reaction to prevent precipitation or denaturation of biological molecules. After addition, a micro-emulsion may result. This is normal for many water-insoluble reagents. The solution usually will become clear during the course of the reaction. Optimal conditions for coupling using iodoacetyl-containing reagents include a pH range of 7.5 to 8.5 in buffer systems that do not contain any extraneous sulfhydryl compounds. In addition, protect all solutions containing iodoacetyl–LC-biotin from light, since photolysis may cause liberation of iodine, degrading the activity of the compound and possibly causing modification of tyrosine or histidine residues by iodination.

Iodoacetyl–LC-biotin has been used to localize the SH1 thiol of myosin by use of an avidin–biotin complex visualized by electron microscopy (Sutoh *et al.*, 1984), to determine the spatial relationship between SH1 and the actin binding site on the myosin subfragment-1 surface (Yamamoto *et al.*, 1984), to study markers for pancreatic cancer (Zhu *et al.*, 2012), and to assay protein–DNA interactions (Ritzefeld and Sewald, 2012).

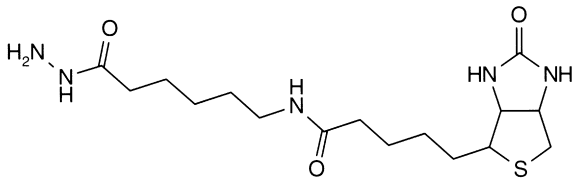
The following protocol is a suggested method for biotinylating sulfhydryl-containing proteins using iodoacetyl–LC-biotin. The required sulfhydryl groups may be provided through reductive cleavage of disulfide bonds or by the use of thiolation reagents (Chapter 2, Section 4.1). Other molecules may be modified with iodoacetyl–LC-biotin using similar techniques.

Protocol

1. Dissolve the sulfhydryl-containing protein to be biotinylated in 50-m*M* Tris, 0.15-*M* NaCl, 10-m*M* EDTA, pH 8.3, at a concentration of 4 mg/ml.
2. Dissolve iodoacetyl–LC-biotin (Thermo Fisher) in DMF at a concentration of 4-m*M* (2 mg/ml). Protect from light.
3. Add 50 µl of the iodoacetyl–LC-biotin solution to each ml of the protein solution. Mix well. This level of addition represents a 3.28-fold molar excess of biotinylation reagent over the quantity of protein present if the protein has a molecular weight of 67,000 and possesses one sulfhydryl. Adjustments to the amount of reagent addition may have to be made to be appropriate for other proteins of different molecular weight. Consideration of the number of sulfhydryls present per protein molecule should also be carried out. React the biotinylation reagent at no more than a 3- to 5-fold molar excess over the amount of sulfhydryls present to ensure specificity of the iodoacetyl group for only –SH groups. Higher ratios of reagent-to-protein may cause reaction with amine groups present on the protein.
4. React for 90 min in the dark at room temperature.
5. Remove excess reactants and reaction byproducts by dialysis or gel filtration using a desalting resin.



6.4. Carbonyl- or Carboxyl-Reactive Biotinylation Agents



Hydrazide- or amine-containing biotinylation compounds can be used to modify carbonyl or carboxyl groups on other molecules. Hydrazides spontaneously react with aldehydes or ketones to give hydrazone linkages. The reaction may be further accelerated by the addition of an aniline catalyst (see Chapter 15, Section 2.4, for additional information on this reaction mechanism). The resulting hydrazone bonds may be further stabilized by reduction with sodium cyanoborohydride. The amine-containing biotinylation reagents (or the hydrazide ones) may be coupled to carboxylate groups using a carbodiimide reaction (Chapter 4, Section 1.1). In addition, amine- or hydrazide-containing biotinylation reagents may be coupled to cytosine residues in DNA or RNA by transamination catalyzed by bisulfite (Chapter 23, Section 2.3).

Biotin–Hydrazide and Biotin–LC-Hydrazide

Biotin–hydrazide is *cis*-tetrahydro-2-oxothieno[3,4-d]-imidazoline-4-valeric acid hydrazide, the hydrazine derivative of D-biotin off its valeric acid carboxylate (Thermo Fisher). The hydrazide functionality reacts with aldehyde and ketone groups to give hydrazone linkages. Although formyl groups are not common in

biological molecules, they may be created by oxidation of diols with sodium periodate (Chapter 2, Section 4.4). Thus, glycoconjugates may be targeted specifically at their sugar residues. Biotinylation of these oxidized carbohydrates with biotin–hydrazide produces modifications that may be away from active centers or binding sites on proteins (Figure 11.21). Particularly, immunoglobulins may be biotinylated with this reagent at their polysaccharide groups which typically are present in the Fc region of the IgG molecule. Directed modification in this manner avoids the antigen-binding sites at the ends of the heavy and light chains, thus preserving antibody activity and allowing avidin or streptavidin probes to dock without blocking or interfering with antigen binding (although care should be taken in this respect, as some antibodies contain carbohydrate near their antigen-binding sites).

Biotin–hydrazide may also be used to couple with carboxylate-containing molecules. Hydrazides can be coupled with carboxylic acid groups by using the carbodiimide reaction (Chapter 4, Section 1.1). The carbodiimide activates a carboxylate to an *o*-acylisourea intermediate. Biotin–hydrazide can react with this intermediate *via* nucleophilic addition to form a stable covalent bond.

Biotin–hydrazide has been used to biotinylate antibodies at their oxidized carbohydrate residues (O'Shanessy *et al.*, 1984, 1985, 1987; Hoffman and O'Shannessy, 1988), to modify the low-density lipoprotein (LDL) receptor (Wade *et al.*, 1985), to biotinylate nerve growth factor (NGF) (Rosenberg *et al.*, 1986), and to modify cytosine groups in oligonucleotides to produce probes suitable for hybridization assays (Reisfeld *et al.*, 1987) (Chapter 23, Section 2.3).

An analog of this biotinylation reagent with a longer spacer arm also exists. Biotin–LC-hydrazide contains a

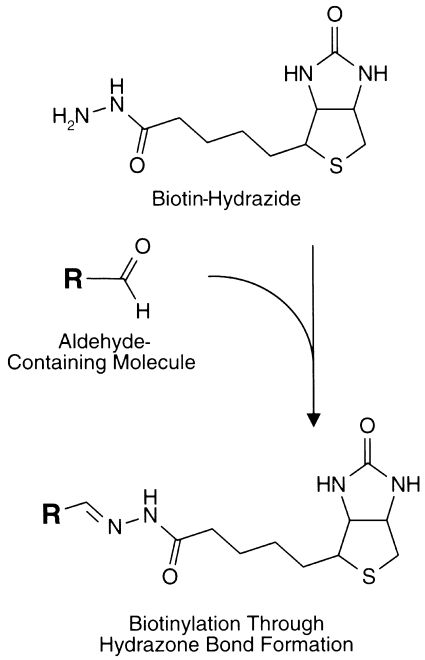


FIGURE 11.21 Biotin–hydrazide can be used to label aldehyde-containing molecules, creating hydrazone bonds.

6-aminocaproic acid extension off its valeric acid group (Thermo Fisher). The increased length of this spacer (24.7 Å) provides more efficient interaction potential with avidin or streptavidin probes, possibly increasing the sensitivity of assay systems. The reactions of biotin–LC-hydrazide are identical to those of biotin–hydrazide.

Both biotin–hydrazide and biotin–LC-hydrazide can be used to identify sites of carbonylation in biomolecules, such as those caused by oxidative stress. These sites typically involve some formation of aldehyde and ketone groups, which can be specifically tagged using hydrazide-containing biotinylation agents. The hydrazide group forms a hydrazone bond at the sites of carbonylation, thus allowing detection using streptavidin conjugates or isolation by using immobilized streptavidin in pull-down assays (Frohnert *et al.*, 2011; Curtis *et al.*, 2012).

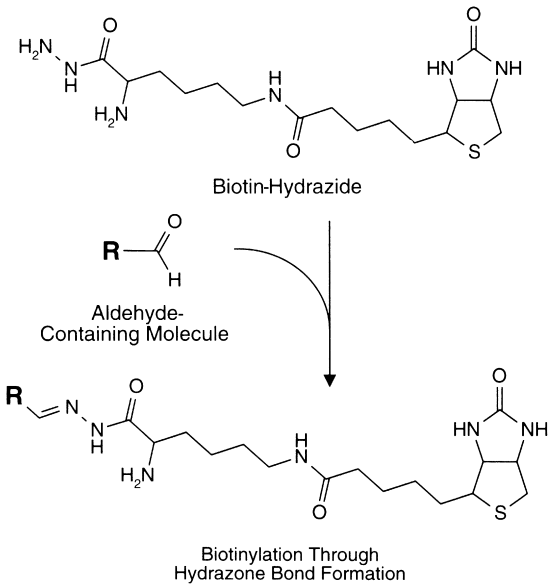
The following protocol describes the use of biotin–hydrazide to label glycosylated proteins at their carbohydrate residues. Control of the periodate oxidation level can result in specific labeling of sialic acid groups or general sugar residues (Chapter 2, Section 4.4).

Protocol

1. Dissolve a periodate-oxidized glycoprotein (i.e., antibodies—see Chapter 20, Section 1.3) in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, at a concentration of 2 mg/ml. Note: The buffer, 0.1-*M* sodium acetate, pH 5.5, is typical of literature references for reaction of a hydrazide compound

with an aldehyde-containing molecule to form a hydrazone linkage. Alternative buffer conditions using higher pH values also work well. Physiological pH conditions with the use of a reducing agent such as sodium cyanoborohydride (step four) produce the most efficient labeling yields when using hydrazide-containing reagents.

2. Add biotin–hydrazide or biotin–LC-hydrazide to a final concentration of 5-m*M*.
3. React for 2 h at room temperature.
4. To reduce the hydrazone bonds to more stable linkages, cool the solution to 4°C and add an equal volume of 30-m*M* sodium cyanoborohydride in PBS. Incubate for 40 min. Note: If the presence of a reducing agent is detrimental to protein activity, eliminate this step. In most cases, the hydrazone linkage is stable enough for avidin–biotin detection experiments.
5. Remove excess reactants by dialysis or gel filtration using a desalting column.



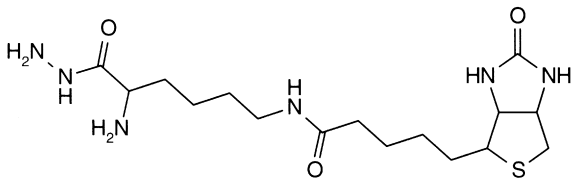


FIGURE 11.22 Biocytin hydrazide reacts with aldehyde-containing molecules to form hydrazone bonds.

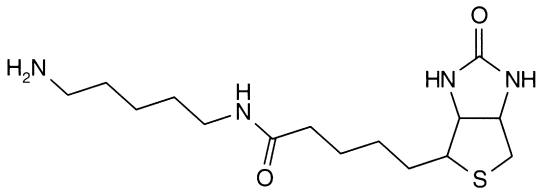
Biocytin Hydrazide

Another biotinylation reagent that can spontaneously couple with aldehyde- or ketone-containing molecules is biocytin hydrazide (Thermo Fisher). Produced by forming the hydrazine derivative of biocytin—a lysine–biotin complex often found naturally in serum (Section 6.2, this chapter)—the compound has better solubility in aqueous solutions than either biotin–hydrazide or biotin–LC-hydrazide discussed previously. The solubility enhancement of biocytin hydrazide is due to the presence of lysine's α-amino group, which is protonated and positively charged at physiological pH. The reagent can be used to label carbohydrate-containing molecules, such as glycoproteins, after they have been oxidized to contain reactive aldehydes (Chapter 2, Section 4.4). The hydrazide group forms a hydrazone linkage with the aldehydes, thus directing the biotinylation reaction toward the polysaccharide regions of glycoconjugates (Figure 11.22).

Biocytin hydrazide was used to label specifically sialic acid residues, galactose residues, and for general sugar modification (Bayer *et al.*, 1988). The galactose residues were oxidized using galactose oxidase after treatment with neuraminidase (Chapter 2, Section 4.4). The use of this approach for labeling glycoproteins *in situ* was found to be optimal, due to the other potential side-reactions that may occur when using sodium periodate.

The reactivity and use of biocytin hydrazide is similar to that described for biotin–hydrazide in Section 6.4, this chapter. The following protocol for labeling glycoproteins at oxidized carbohydrate (galactose) sites is from Bayer and Wilcheck (1992).



Protocol

1. Dissolve the glycoprotein to be labeled in 0.1-*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4, containing 1-m*M* $CaCl_2$ and 1-m*M* $MgCl_2$ (labeling buffer), at a concentration of 1 mg/ml.
2. Dissolve biocytin hydrazide (Thermo Fisher) in 0.1–*M* sodium phosphate, 0.15-*M* NaCl, pH 7.4 (PBS), at a concentration of 20 mg/ml.
3. To each ml of glycoprotein solution, add 30 µl of neuraminidase (1 unit/ml as supplied by Behringwerke AF), then 30 µl of galactose oxidase (previously dissolved at 100 units/ml in the labeling buffer of step one), and finally 100 µl of the biocytin hydrazide solution.
4. React for 2 h at 37°C.
5. Remove unreacted reagents by dialysis or gel filtration.

5-(Biotinamido)pentylamine

The D-biotin derivative, 5-(biotinamido)pentylamine, contains a 5-carbon cadaverine spacer group attached to the valeric acid side chain (Thermo Fisher).

The compound can be used in a carbodiimide reaction process to label carboxylate groups in proteins and other molecules, forming amide bond linkages (Chapter 4, Section 1). However, the main use of this biotinylation reagent is in the determination of factor XIIIa or transglutaminase enzymes in plasma, cell, or tissue extracts.

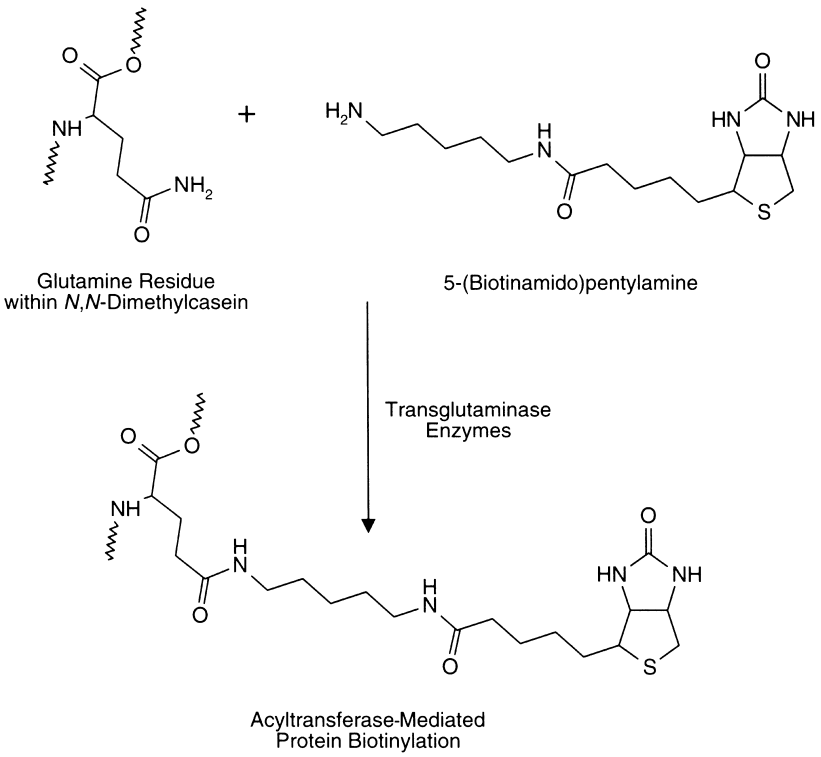
5-(Biotinamido)pentylamine
MW 328.48

Factor XIII, also known as plasma transglutaminase, is an enzyme of the blood coagulation cascade. It is activated by thrombin and calcium to factor XIIIa, at which point it catalyzes covalent crosslinks between the ε-amine group of lysine side chains and the γ-glutamyl side chain of glutamine residues. Abnormal levels of factor XIII in plasma are clinically important, being associated with cancer, liver or renal dysfunction, or various bleeding disorders. The assay of transglutaminase activity therefore is important for investigating the activity and function of this enzyme as it relates to post-translational protein modification as well as various disease states.

5-(Biotinamido)pentylamine is able to participate in the acyltransferase reaction, becoming covalently attached to protein substrates at their glutamine residues (Figure 11.23). Lee *et al.* (1988) used this biotinylation reagent to quantify factor XIII in plasma (D'Eletto *et al.*, 2012; Kuper *et al.*, 2012). Transglutaminase activity resulted in the modification of an *N,N'*-dimethylcasein substrate which was subsequently detected by an avidin–biotin assay procedure. The assay may be carried out in microplates using wells coated with the substrate protein and quantifying the enzyme activity with streptavidin–alkaline phosphatase (Slaughter *et al.*, 1992). Jeon *et al.* (1989) subsequently applied the assay to the measurement of transglutaminase activity in cells. Components biotinylated in cellular systems also can be isolated by use of affinity chromatography on immobilized avidin (Lee *et al.*, 1992).

6.5. Photoreactive Biotinylation Agents

Biotin derivatives containing a photoreactive group provide nonselective biotinylation potential at certain reactive hydrogen sites or nucleophilic groups. They can be used to incorporate an avidin-binding biotin group into molecules that do not possess amines, sulfhydryls, or other easily modifiable functional groups. Many of these photoreactive derivatives



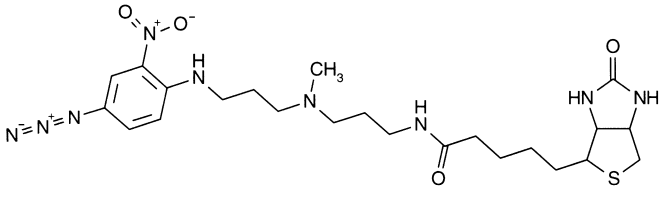


FIGURE 11.23 5-(Biotinamido)pentylamine can be used to label glutamine residues in proteins by enzymatic action of transglutaminase.

utilize the phenyl azide-type of photosensitive group, which can be activated by exposure to UV light to an intermediate nitrene or the nucleophile-reactive dehydroazepine (Chapter 3, Section 7.1, and Chapter 6, Section 3). However, additional photoreactive groups that are also useful include a psoralen ring system and a benzophenone group. A psoralen-based biotinylation agent is presented in this section, while a benzophenone-containing biotin compound with a water soluble PEG spacer is discussed in Chapter 18, Section 1.3.

Photobiotin

Perhaps the most common photoreactive biotin derivative is *N*-(4-azido-2-nitrophenyl)-aminopropyl-*N*′-(*N*-d-biotinyl-3-aminopropyl)-*N*′-methyl-1,3-propanediamine, simply called photoactivatable biotin or photobiotin (Forster *et al.*, 1985) (Thermo Fisher). The compound contains a 9-atom diamine spacer group on the biotin valeric acid side chain at one end, while the other end of the spacer terminates in an aryl azide reactive group. The presence of a nitro group on the phenyl azide ring allows for photoactivation at higher UV wavelengths approaching the visible region of the spectrum, thus avoiding potential breakdown of biological molecules through UV exposure. Photolyzing with light at a wavelength of 350 nm causes rapid activation with nitrene formation. The nitrene can couple to replaceable hydrogen sites in target molecules, add to double bonds within van der Waals distance, or undergo ring expansion to the dehydroazepine. If ring expansion occurs, the principal target group for coupling is a nucleophile, such as a primary amine (Figure 11.24).

Photobiotin

N′-(*N*-d-biotinyl-3-aminopropyl)-*N*′-methyl-1,3-propanediamine
MW 533.65
30.0 Å

Photobiotin has been used to biotinylate numerous macromolecules, including proteins and nucleic acids. The biotinylation of alkaline phosphatase was carried out with complete retention of activity (Forster *et al.*, 1985). Tubulin was labeled with photobiotin and detected on dot blots down to a level of 10 pg of sample using an avidin–enzyme conjugate (Lacey and Grant, 1987). DNA and RNA were labeled for use in hybridization assays (Forster *et al.*, 1985; Keller, 1989). For instance, photobiotin-modified probes have been used to detect flavivirum RNA in infected cells (Khan and Wright, 1987), to detect single-copy genes and low-abundance mRNA (McInnes *et al.*, 1987), for the diagnosis of barley yellow dwarf virus (Habili *et al.*, 1987), to assay luteinizing hormone β mRNA in individual gonadotropes (Childs *et al.*, 1987), to perform DNA mapping using a cross-hybridization technique (Chetrit *et al.*, 1989), to create patterns of fluorescent streptavidin molecules on dextran-coated surfaces (Ahn *et al.*, 2011), and to form multilayer films on titanium dioxide substrates (Weng *et al.*, 2011).

Photobiotin can be dissolved in water or buffer at a concentration of 1 mg/ml and stored in the dark at −20°C until needed. As long as no exposure to light is permitted, the compound is stable for at least 1 year under these conditions.

The protocol for modifying DNA probes with photobiotin can be found in Chapter 23, Section 2.3. It is based on the method of Forster *et al.* (1985). The following method is a suggested protocol for the modification of proteins using a photoreactive biotin derivative. Some optimization may be necessary to obtain the best incorporation levels.

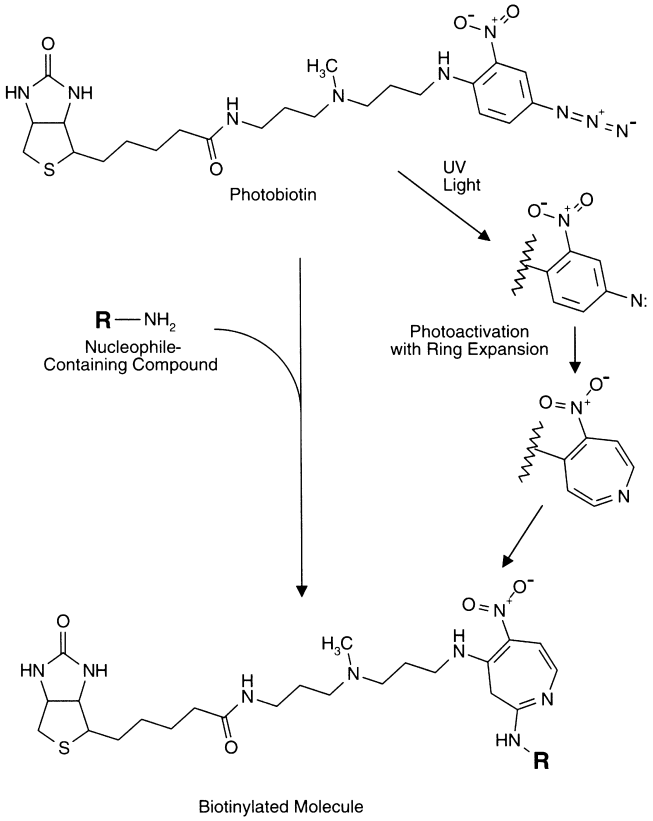

FIGURE 11.24 Photobiotin can be made to couple spontaneously with nucleophiles by exposure to UV light. The phenyl azide ring undergoes ring expansion to a highly reactive dehydroazepine intermediate, which can react with amines.

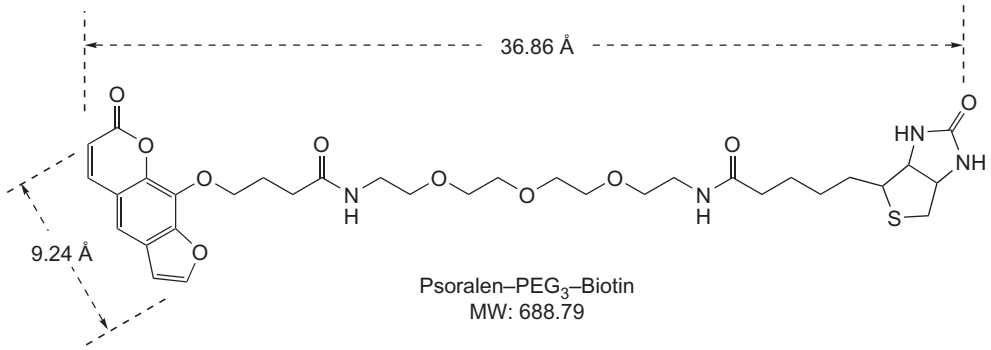
Protocol

1. Dissolve the protein to be biotinylated at a concentration of at least 1 mg/ml in water or dilute buffer at neutral pH.
2. In subdued light, dissolve photobiotin (Thermo Fisher) in water at a concentration of 1 mg/ml.
3. Add a quantity of photobiotin solution to the protein solution to give at least a 5-fold molar excess of biotinylation reagent.
4. Place in an ice bath and irradiate from above (about 10 cm away) for 15 min using a sunlamp (such as Philips Ultrapnil MLU 300 W, General Electric sunlamp RSM 275 W, or National Self-Ballasted BHRF 240–250 V 250 W W-P lamp).
5. Remove excess photobiotin by dialysis or gel filtration using a desalting column.

Psoralen–PEG$_3$–Biotin

Psoralen–PEG$_3$–biotin is a photoreactive biotinylation reagent containing a psoralen group at one end and a triethylene glycol (PEG-based) spacer in the middle (Thermo Fisher). This compound is water soluble due to the presence of the hydrophilic PEG arm. It is able to photo-insert into double-stranded DNA and to a lesser extent into double-stranded regions of RNA. The reaction occurs upon exposure to UV light in the range of 320 to 400 nm, which forms an excited triplet state intermediate that can insert in certain double-bond structures, especially at the 5,6-double bond of thymine bases.

The psoralen ring system can intercalate within double-stranded DNA or RNA and induce the formation of adducts with adjacent thymine bases (Stutz *et al.*, 2011) (Figure 11.25). The furan side and pyrone side of the tricyclic rings in psoralen can both form cycloaddition products with the 5,6-double bond of thymine residues, which results in crosslinks between the DNA strands with a PEG–biotin label sticking out.



Psoralen–PEG$_3$–biotin has been used to label double-stranded DNA for detection using (strept)avidin reagents (Henriksen *et al.*, 1991; Wygrecka *et al.*, 2007). The psoralen photoreactive group provides better insertion yields than typical phenyl azide-based systems, such as the standard photobiotin probe discussed previously in this section.

Protocol

1. Dissolve the DNA sample to be modified at a concentration of 20 to 100 µg/ml in 10-m*M* Tris, 1-m*M* EDTA, pH 7.4. Note: The sample may be heated to denature and solubilize genomic DNA and then cooled to form dsDNA for modification.
2. Dissolve the psoralen–PEG$_3$–biotin reagent in DMF at a concentration of 20-m*M* (use a fume hood). Protect from light.
3. Add a quantity of the psoralen–PEG$_3$–biotin solution to the DNA solution to result in a final concentration of 200 µ*M*. Mix well.
4. Expose the solution to long-wavelength UV light at about 365 nm (Philips TL 20 W/09 UV light works well) for 10 to 30 min. The solution may be cooled on ice to prevent heating during the irradiation process.
5. Precipitate the sample to remove unreacted biotinylation reagent by adding 0.1-*M* potassium acetate and ethanol (1 : 2 ratio). Centrifuge and wash the biotinylated DNA pellet with ethanol, then dry it under nitrogen. The purified sample may be dissolved in water or buffer.

6.6. Active Hydrogen-Reactive *p*-Aminobenzoyl Biocytin, Diazotized

p-Aminobenzoyl biocytin contains a 4-aminobenzoic acid amide derivative off the α-amino group of biocytin (Section 6.2, this chapter) lysine residue (Thermo Fisher). The aromatic amine can be treated with sodium nitrite in dilute HCl to form a highly reactive diazonium group (Figure 11.26), which is able to couple with active hydrogen-containing compounds. A diazonium reacts rapidly with histidine or tyrosine residues within proteins, forming covalent diazo

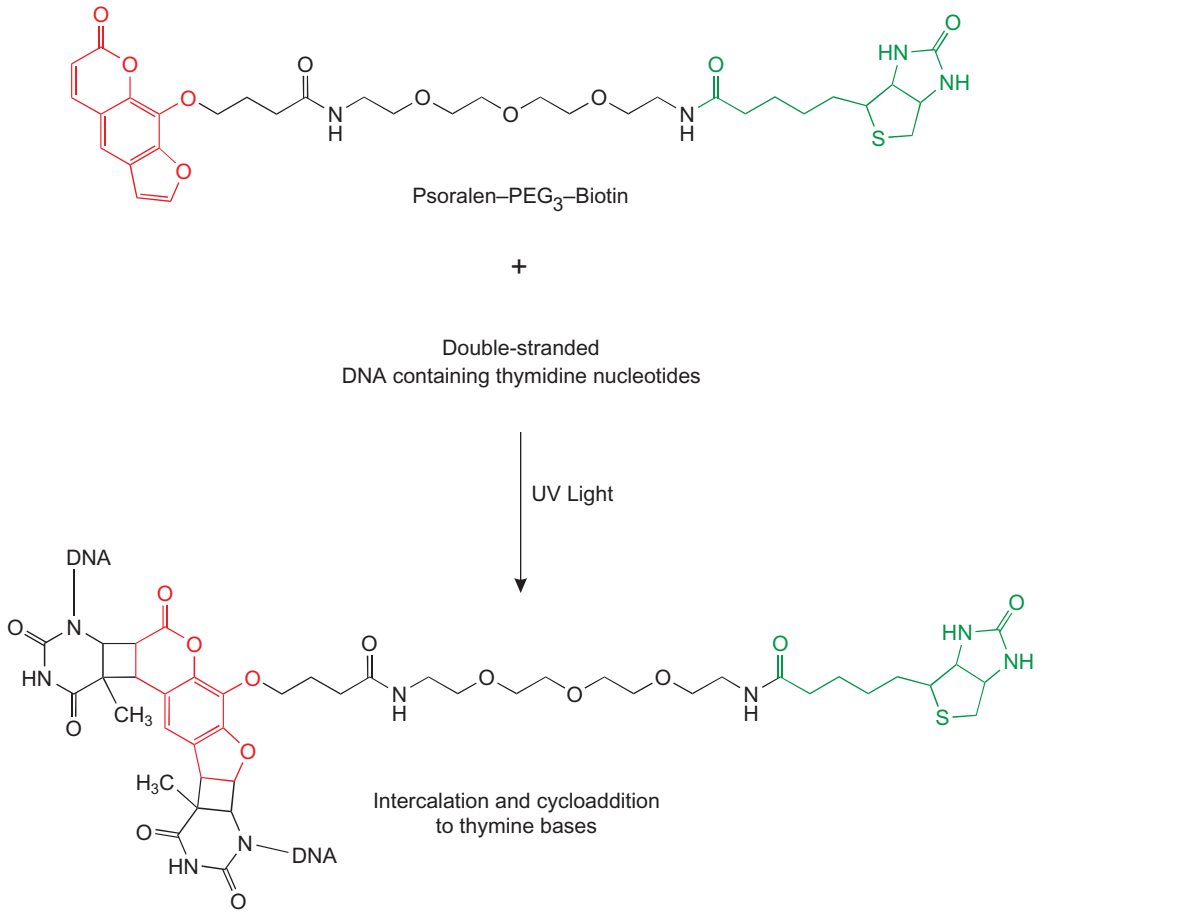


FIGURE 11.25 The photoreactive compound psoralen–PEO_3–biotin can intercalate into double-stranded DNA or RNA segments and covalently link to thymine bases *via* a photoreaction process.

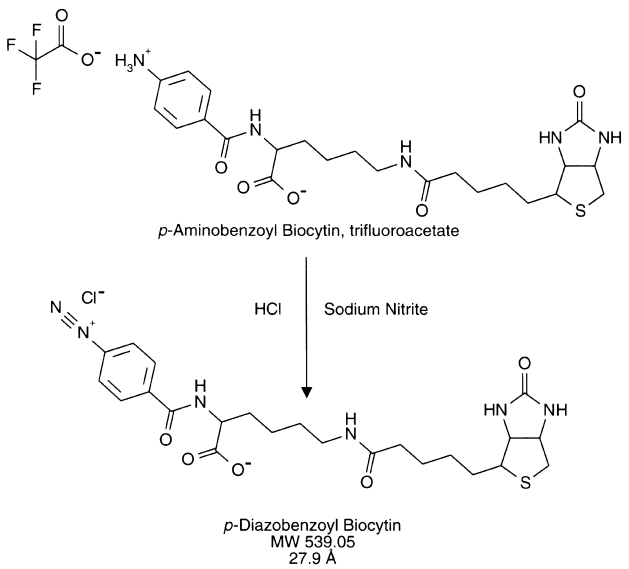

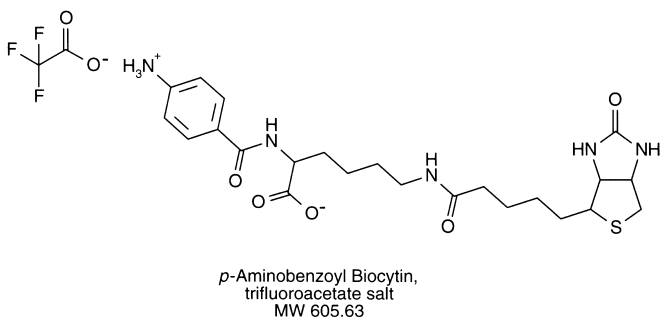

FIGURE 11.26 The aminophenyl group of this biotin derivative can be transformed into a diazonium reactive group by treatment with sodium nitrite in dilute HCl.

bonds (Wilchek *et al.*, 1986) (Figure 11.27). It can also react with guanidine residues within DNA at position eight of the base (Rothenberg and Wilchek, 1988) (Figure 11.28). Biotinylation *via* diazo linkages is reversible by treatment with a 10-fold molar excess of $Na_2S_2O_4$ (sodium dithionite) in 50-m*M* Tris, pH 8.5 (Gorecki *et al.*, 1971) (Chapter 3, Section 6.1, and Chapter 5, Section 9).

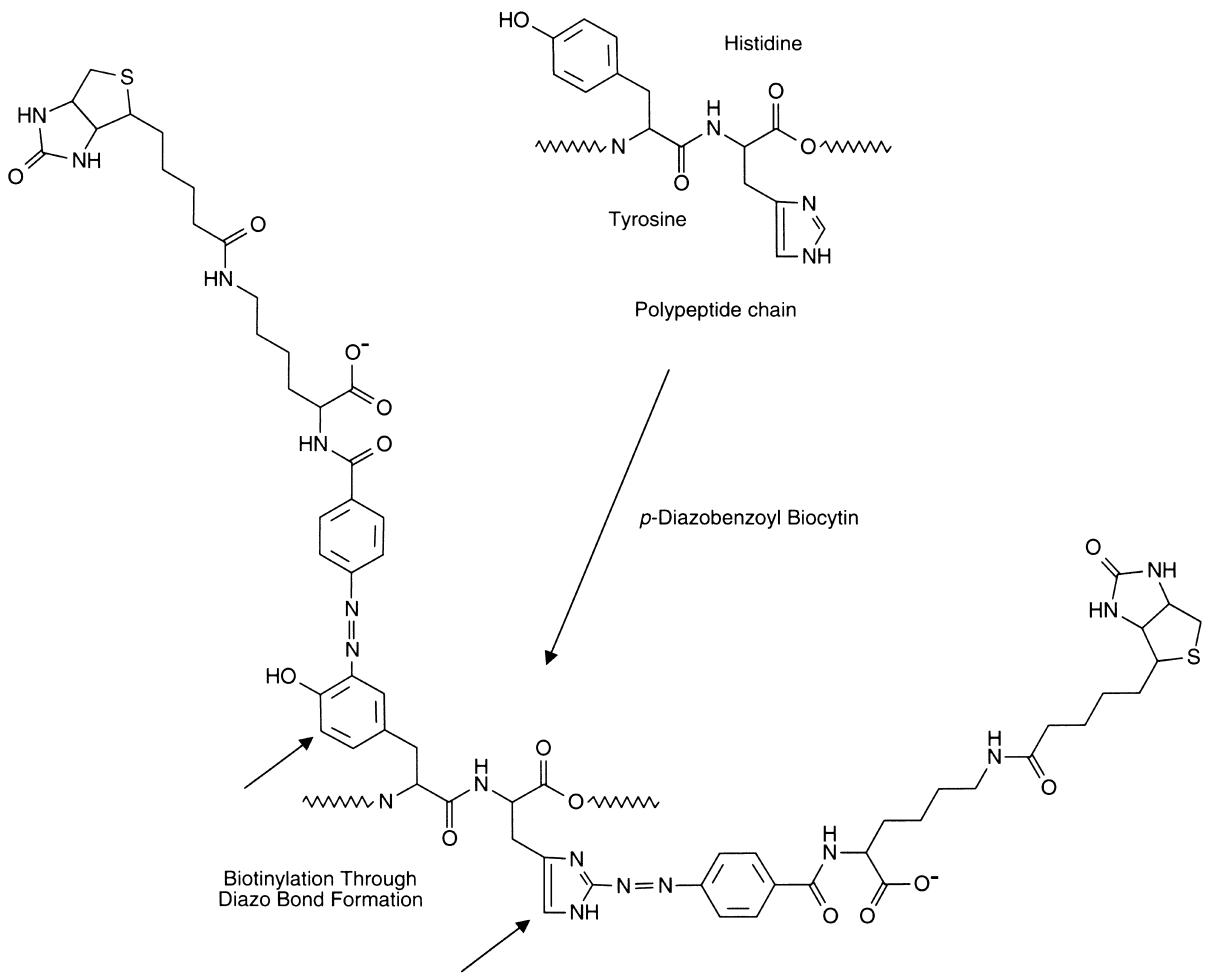

FIGURE 11.27 The diazonium group of *p*-diazobenzoylbiocytin can react with tyrosine or histidine residues in proteins to form diazo bonds.

The following procedure describes the process for creating a diazonium derivative of *p*-aminobenzoyl biocytin along with the subsequent coupling of the activated species to a protein or a nucleic acid probe.

Protocol for Formation of the Diazonium Derivative

1. Dissolve 2 mg of *p*-aminobenzoyl biocytin (Thermo Fisher) in 40 µl of 1-*N* HCl (concentration of 50 mg/ml). Cool the solution on ice.
2. Dissolve 7.7 mg of sodium nitrite in 1 ml of ice-cold water. Prepare fresh.
3. Mix 40 µl of the *p*-aminobenzoyl biocytin solution with 40 µl of the sodium nitrite solution.
4. React for 5 min on ice to create the diazonium derivative.
5. Stop the reaction by the addition of 35 µl of 1-*N* NaOH. Use immediately for biotinylation.

Protocol for Biotinylation of Proteins on Blots Using the Diazonium Derivative of p-Aminobenzoyl Biocytin

1. Dilute the diazonium derivative of *p*-aminobenzoyl biocytin with 0.2-*M* sodium borate, pH 8.4, to a concentration of 10 µg/ml.
2. Transfer proteins onto a nitrocellulose membrane using any appropriate procedure, including dot blotting the protein solution onto the surface.
3. Incubate the membrane with the biotin derivative at a ratio of 1 ml/cc^3 of membrane.
4. React for 1 h at room temperature.
5. Wash the membrane thoroughly with 0.1-*M* Tris, 0.15-*M* NaCl, pH 7.5.
6. Block nonspecific sites on the membrane with an appropriate blocking component (such as BSA) and detect the biotinylated proteins using an avidin or streptavidin conjugate.

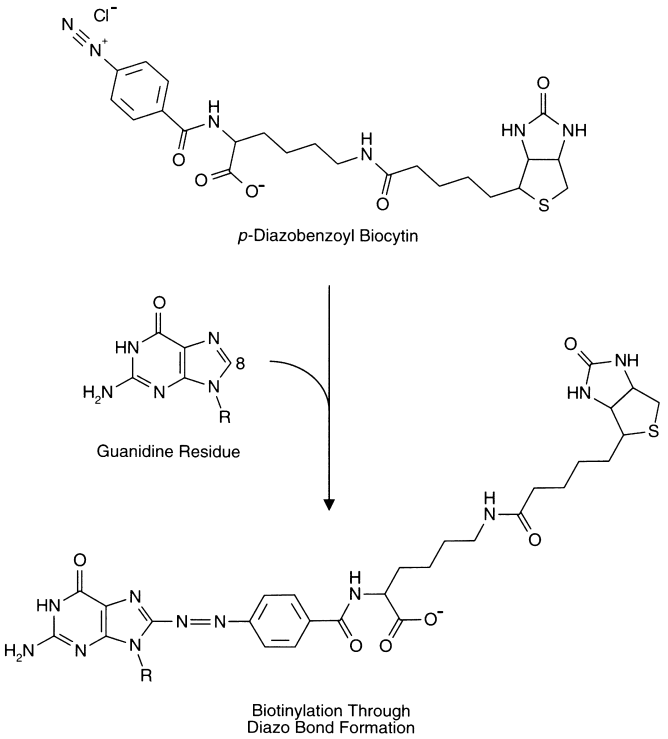

FIGURE 11.28 The diazonium group of p-diazobenzoylbiocytin can couple to the C-8 position of guanidine bases in nucleic acids, forming diazo bonds.

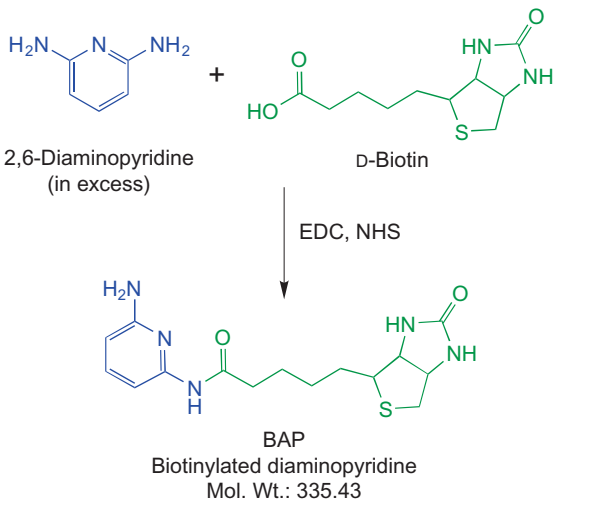

FIGURE 11.29 The synthesis of BAP can be done by the reaction of an excess of diaminopyridine with biotin in the presence of EDC and NHS.

6.7. Glycan Biotinylation Reagents

Biotinylated oligosaccharides are convenient probes of carbohydrate interactions, because the biotin label can be captured or detected using an avidin or streptavidin derivative. For instance, immobilized streptavidin can be used to purify glycoconjugates that have been labeled with a biotin group, potentially isolating glycoproteins or carbohydrate binding proteins (see Chapter 15). Enzyme-labeled or fluorescently labeled avidin or streptavidin can be used to probe for biotin-labeled carbohydrates in cells or tissue samples. In addition, a biotinylated glycan can be displayed on avidin or streptavidin to make an immunogen for developing specific antibodies to the carbohydrate.

Complex glycans on glycoproteins or other carbohydrate-bearing molecules can be modified with a biotinylation reagent using a number of reaction strategies. Oxidation with sodium meta periodate can be used to create aldehyde residues from diols on sugars, and this technique has been used to specifically modify sialic acids on glycans by reductive amination with a biocytin-hydrazide compound (see Section 6.4, this chapter) (Bayer *et al.*, 1988). Other procedures make use of released glycans from glycoproteins or other glycoconjugates, which contain reducing ends upon cleavage. The reducing ends can then be reacted with amine- or hydrazide-containing biotinylation compounds to couple with the open aldehyde group at the reducing end, thus forming a hydrazone linkage. The hydrazone bond may be reduced to stabilize the bond (recommended when reacting with amine-containing biotin compounds) or left as the unreduced hydrazone, which typically is carried out when coupling with hydrazide-biotin compounds. Alternatively, the reducing end of a carbohydrate can be reacted with an amine to form a glycosylamine derivative without opening the hemiacetal ring, thus better preserving the native structure of a glycan, which is important in some studies involving protein interactions.

A recent addition to the methods of glycan biotinylation makes use of the Staudinger ligation reaction with a phosphine–biotin derivative (see also Chapter 17, Section 6). Carbohydrates containing azide derivatives have been modified with this biotin compound to probe for glycoconjugates *in vivo*. This reaction is particularly useful for doing cell-based assays, because the ligation reaction is completely orthogonal to any biological reactions or interactions.

The following sections describe fluorescent biotinylation reagents that can be used to study carbohydrate function and interactions.

Biotinylated Aminopyridine

BAP (biotinylated aminopyridine or 2-amino-(6-amidobiotinyl)pyridine) is a derivative of D-biotin made by reacting the NHS ester of this vitamin with 2,6-diaminopyridine (DAP) in large molar excess, typically carried out using a carbodiimide EDC/NHS reaction (Figure 11.29). The resultant compound has fluorescent

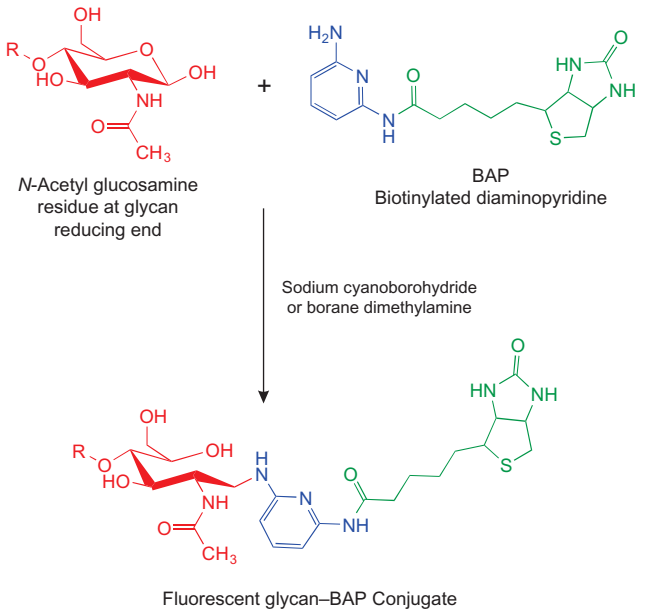

FIGURE 11.30 BAP can be used to label the reducing end of released glycans by reductive amination in the presence of a reducing agent.

properties due to the present of the aminopyridine ring, and its remaining free amine group may be used to modify reducing saccharides and glycans by reductive amination (Figure 11.30). BAP can be used to label oligosaccharides under mild conditions and without the carbohydrate structural degradation that results using periodate oxidation of carbohydrates. After modification, the glycans or carbohydrates can be analyzed by chromatography, electrophoresis, or mass spectrometry (Harvey, 2011; Nakano *et al.*, 2011).

Rothenberg *et al.* (1993) demonstrated the utility of BAP for highly sensitive fluorescence detection and separation of oligosaccharides by reverse-phase HPLC, with limits of detection down to about the 50-femtomole level (low picomole levels if using a cuvette reader with a 1-cm path length). Toomre and Varki (1994) subsequently published an improvement on the synthesis and use of the BAP reagent. In addition, the biotin group of BAP-labeled glycans can be used to create neoglycoproteins by interaction with tetrameric avidin or streptavidin molecules. The resultant glyco-complexes have been shown to be potent immunogens for evoking an IgG immune response in mice toward the glycan components (Srikrishna, 2001).

BAP-modified glycans also can be used to probe for receptors or binding proteins, which can then be detected by use of streptavidin conjugates or isolated by affinity chromatography on immobilized streptavidin or immobilized monomeric avidin (Thermo Fisher). The use of immobilized monomeric avidin is convenient, because the biotinylated glycans can be released by elution with acid pH or by using a solution containing biotin. BAP–carbohydrate adducts have been shown to be high affinity binders of both streptavidin and avidin, despite the relatively short spacer afforded by the diaminopyridine–biotin linker (Toomre and Varki, 1994).

The biotin group of BAP makes the compound somewhat hydrophobic, but attached to glycans the conjugates should display good water solubility due to the abundance of hydroxyl groups in addition to potentially having other charged groups on the sugars. BAP solubility in water was reported to be about 1 mg/ml, but with the addition of less than 1% DMSO, this solubility can be increased more than 10-fold (Toomre and Varki, 1994).

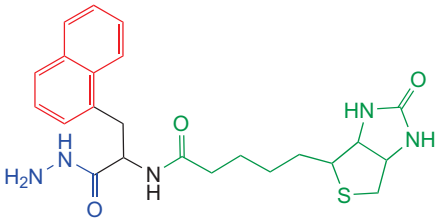
Fluorescence of the diaminopyridine group allows detection of conjugates down to the picomole range, with excitation and emission maxima at 345 nm and 400 nm, respectively. For detection of BAP and its conjugates, the optimal buffer environment is less than pH 5, because its fluorescent properties are pH dependent. A preferred buffer is sodium acetate at pH 4.

After BAP conjugation to saccharides or glycans, separation of the conjugates and unreacted BAP can be fluorescently followed using size exclusion chromatography (SEC) on a TSK-G3000PW column, which successfully resolves most of the lower molecular weight conjugate species, including single-sugar adducts through three-sugar carbohydrates. BAP–glycan conjugates containing more than three sugars elute early in the separation and do not resolve into discrete peaks, as smaller adducts do. Unreacted BAP elutes last in the SEC separation.

Alternatively, separations can be carried out by anion-exchange chromatography using a column packed with the HPLC support TSK-DEAE-2SW, which effectively resolves negatively charged carbohydrates, such as those containing sialic acid residues. BAP–glycan conjugates will elute according to their degree of negative charge character. Sulfate-containing sugars in general will interact more strongly with the matrix and have longer retention times than those containing only carboxylates.

BAP may be prepared by the reaction of NHS–biotin with DAP. The biotinylation compound is commercially available (Thermo Fisher) or it may be formed *in situ* by reaction of D-biotin with EDC and NHS. An optimized protocol for preparation of the reactive intermediate ester and the final BAP compound can be determined from Rothenberg *et al.* (1993) with modifications by Toomre and Varki (1994). Basically, a solution of 0.3-*M* DAP is prepared in 40 ml of 50-m*M* MES, pH 6.5, and 10 ml of 0.1-*M* D-biotin in DMSO is added. The reaction is initiated by the addition of EDC and NHS to a final concentration of 150-m*M* and 50-m*M*, respectively. The reaction is allowed to continue overnight at room temperature with mixing before purification of BAP on a C_{18} sample prep cartridge. The reaction mixture is applied to the cartridge and reaction byproducts and

DAP removed by washing with water and 10% acetonitrile. BAP is finally eluted in high purity by washing with 50% acetonitrile.



The conjugation of BAP to oligosaccharides can be achieved by the following protocol based on the method of Toomre and Varki (1994).

Protocol

1. Dissolve an oligosaccharide or glycan having a reducing end to be modified in 2:1 pyridine/glacial acetic acid (vol/vol) with a total reaction volume of 10 to 100 µl. If the carbohydrate initially is insoluble in the reaction solution, a prior dissolution in a minimal amount of DMSO or water can be carried out and then an aliquot transferred to the reaction medium.
2. Add to the solution a 50-fold molar excess of BAP over the estimated amount of carbohydrate present in the reaction mixture.
3. Heat at 80°C in a sealed Reactivial (Thermo Fisher) for 1 h.
4. Add to the reaction mixture an equal volume of the reducing agent borane-dimethylamine (BDA) complex, which was previously prepared in the reaction buffer at a concentration of 125 mg/ml.
5. React for another hour at 80°C.
6. Purify the BAP–glycan conjugate from unreacted glycans by use of a C_{18} sample prep cartridge, as described above for the synthesis of BAP. Separation of excess BAP from the conjugates may be carried out by SEC or anion-exchange chromatography, depending on the size of carbohydrates being modified and their intrinsic charge. Follow the separations by visualization of BAP fluorescence with a hand-held UV lamp or through the use of a fluorescence detector.

Biotinyl-L-3-(2-Naphthyl)-Alanine Hydrazide (BNAH)

BNAH is a biotin–hydrazide derivative containing a UV-absorbing and fluorescent naphthalene group (biotinyl-L-3-(2-naphthyl)-alanine hydrazide) (Leteux *et al.*, 1998). Unlike BAP described previously, BNAH has a hydrazide group for coupling to the reducing end of carbohydrates, instead of an amine. While both groups can be successfully conjugated to an aldehyde of a released glycan, the biotin–amine compounds require a reducing agent to stabilize the resultant hydrazone bond. BNAH may be coupled to reducing sugars without reduction, since the linkage formed between a hydrazide and an aldehyde is much more stable than that with an amine. The modified glycans or carbohydrates can be detected using the fluorescent properties of the naphthalene group or captured by immobilized streptavidin for further analysis (Harvey, 2011).

BNAH
Biotinyl-L-3-(2-naphthyl)-alanine hydrazide
Mol. Wt.: 455.57

In some cases, the ability to modify glycans at the reducing end without reduction preserves the carbohydrate's native structure sufficiently to allow interactions with proteins that would otherwise not interact if the bond were reduced. Therefore, depending on the ultimate use of the biotinylated carbohydrate, using a hydrazide-mediated conjugation process can have advantages over the use of amine–biotin compounds.

In the case of BNAH, however, it was determined that the resultant linkage with the reducing end of an oligosaccharide or glycan was not a hydrazone bond, but a glycosylhydrazide derivative, which preserves the pyranose ring structure of the sugar (Figure 11.31). This finding is the main reason a BNAH-modified glycan effectively displays a near-native conformation at the reducing end. In addition, the biotin label in this configuration is reversible and can be released by incubation under acidic conditions, thus allowing recovery of the carbohydrate.

Another advantage of the BNAH derivative is that the conjugation reaction with reducing sugars can be carried out in aqueous conditions and in an environment that permits carbohydrate and biotinylation reagent solubility.

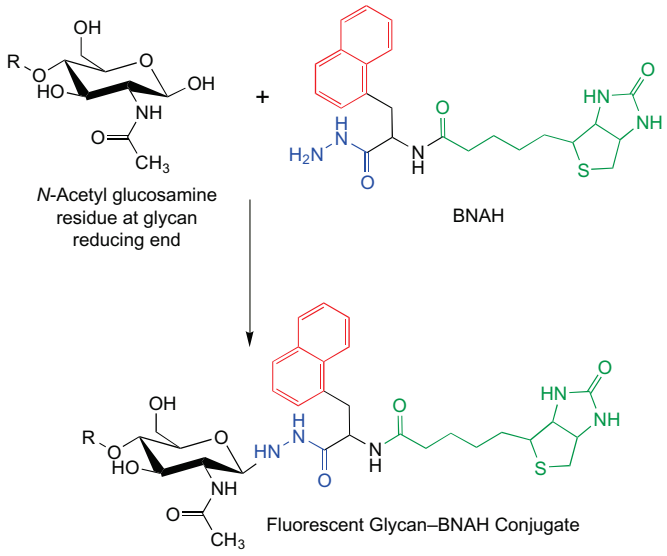


FIGURE 11.31 BNAH contains a hydrazide group that can be used to label the reducing end of released glycans through the formation of a hydrazone bond.

Modified carbohydrates may be stored for at least one year at −20°C in a solution of water/methanol (9:1, v/v) without degradation.

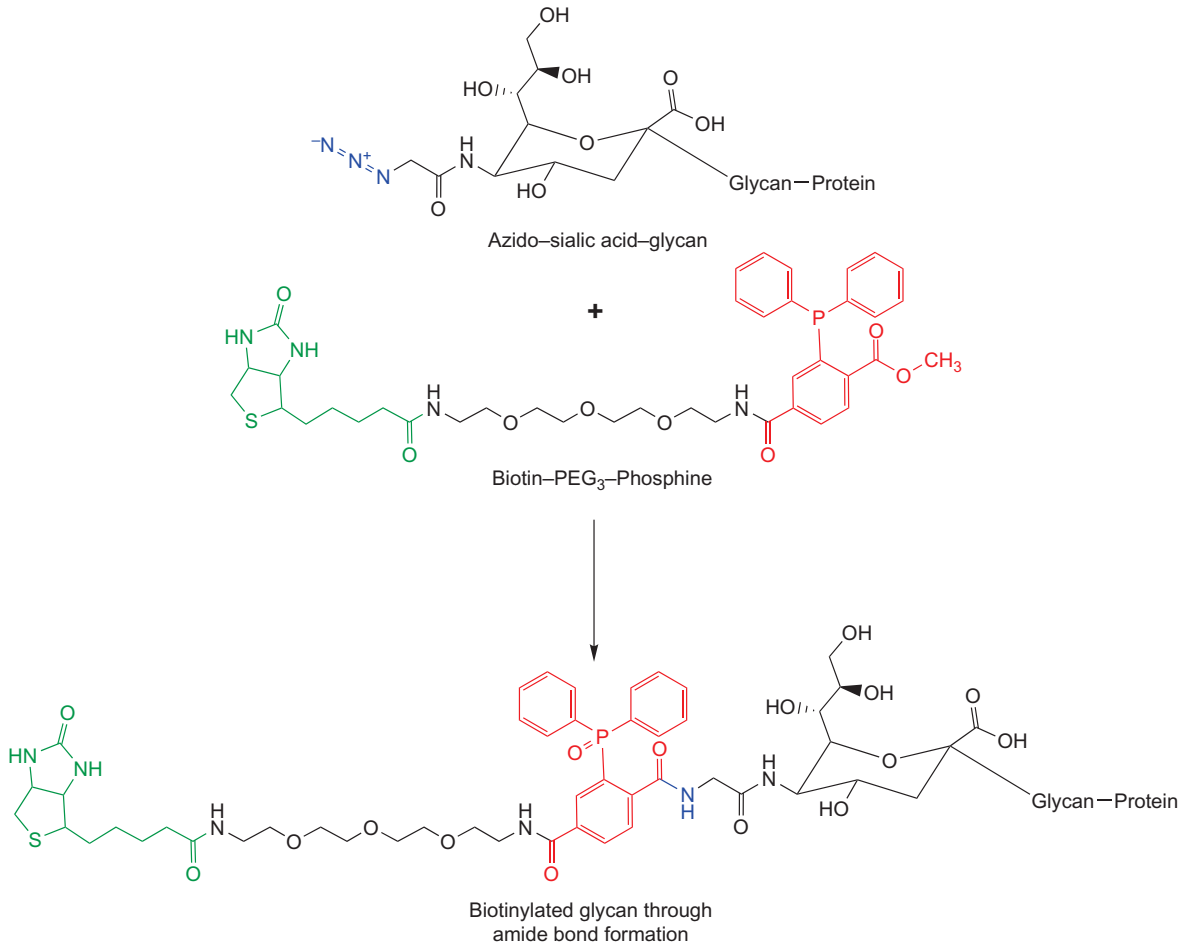
The following protocol is based on the method of Leteux *et al.* (1998).

Protocol

1. Dissolve 100 nmol of the carbohydrate to be modified and 500 nmol of BNAH in 25 µl of methanol (20-m*M* BNAH solution).
2. Evaporate the solution to dryness and re-dissolve in 25 µl an acidic solution of methanol/water/acetic acid (74:8:8, v/v) or in a neutral solution consisting of methanol/water (9:1, v/v), depending on the relative solubility of the carbohydrate.
3. React for at least 5 h at 60°C if using the acidic reaction solution or for a total of 16 h at 60°C if using the neutral solution.
4. Purification of the conjugates may be achieved by reverse-phase HPLC separation. Dry the reaction solution under a nitrogen stream and reconstitute in a minimum volume of acetonitrile/water (1:1, v/v). Apply the sample to a 5-µm C_{18}-silica HPLC column (250 × 4.6 mm, Nucleosil). Elute with a gradient of water to acetonitrile at a flow rate of 1 ml/min over a time course of 30 min. Free BNAH and BNAH–glycan derivatives can be monitored by absorbance at 275 nm. The conjugate peak will also be positive for carbohydrate by reaction with orcinol, which can be detected by spray after spotting a small eluted sample on a TLC plate.

Biotin–PEG$_3$–Phosphine

Saxon and Bertozzi (2000) reported on the synthesis and use of a novel biotinylation compound containing a phosphine group for coupling to azide containing molecules. The reagent has a biotin handle at one end, a triethyleneglycol (PEG) diamine spacer imparting increased water solubility in the middle, and a 3-(diphenylphosphino)-4-(methoxycarbonyl)benzamide group on the other end. Biotin–PEG$_3$–phosphine reacts with azide derivatives of amino acids, sugars, and cross-linkers to form an intermediate aza-ylide, which spontaneously rearranges in aqueous solution to create a stable amide bond (Figure 11.32).



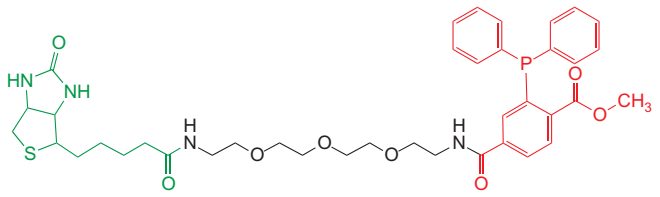


FIGURE 11.32 Azido–sialic acid-containing glycans can be labeled *in vivo* with biotin–PEG–phosphine using the Staudinger ligation reaction, which forms an amide bond.

This reaction is a modified Staudinger ligation that can be used to target azide-containing glycans or proteins *in vivo*.

Biotin–PEG_3–Phosphine
Mol. Wt.: 764.87

Cells grown in the presence of azide analogs of certain amino acids or sugars will incorporate these derivatives into proteins or carbohydrates through enzymatic synthesis using the native cell machinery. Azides thus displayed on biomolecules are unreactive with other substances typically found within the cell, but the azide derivatives may be targeted for conjugation using the modified Staudinger reaction (see Chapter 17, Section 6, for additional information on this reaction and its use in biological labeling).

Biotin–PEG_3–phosphine can be used to label glycans or proteins that have been modified to contain azide groups. The beautiful specificity of this reaction and its lack of toxic side reactions or additives make it suitable for use in living organisms, including cells and animals. The reaction is completely orthogonal to functional groups and reactions found in living systems, so the biotinylation process proceeds with no cross-reactions with other biomolecules. In addition, no cell toxicity has been observed due to the phosphine or the phosphine oxide byproduct of the coupling reaction. The phosphine also does not appear to be capable of reducing disulfides within proteins.

Prescher *et al.* (2004) have shown that mice fed with the peracetylated azido–mannose sugar derivative Ac_4ManNAz efficiently convert it through deacetylation by cytosolic esterases into an azido–sialic acid (SiaNAz), which then gets incorporated enzymatically into cell surface glycans. Biotinylation of these aberrant carbohydrates provides a method of detecting or isolating glycoproteins or other glycoconjugates (Vainauskas *et al.*, 2012). For instance, fluorescently labeled streptavidin can be used to image the cell surface structures containing the biotinylated azido–sugar derivatives. Alternatively, immobilized streptavidin or immobilized monomeric avidin can be used to purify biotinylated azido–glycoconjugates after cell lysis and provide a method for studying glycoprotein function and interactions.

The following protocol is based on the methods of Saxon and Bertozzi (2000) and Prescher *et al.* (2004).

Protocol

1. Treat and grow cells in the presence of 20-μ*M* Ac_4ManNAz for at least 3 days. The azide–mannose derivative may be solubilized in 70% DMSO as a more concentrated stock solution and then an aliquot added to the media containing the cells. Alternatively, mice may be treated with the azide–sugar derivative in aqueous DMSO at a level of 100 to 300 mg/kg, using an injection of 200 μl administered intraperitoneally daily for 7 days.
2. When working with cells, first wash them several times with PBS, pH 7.4, to remove any remaining Ac_4ManNAz from the media. Alternatively, if working with animals, isolate the tissue type desired and prepare the cells to be labeled in PBS, pH 7.4.
3. To label cell surface azide–glycans, the cells are reacted for 1 h using a final concentration of 1-m*M* biotin–PEG_3–phosphine reagent dissolved in PBS, pH 7.4.
4. Wash the cells several times with PBS, pH 7.4, to remove excess biotinylation compound.
5. The labeled glycans may be analyzed by cell sorting after staining with fluorescently modified streptavidin. Alternatively, the cells may be lysed and the labeled glycans isolated using immobilized streptavidin.

Additional biotinylation reagents are discussed in Chapter 18, Section 1.3, which describes newer hydrophilic biotin compounds containing PEG spacers. These reagents offer significant advantages over the more traditional aliphatic compounds, because the pronounced water solubility of the PEG cross-bridge can prevent aggregation of biotinylated molecules. With some longer chain biotin compounds that contain hydrophobic hydrocarbon spacers, proteins can precipitate or lose activity over time due to the insolubility of the biotin modifications. Biotinylated antibodies are particularly susceptible to aggregation and loss of antigen binding ability if they are modified using hydrophobic biotin compounds. The PEG-based biotin reagents show better solubility and longer stability than their corresponding aliphatic biotinylation compounds of equivalent size.

CHAPTER

12

Isotopic Labeling Techniques

1. BIFUNCTIONAL CHELATING AGENTS AND RADIOIMMUNOCONJUGATES

Monoclonal antibodies provide extremely high antigen specificity that can be useful as cancer-targeting and therapeutic reagents *in vivo* (Waldmann, 1991; Dougan and Dranoff, 2012; Modjtahedi *et al*., 2012). Radiolabeled monoclonals are currently undergoing developmental clinical trials for their use in the diagnosis or treatment of cancer. The antigen binding specificity of the radioimmunoconjugate provides the targeting capability to localize in tumor sites, while the associated radiolabel provides cytotoxic properties or detectability for imaging applications (Schlom, 1986) (see also Chapter 1, Section 3.5).

Iodine-131 was among the first radioactive isotopes used for radioimmunoconjugate preparation (Order, 1982; Regoeczi, 1984). Since the earliest studies on the efficacy of radiotherapy, additional isotopes have been employed, such as iodine-125, bismuth-212, yttrium-90, yttrium-88, technetium-99m, copper-67, rhenium-188, rhenium-186, galium-66, galium-67, indium-111, indium-114m, indium-115, and boron-10.

There are several methods commonly used to label monoclonal antibodies with radionuclides. In a direct labeling process, a radioactive atom is attached to functional groups on the antibody without the use of an intervening chemical spacer. For instance, radioiodination can be done through modification of tyrosine side chains using established techniques and reagents (see Section 2). Another direct method uses indigenous sulfhydryl groups or those formed through disulfide reduction to couple covalently certain metal nuclides (Holmberg and Meurling, 1993; Ranadive *et al*., 1993). Thiolation reagents also can be used in this regard to create the requisite SH groups by modification of other protein functional sites (Joiris *et al*., 1991) (Chapter 2, Section 4.1).

Indirect methods of protein labeling with radiolabels utilize organic compounds able to chelate metal ions in a coordination complex. Bifunctional chelating agents (BCAs), as they are called, contain a reactive group for coupling to proteins or other molecules and a strong metal chelating group for complexing certain radioactive metals (Lattuada *et al*., 2011; Maruk *et al*., 2011). Their extensive use with monoclonal antibodies that are able to target specific cellular antigens has resulted in important radiopharmaceutical applications for the diagnosis and treatment of cancer (Wessels and Rogus, 1984; Meares, 1986; Otsuka and Welch, 1987; Hnatowich, 1990; Liu and Wu, 1991; Subramanian and Meares, 1991). The BCAs may be loaded with the radioactive metal before or after their conjugation with a monoclonal antibody (Frytak *et al*., 1991). If they are loaded with radionuclides prior to modifying the antibody, the BCA–metal pair is called a preformed complex (Kasina *et al*., 1991).

The following sections describe the major methods and BCAs used to create radioimmunoconjugates.

1.1. DTPA

DTPA is diethylenetriaminepentaacetic anhydride, a bifunctional chelating agent containing two amine-reactive anhydride groups. The compound reacts with N-terminal and ε-amine groups of proteins to form amide linkages. The anhydride rings open to create multivalent, metal-chelating arms able to bind metals tightly in a coordination complex (Figure 12.1) (Hnatowich *et al*., 1982). Metal-chelate bonds are created through dative interactions with the unshared pair of electrons on each oxygen and nitrogen atom on DTPA, thus creating the potential for eight coordination sites with metal ions (from three nitrogens and five oxygens). Targeting molecules modified with DTPA can be used to carry radioactive or nonradioactive metal ions for *in vivo* imaging purposes, including PET/CT scanning and high-contrast imaging (Krausz *et al*., 2011; Nayak *et al*., 2011).

Optimal reaction conditions for antibody modification with DTPA are neutral to slightly alkaline pH environments containing no extraneous amines. A pH of 7 to 8 may be used with buffering provided by phosphate or bicarbonate buffers at 0.1-*M*. Since two anhydride groups are present on each DTPA molecule there is potential for creating crosslinks between two

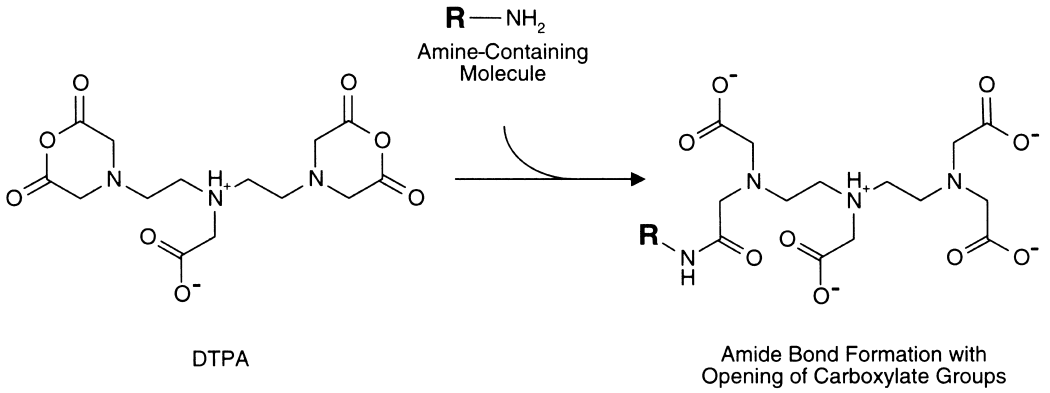

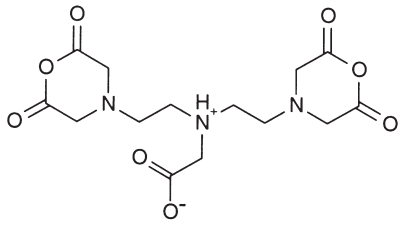

FIGURE 12.1 DTPA reacts with amine-containing molecules via ring opening of its anhydride groups to create amide bond linkages. The potential also exists for both anhydride groups to react and cause crosslinking of modified molecules, which is undesirable.

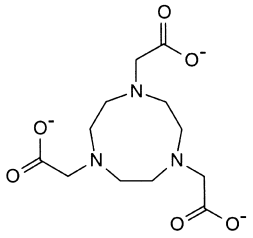
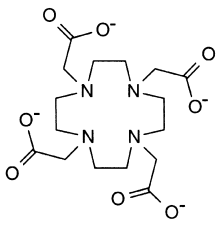
amine-containing molecules. Conjugation of antibody through DTPA crosslinks may be a major reason some immunoglobulins lose antigen-binding activity after modification (Lanteigne and Hnatowich, 1984). Optimization of the amount of protein present and the quantity of DTPA added to the reaction may have to be done to avoid this type of crosslinking and polymerization.

DTPA
Diethylenetriamine-pentaacetic anhydride
MW 357. 33



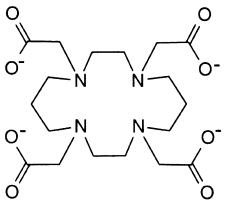
DTPA also can be used to modify amine-containing polymers, such as poly-L-lysine, to create a chelating polymer possessing multiple metal binding sites (Trubetskoy *et al.*, 1993). Subsequent polymer modification of antibodies provides much higher radioactivity per molecule than if DTPA is directly coupled to the protein. Such chelating polymers can introduce into proteins as many as 100 DTPA residues, each one able to hold one radiolabel, for each 55,000-Dalton poly-L-lysine chain modified (Torchilin *et al.*, 1993). Directed coupling to the antibody through only the N-terminal of the poly-L-lysine chain limits the modification to a single point along the polymer, thus avoiding crosslinking or multi-site attachment that can affect antibody activity (Slinkin *et al.*, 1991). This approach can dramatically increase the radioactivity level at tumor sites, thus increasing cytotoxicity or enhancing imaging capability. Similar DTPA–polymer constructs can be formed using PAMAM dendrimers (Chapter 8), which can provide an amine-containing scaffold that can hold dozens of chelating groups, depending on its size.

While DTPA has been used extensively as a BCA to prepare radiopharmaceutical reagents, newer metal chelators such as those discussed below may show greater promise for *in vivo* applications.



1.2. DOTA, NOTA, and TETA

Cyclic chelating compounds have been developed that have both nitrogens and carboxylates and are able to tightly coordinate metal ions useful for *in vivo* imaging in diagnostics and drug discovery (Brechbiel, 2008; Stasiuk *et al.*, 2012). Such metal chelates attached to antibodies and other targeting agents have widespread utility in the major imaging modalities, including MRI (chelates of Gd), PET (chelates of ^{64}Cu and ^{68}Ga), and SPECT (using ^{99m}Tc). Three of the most commonly used cyclic, bifunctional chelating agents are DOTA, NOTA, and TETA.



DOTA is 1,4,7,10-tetraazacyclododecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid, a chelating ring structure containing four acetic acid carboxylate groups off the four nitrogens of its 12-atom cyclic structure. C- or N-functionalized derivatives of this basic structure produce a BCA capable of modifying proteins and binding radioactive metal ions in strong coordination complexes of up to eight dative bonds (Cox *et al.*, 1990; Renn and Meares, 1992). Perhaps the simplest method of DOTA functionalization is through modification of one of its carboxylates to contain a short spacer terminating in a reactive group capable of being coupled to proteins (Li and Meares, 1993). However, modification of carbons on its cyclic backbone also is possible, which preserves all of the carboxylates for coordinating with a metal ion (Moi and Meares, 1988; Brechbiel *et al.*, 1993). Complexes of metal ions with DOTA have been studied in detail (Sherry *et al.*, 1989; Aime *et al.*, 1992).

NOTA

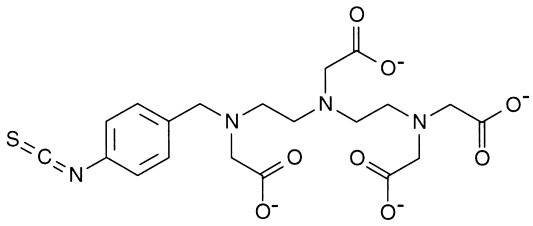
DOTA
1,4,7,10-Tetraazacyclododecane-*N*, *N*', *N*'', *N*'''-tetraacetic acid



TETA
1,4,8,11-Tetraazacyclotetradecane-*N*, *N*', *N*'', *N*'''-tetraacetic acid

A BCA similar to DOTA is NOTA, which is 1,4,7-triazacyclononane-*N*,*N*′,*N*″-triacetic acid. NOTA contains a smaller ring structure in comparison to DOTA and only has three chelating carboxylate groups and three nitrogens, creating a maximal coordination potential for six dative bonds with metal ions. Some reports indicate that NOTA is superior to DOTA (Zhang *et al.*, 2011). Synthesis of functional derivatives can be done through C- or N-modifications, creating reactive groups able to couple to proteins and other molecules (Cox *et al.*, 1990). Cox and co-workers (1990) have prepared an (S)-lysine derivative of a benzamide-protected, C-substituted NOTA. Since coupling antibodies with NOTA through an amide linkage leaves only two free carboxylic acids, potentially making the reagent pentadentate for chelating purposes, metal complexes formed with this reagent may have lower stability than those containing greater numbers of chelating groups.

A third compound in the same category as DOTA and NOTA is TETA, which is 1,4,8,11-tetraazacyclotetradecane-*N*,*N*′,*N*″,*N*‴-tetraacetic acid. TETA contains a larger ring structure than the other two BCAs and has four chelating carboxylate groups and four nitrogens. Similar to the other two chelators, C- and N-functionalized derivatives can be prepared with TETA (Brechbiel *et al.*, 1993). In addition, a novel *p*-bromoacetamidobenzyl–TETA derivative could be used to label antibodies through sulfhydryl groups and securely bind radioactive copper for probing biological systems *in vivo* (Moi *et al.*, 1985).

1.3. DTTA

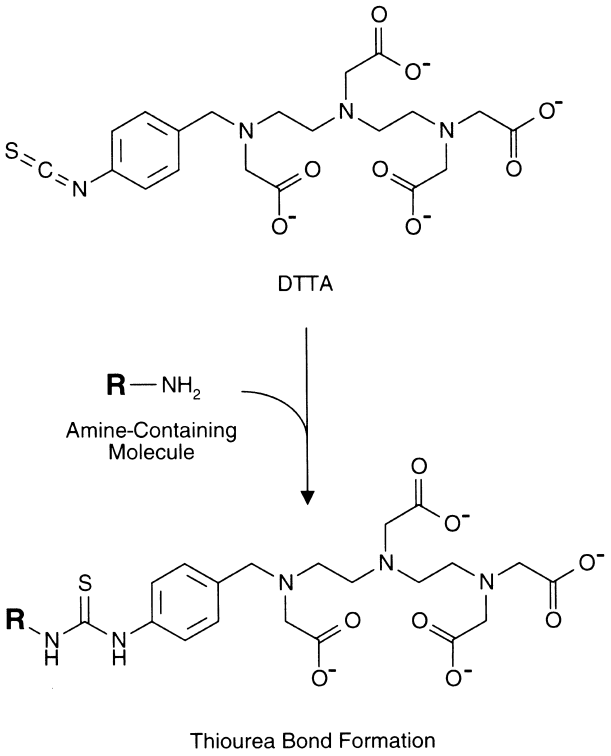
DTTA is N^1-(*p*-isothiocyanatobenzyl)-diethylenetriamine-N^1,N^2,N^3,N^3-tetraacetic acid. This BCA contains four carboxylate groups and three nitrogens that can hold metals tightly in a coordination complex of seven dative bonds. The compound is especially good at chelating lanthanide-series elements, such as europium, samarium, terbium, and dysprosium (Appel *et al.*, 2011). Unlike the previous bifunctional chelating agents which are used to prepare radiopharmaceutical reagents, this one is used primarily for complexing metals to form fluorescent probes for time-resolved fluoroimmunoassays (Hemmila, 1988) (see Chapter 10, Section 9). The most commonly used lanthanides for this purpose are europium (Eu^{3+}), terbium (Tb^{3+}), and samarium (Sm^{3+}). Proteins modified with DTTA and complexed with lanthanide metal ions form the basis for unique fluorescent probes possessing long-lived signals upon excitation.

DTTA
N^1-(*p*-isothiocyanatobenzyl)-diethylenetriamine-N^1, N^2, N^3, N^3-tetraacetic acid

The isothiocyanate group of DTTA reacts with primary amines in proteins and other molecules to form stable thiourea bonds (Figure 12.2) (Mukkala *et al.*, 1989). The reagent is water soluble and can be reacted under relatively mild conditions (in 0.1-*M* sodium carbonate, pH 9.0). The isothiocyanate group is reasonably stable in aqueous solution for short periods, but will degrade. Best results will be obtained if fresh DTTA is used. The reaction involves attack of the nucleophile on the central, electrophilic carbon of the isothiocyanate group. The resulting electron shift creates a thiourea linkage between the chelating compound and the protein with no leaving group. Modification of antibodies can be done without loss of significant antigen binding activity, even when up to 10 to 15 DTTA chelates are substituted per immunoglobulin molecule (Stahlberg *et al.*, 1993). Diagnostic assays using DTTA–Eu^{3+} chelates are commercially available employing the DELFIA® (Wallac Oy, Turku, Finland) time-resolved fluoroimmunoassay system.

1.4. DFA

DFA or deferoxamine is *N*′-[5-[[4-[[5-(acetylhydroxyamino)pentyl]amino]-1,4-dioxobutyl]hydroxyamino]pentyl]-*N*-(5-aminopentyl)-*N*-hydroxybutanediamide, a naturally occurring product isolated from *Streptomyces pilosus*. Its native activity is forming iron complexes, but it is also very proficient at forming coordination



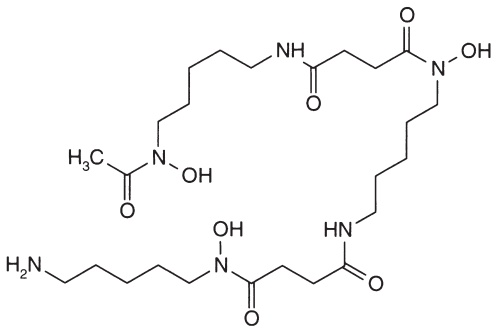


FIGURE 12.2 The isothiocyanate group of DTTA can react with amine-containing molecules to form isothiourea bonds.

chelates with other metals, particularly lanthanides such as galium-68 (Motta-Hennessy *et al.*, 1985) and ^{99m}Tc (Maruk *et al.*, 2011). Radiopharmaceutical agents for imaging can be produced by modification of targeting molecules with DFA complexes containing radioactive metals. The amine group of DFA can be utilized for direct labeling of antibodies and other proteins through coupling with available carboxylates using carbodiimide-mediated conjugation with EDC (Chapter 4, Section 1.1). The use of amine-reactive, homobifunctional crosslinkers (Section 2.2) also can be employed to modify proteins with DFA at their amino groups.

DFA–polymer conjugates can be made containing multiple chelating groups along the length of the polymer. The polymer backbone utilized for this synthesis can be either activated dextran (Torchilin *et al.*, 1989) or succinylated poly-L-lysine (Slinkin *et al.*, 1990; Torchilin *et al.*, 1993). These DFA–polymer constructs can be attached to antibody molecules through additional functional groups on the polymer. Chelating polymers can provide much higher signals than direct attachment of DFA to antibodies, since each coupled polymer derivative can possess dozens of chelated radioactive metals. In addition, high substitution levels of DFA directly coupled to antibodies can significantly affect activity by denaturation or blocking of the antigen binding sites.

1.5. Use of Thiolation Reagents for Direct Labeling to Sulfhydryl Groups

Proteins containing sulfhydryl residues can be labeled with a radioactive element by direct coordination to the SH group through a dative bond (Chapter 3, Section 2.8), avoiding entirely the use of a bifunctional chelating agent. Particularly, reduced sulfhydryls in antibody molecules can be coupled with ^{99m}Tc to yield thiol–metal derivatives (Thakur and DeFulvio, 1991; Rhodes, 1991). However, cleavage of disulfide linkages within the antibody can lead to activity losses and fragmentation (Pimm *et al.*, 1991). The required sulfhydryl groups can be introduced into antibodies without disulfide reduction through the use of a thiolation reagent that modifies amine residues within the antibody (Joiris, 1991). Thiolating agents such as 2-iminothiolane or SATA provide efficient ways of introducing multiple sulfhydryl groups for this type of radiopharmaceutical preparation (Chapter 2, Section 4.1).

Site-directed thiolation at carbohydrate residues within the Fc region of antibody molecules may prove to be the best choice for SH group introduction while maintain antigen-binding activity. Ranadive and coworkers (1993) used the heterobifunctional crosslinking agent PDPH (3-(2-pyridyldithio)propionyl hydrazide) (Chapter 6, Section 2.3) to react specifically with oxidized polysaccharide components of monoclonals. The polysaccharide chains are treated first with sodium periodate (Chapter 2, Section 4.4) to generate reactive aldehyde residues. PDPH then is coupled to these aldehydes via its hydrazide end to create stable hydrazone linkages. The other end of the crosslinker, containing a pyridyl disulfide group, is reduced with DTT under mild conditions (25-m*M* DTT, pH 4.5, 30 min) to produce the free sulfhydryl groups. Since the thiolation occurs only at carbohydrate locations within the antibody, the modification has a better chance of being away from the antigen binding sites, thus preserving

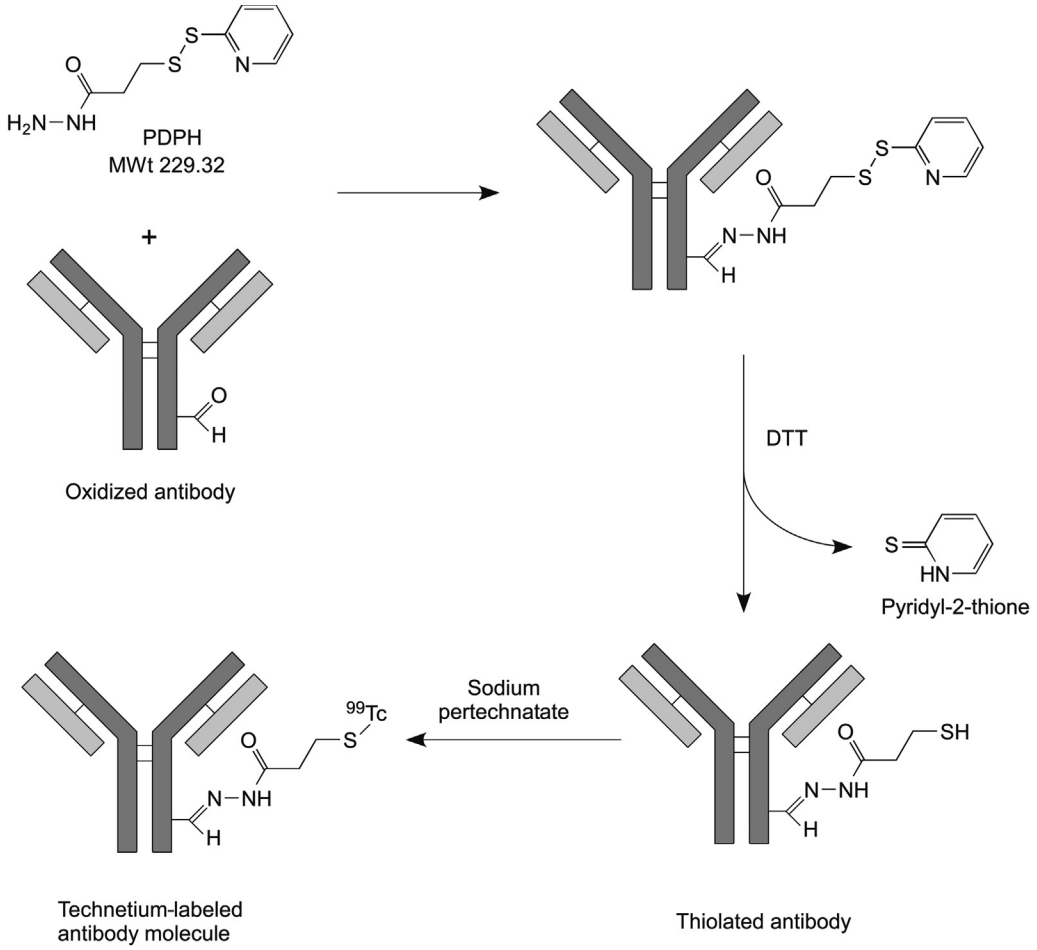

FIGURE 12.3 Antibody molecules oxidized with sodium periodate to create aldehyde groups on their polysaccharide chains can be modified with PDPH to produce thiols after reduction of the pyridyl disulfide. Direct labeling of the sulfhydryls with ^{99}Tc produces a radioactive complex.

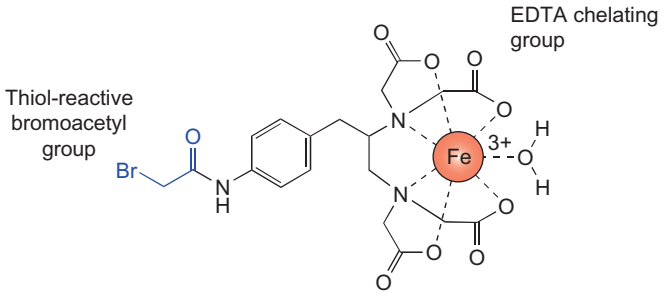

immunoglobulin activity. Subsequent treatment with sodium pertechnatate yields the ^{99m}Tc derivative on the sulfhydryl groups (Figure 12.3).

1.6. FeBABE

FeBABE (pronounced "iron-babe") is Fe(III) (S)-1-(*p*-bromoacetamido-benzyl)ethylene diamine tetraacetic acid, a bifunctional chelating agent designed to be a hydroxyl radical probe to footprint interacting domains between proteins (Rana and Meares, 1990, 1991). The bromoacetyl group reacts with thiols to form a thioether bond. The EDTA chelating group coordinates Fe^{3+} to create a redox active complex that is able to form reactive oxygen species in aqueous solution. Iron–EDTA chelates are effective at generating hydroxyl radicals (·OH) that can react with peptide bonds to oxidize and cut them non-selectively. The reaction is initiated with the addition of peroxide and ascorbate, which catalyzes the peptide cleavage reaction. Thus, one protein labeled with FeBABE can be allowed to interact with a protein-binding partner and the cleavage reaction initiated, which results in cuts in the peptide structure immediately surrounding the region where FeBABE is attached. The pattern of peptide cutting can be used to determine the area on both interacting proteins that constitutes the binding region, because all other peptide regions will be affected by the oxidation reaction.

FeBABE has been used to study the interactions of the RNA polymerase RbpA (Hu *et al.*, 2012), to map the protein–protein interactions of ATP-dependent chromatin remodelers (Hota *et al.*, 2012), to investigate the binding of the Swi2/Snf2 remodeller Mot1 in complex with its substrate TBP (Wollmann *et al.*, 2011), and to study the interaction of transcriptional factor SoxS and a subunit of RNA polymerase (Zafar *et al.*, 2011).

Chapter 24, Section 4.1, provides additional information about the FeBABE chelator and its use in studying protein interactions.

2. IODINATION REAGENTS

Modification of proteins and other molecules with a radioactive element provides a means of detection that can be extremely sensitive for assay, localization, and imaging applications. Among the most common radiolabels for biological studies are ^{14}C, ^{32}P, ^{35}S, ^{3}H, and the isotopes of iodine, ^{124}I, ^{125}I, and ^{131}I. The unstable isotopes of carbon, phosphorus, sulfur, and hydrogen are all β emitters, releasing subatomic particle radiation consisting of either positrons or electrons. To measure labeled molecules containing β emitters often necessitates tedious sample manipulation including tissue homogenization and mixing with scintillation cocktails for subsequent counting.

The radioactive isotopes of iodine, by contrast, are both γ emitters, providing a much easier route to measurement than β-particle-emitting radioisotopes. High-energy electromagnetic radiation can be detected directly without the need for intermediate scintillation cocktails. Iodine-131 was the first unstable iodine isotope to be used for labeling protein molecules (Li, 1945; Pressman and Keighley, 1948). The ^{131}I isotope decays by both β^- (electron) and γ emission. The specific activity of this element can be as high as 6550 Ci/mmol, providing extraordinary sensitivity for detecting labeled molecules.

Iodine-125 decays by electron capture followed by γ emission. However, the maximum energy of ^{125}I electromagnetic energy emission can be as little as 1/10 to 1/3 that of ^{131}I (Wilbur, 1992; Powsner, 1994). The greater energy intensity of ^{131}I emission actually can be a disadvantage, since γ rays emanating from it are more penetrating, requiring increased precautions and greater protective equipment. In addition, the relatively short half-life of ^{131}I (8.1 days) as compared to ^{125}I (60 days) necessitates that labeled compounds be prepared more often, since activity losses will be severe upon storage. Because ^{125}I is not a particle emitter, its use *in vivo* for imaging applications limits radiation damage to the immediate surrounding proteins, cells, and tissues.

$$I_3^- \rightleftharpoons I_2 + I^-$$

$$I_2 + H_2O \rightleftharpoons H_2OI^+ + I^-$$

FIGURE 12.4 Iodide anion in aqueous solution undergoes an equilibrium reaction process to form the reactive H_2OI^+ species.

Iodine-124 also is being used routinely for developing imaging probes for radiopharmacological evaluation (Koehler *et al.*, 2010).

These factors make ^{125}I the iodine label of choice for radiolabeling biological molecules. Its commercial availability from a number of suppliers at relatively low cost further adds to its popularity. Even though it has lower specific activity than ^{131}I, iodine-125 still provides much greater sensitivity than ^{14}C, ^{32}P, ^{35}S, or ^{3}H in labeling biomolecules. In fact, the use of a radioactive iodine label can create probes that have 150-fold more sensitivity than tritiated molecules and as much as 35,000-times the detectability of ^{14}C-labeled molecules (Bolton and Hunter, 1986).

Radioiodination is the process of chemically modifying a molecule to contain one or more atoms of radioactive iodine. Early studies on protein modification determined that iodine in aqueous solution formed a reactive ion, H_2OI^+ (Figure 12.4), that is capable of modifying tyrosine side chains, the imidazole groups of histidine, and either modifying sulfhydryl groups or catalyzing their oxidation to disulfides (Figure 12.5). Most methods now utilize a chemical agent to create the reactive iodine species, thus driving the reaction at much greater rates.

There are two main methods of radioiodination that are commonly employed to modify proteins and other molecules: (1) direct labeling of the desired protein or other target molecule in the presence of an oxidizing agent; or (2) indirect labeling of the desired molecule by first labeling an intermediate compound which is then used to perform the final modification. Direct labeling methods are by far the most common, and the chemistries used in this process have been reviewed (Regoeczi, 1984). For a review of radioiodination methods and chemistry, see Eisenhut and Mier (2011).

The prevailing procedures for direct coupling of ^{125}I to a protein or other molecule are through the use of oxidizing agents. The *in situ* preparation of an electrophilic radioiodine species is fundamental to the ability to modify certain reactive sites within the desired molecules. The most common oxidizing compounds are *N*-haloamine derivatives, such as *N*-chlorotoluenesulfonamide (chloramine-T) or 1,3,4,6-tetrachloro-3α,6α-diphenylglycouril (Iodogen). In most instances, such compounds do not harm the proteins being labeled, although reaction times should be carefully controlled to prevent over-labeling or oxidative damage. A secondary method of producing an

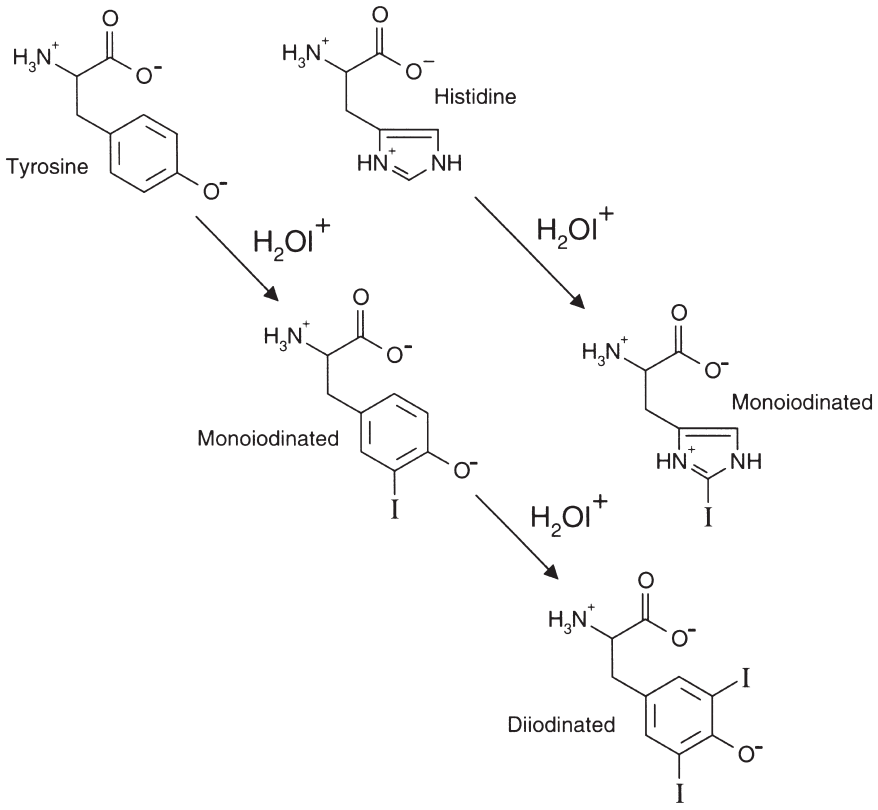

FIGURE 12.5 The iodination of tyrosine or histidine residues in proteins by H_2OI^+.

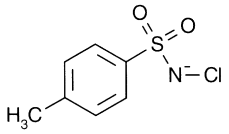
oxidative effect is to use an enzyme-driven system. The glucose oxidase/lactoperoxidase reaction creates reactive iodine through the production of hydrogen peroxide from glucose with the subsequent action of peroxidase to form I_2 from I^-.

Formation of the electrophilic halogen species leads to the potential for rapid reaction with compounds containing strongly activating groups, such as in activated aryl compounds. Particularly, substances containing aromatic ring structures that have substituents on the ring which are electron donating can sufficiently activate the carbons on the ring to undergo electrophilic substitution reactions. Therefore, phenols, aniline derivatives, or alkyl anilines that contain OH, NH_2, or NHR constituents, respectively, are very susceptible to being iodinated. In proteins, this translates into tyrosine side-chain phenolic groups and histidine side-chain imidazole groups. Crosslinking compounds or modification reagents containing ring-activated groups also are capable of being iodinated.

The addition of a radioactive iodine atom to a protein molecule typically has little effect on the resultant protein activity, unless the active center is modified in the process. The size of an iodine atom is relatively small and does not result in many steric problems with large molecules. The sites of potential protein modification are tyrosine and histidine side chains. Tyrosine may be modified with a total of two iodine atoms per phenolate group, whereas histidine can incorporate one iodine atom. Sulfhydryl modification at cysteine residues is typically unstable.

The result of iodination at tyrosine groups can alter the spectral characteristics of the protein in solution (Hughes, 1950). The typical protein absorbency at 280 nm can shift to a maximum at about 305 to 315 nm due to the addition of iodine atoms to the phenolate ring of tyrosine. The degree of absorbance shift is dependent on how many iodine atoms are incorporated into the protein and whether they result in mainly mono-iodotyrosine or di-iodotyrosine formation. In addition, as the level of iodination increases, the solubility of a protein in aqueous solution can dramatically decrease until complete insolubility results in proteins with high numbers of tyrosines.



Thus, controlling the degree of iodination is an important consideration both in choosing the oxidant used and in controlling the time of reaction. Typically, most radiohalogenations are done in a time period of 30 s to as long as 30 min. Optimization may have to be performed to determine the correct time of use for a particular modification reaction. Termination of the iodination reaction may be done through addition of a reducing agent, such as sodium metabisulfite. Bisulfite

reduces the electrophilic iodine species to unreactive iodide, effectively stopping the modification process.

The following sections discuss the major radioiodination reagents available for direct labeling as well as the main crosslinkers or modification reagents used for indirect labeling techniques.

2.1. Chloramine-T

Chloramine-T, or *N*-chlorotoluenesulfonamide (Sigma), has been one of the most popular oxidizing reagents used for radioiodination techniques since its introduction by Greenwood *et al.* in 1963. It has strong oxidizing properties that readily lead to the formation of the required electrophilic halogen species that result in iodine incorporation into target molecules. The reactions of chloramine-T are well documented, being suitable for both macromolecular protein iodination and small-molecule modification (Wilbur, 1992). It also can be used to modify molecules with other radioactive halogen elements, such as isotopes of bromine and astatine (Hadi *et al.*, 1979; Mazaitis *et al.*, 1981).

Chloramine-T
N-chlorotoluenesulfonamide

The reaction of chloramine-T with iodide ion in solution results in oxidation with subsequent formation of a reactive, mixed halogen species, ICl (Figure 12.6). Either ^{125}I or ^{131}I can be used in this reaction. The ICl then rapidly reacts with any sites within target molecules that can undergo electrophilic substitution reactions. Within proteins, any tyrosine and histidine side-chain groups can be modified with iodine within 30 s to 30 m. Since chloramine-T is a water soluble reagent and the reaction is done completely in the solution phase, higher incorporation of radioactive iodine can be obtained than when using insoluble or immobilized oxidants (see subsequent sections). However, a greater yield of specific radioactivity does not always translate into a better radiolabeled probe. Chloramine-T, being a strong oxidant with rapid reaction rates, can easily over-label a target molecule or cause oxidative damage to sensitive proteins (Lee and Griffiths, 1984). The reaction may be quenched with a reductant, usually done by addition of sodium metabisulfite. Although chloramine-T is still widely used, alternative iodination reagents that are insoluble or immobilized on insoluble supports may provide milder reaction conditions and be more controllable. Hussien *et al.* (2011) compared chloramine-T with Iodogen (Section 2.3) in the radioiodination of etodolac, an imaging agent for inflammation. Both iodination agents performed similarly; however, the concentration of Iodogen required to result in similar iodination yields was less than required for chloramine-T. Both agents had an optimum pH for the reaction at about pH 7 and

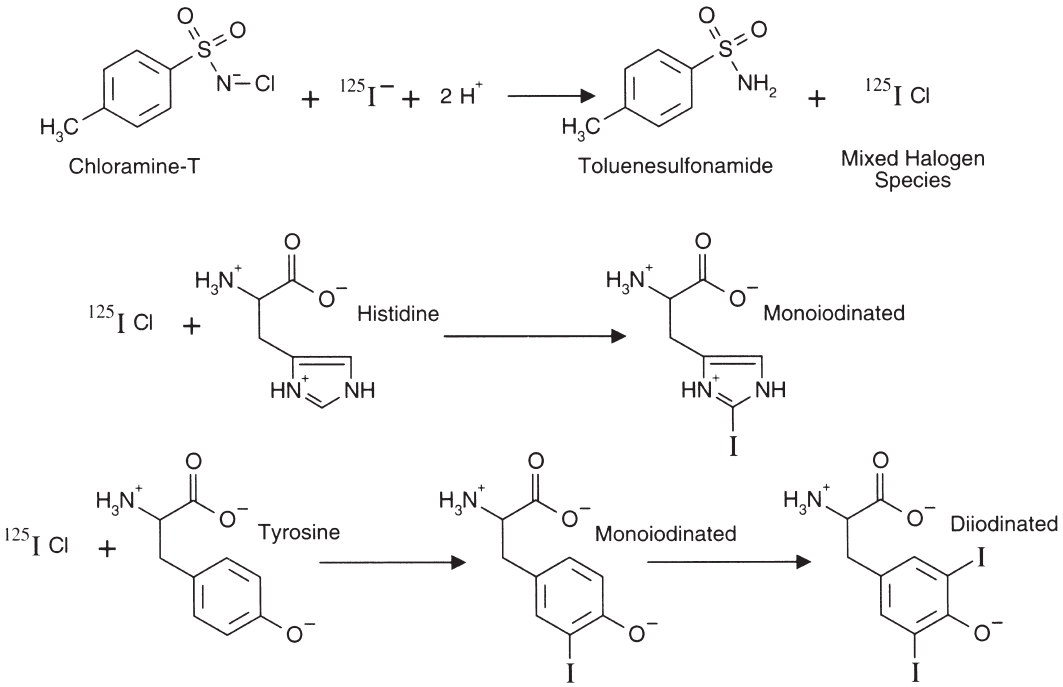


FIGURE 12.6 The strong oxidant chloramine-T can react with iodide anions in aqueous solution to form a highly reactive mixed halogen species. ^{125}ICl then can modify tyrosine and histidine groups in proteins to form radiolabeled products.

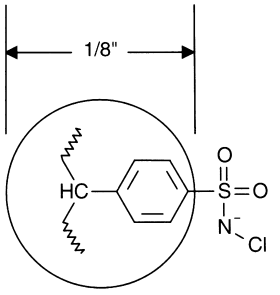
resulted in about 83 to 88% yield of iodine incorporation into etodolac.

The following protocol is representative of those found in the literature for iodination of protein molecules using chloramine-T.



Protocol

Caution: Handle all radioactive substances according to the radiation safety regulations instituted at each facility approved to handle such materials. Use adequate precautions to protect personal safety and the environment. Dispose of radioactive waste only by following approved guidelines.

1. Dissolve chloramine-T in 50-m*M* sodium phosphate, pH 7.0, at a concentration of 4 mg/ml. Prepare fresh. Approximately 25 µl of this solution (100 µg) is required to iodinate 5 µg of a protein.
2. Dissolve sodium metabisulfite in 50-m*M* sodium phosphate, pH 7.0, at a concentration of 12.6-m*M* (240 µg/100 µl). Prepare fresh. Approximately 100 µl of this solution is required for a 5-µg protein iodination.
3. Obtain fresh $Na^{125}I$ and adjust its concentration to approximately 0.5 µmCi/µl. Two microliters of this solution are required to iodinate 5 µg of protein.
4. Add to a suitable reaction vial 25 µl of a solution consisting of 5 µg of a protein dissolved in 50-m*M* sodium phosphate, pH 7.0. Mix using a small magnetic stirring chip.
5. Add 2 µl of the $Na^{125}I$ solution (about 1 mCi) to the protein in the vial. Seal the vial using a screw-cap septum that can be penetrated with a syringe.
6. Using a syringe, add 25 µl of the chloramine-T solution and continue to mix for at least 30 s. Longer reaction times can be used, but the solution-phase iodination usually proceeds very rapidly.
7. Add 100 µl of the sodium metabisulfite solution to the iodination reaction to stop it. Stir for 10 s.
8. Purify the iodinated protein from excess reactants by gel filtration using a desalting resin. The column may be pre-treated by passing a solution of bovine serum albumin (BSA) through it to eliminate nonspecific binding sites that could cause significant protein loss in small-sample applications.

2.2. IODO-BEADS

IODO-BEADS (Thermo Fisher) are an immobilized preparation of a chloramine-T analog, consisting of nonporous, polystyrene beads of diameter 1/8″ that have been derivatized to contain *N*-chlorobenzenesulfonamide groups (as the sodium salt) (refer to U.S. patents 4,448,764 and 4,436,718). During the manufacturing process, the hydrophobic nature of the polystyrene is changed to a rather hydrophilic surface due to the chlorosulfonamide modifications. The surface character results in excellent protein recoveries (typically greater than 90%). The oxidizing capability of IODO-BEADS is limited to surface reactions on the outer shell of the nonporous polystyrene ball. The effect is to reduce the rate of iodine incorporation into macromolecules from the extremely rapid 30-s reaction of soluble chloramine-T to a more relaxed pace of about 2 to 15 min to obtain a similar yield. This also creates a milder oxidizing environment, thus minimizing the potential for protein degradation or activity loss. A slower iodination process allows more control over the level of iodine derivatization. Often, tyrosine iodination can be limited to mono-iodo forms, avoiding the detrimental effects on solubility or activity that excessive modification can cause.

IODO-BEADS Containing
N-Chlorobenzenesulfonamide
Groups on a Polystyrene Backbone

Markwell (1982) reported that the reaction mechanism for creating the electrophilic iodine species may be somewhat different for IODO-BEADS than other oxidizing agents. It was demonstrated that the active component remained at or near the surface of the beads during the course of the iodination process. Markwell speculated that an intermediate reactive species, *N*-iodobenzenesulfonamide, is formed from substitution of the chlorine atoms on the bead (Figure 12.7). It is possibly that this intermediate is involved in the direct iodination of target molecules that approach the bead surface.

IODO-BEADS may be used in a variety of buffer salts and in the presence of detergents or denaturants without affecting iodination. The reagent, however, is susceptible to inactivation by reducing agents such as disulfide reductants, and it can be inactivated by moisture upon storage. Also, avoid organic solvents that can dissolve or affect the surface characteristics of polystyrene, such as dimethylformamide (DMF) or dimethyl sulfoxide (DMSO).

To determine the optimal reaction time for a particular radioiodination, 5-µl aliquots of the reaction medium can be removed every 30 seconds, diluted 1:20,000 with 20-m*M* Tris, 1-m*M* ethylenediaminetetraacetic acid (EDTA), pH 7.4, containing 0.5 mg/ml BSA

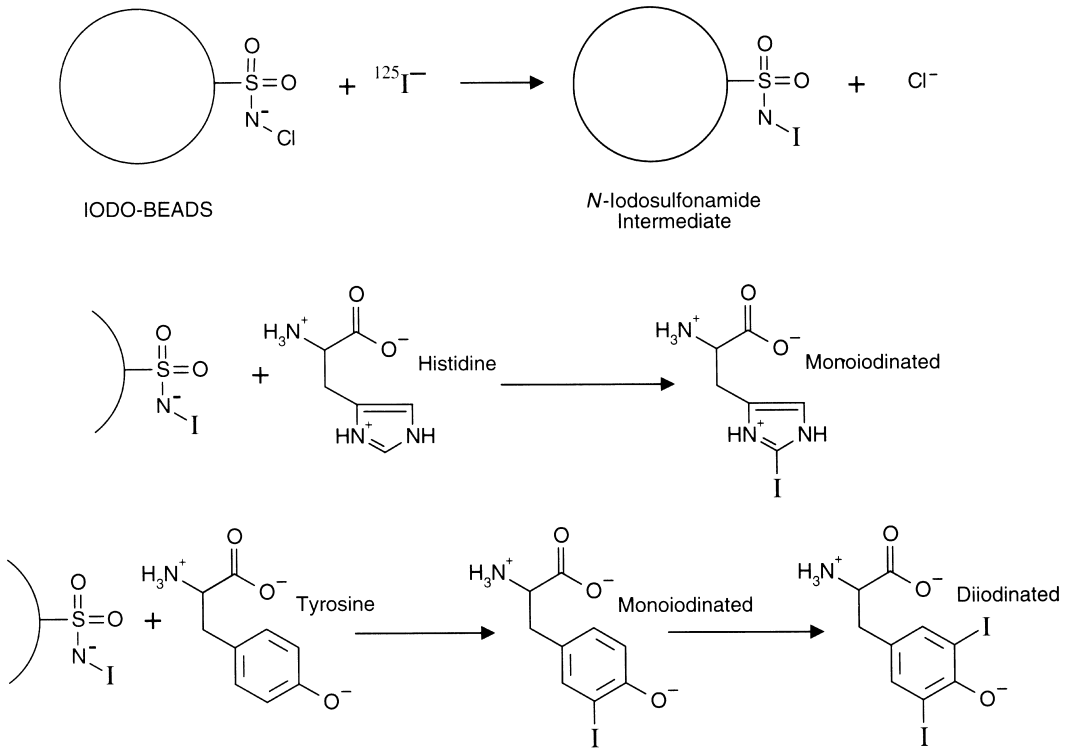


FIGURE 12.7 IODO-BEADS contains immobilized chloramine-T groups that can react with radioactive iodide in aqueous solution to form a highly reactive intermediate. The active species may be an iodosulfonamide derivative, which then can iodinate tyrosine or histidine residues in proteins.

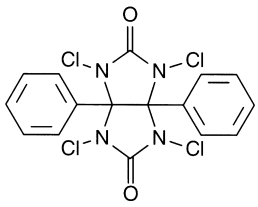
as a carrier protein. Finally, precipitate a small amount of the diluted aliquot with trichloroacetic acid (TCA, 60%), centrifuge to recover the pellet, wash the pellet once with TCA, and measure the amount of radioactivity in the pellet and supernatant using a gamma counter. The reaction period representing optimal radiolabel incorporation should be used for subsequent radioiodination reactions.

Directing the iodination reaction toward histidine residues in proteins, as opposed to principally tyrosine modification, is possible simply by increasing the pH of the IODO-BEADS reaction from the manufacturer's recommended pH 7.0 to pH 8.2 (Tsomides *et al.*, 1991). No reducing agent is required to stop the iodination reaction as is the case with chloramine-T and other methods. Simple removal of the bead(s) from the reaction is enough to eliminate the iodination process. The mild nature of the IODO-BEADS iodination reaction can result in better recovery of active protein than using soluble oxidants (Lee and Griffiths, 1984).

IODO-BEADS are being used extensively for the radioiodination of peptides, proteins, and other molecules for *in vivo* imaging and therapeutic purposes (Bertrand *et al.*, 2010; Koehler *et al.*, 2010; Ha *et al.*, 2012).

Each bead is able to iodinate up to 500 µg of tyrosine-containing protein or peptide. This translates into an oxidative capacity of about 0.55 µmoles per bead. The rate of reaction can be controlled by changing the number of beads that are used and altering the sodium iodide concentration added to the reaction. Reaction volumes of 100 to 1000 µl are possible per bead. The following protocol is suggested for iodinating proteins. Optimization should be done to determine the best incorporation level to obtain good radiolabel incorporation with retention of protein activity.

Protocol



Caution: Handle all radioactive substances according to the radiation safety regulations instituted at each facility approved to handle such materials. Use adequate precautions to protect personal safety and the environment from contamination. Dispose of radioactive waste by following approved guidelines.

1. Wash one or more IODO-BEADS (Thermo Fisher) with the iodination buffer of choice. Buffers containing 0.1-*M* sodium phosphate or 0.1-*M* Tris at slightly acidic to slightly alkaline pH work well. A buffer consisting of 0.1-*M* sodium phosphate, pH 6.5, will give the highest possible reaction rates and yields.
2. Add the desired number of beads to a solution of carrier-free $Na^{125}I$ in iodination buffer at a

concentration level of about 1 mCi per 100 µg of protein to be modified. The total reaction volume should be 100 to 1,000 µl per bead.
3. Add from 5 µg to 500 µg of a tyrosine-containing peptide or protein dissolved in iodination buffer to the reaction mixture.
4. React for 2 to 15 min at room temperature. Reactions carried out at 4°C are possible, but will result in slightly lower incorporation of iodine.
5. Stop the reaction by removing the solution from the beads. This can be done by simply pipetting the solution away from the beads or by physically removing the beads. The beads may be washed once with iodination buffer to ensure complete recovery of protein. Exact timing of the reaction is important to obtain reproducible results.
6. Remove excess ^{125}I from the iodinated protein by gel filtration using a desalting resin.

2.3. Iodogen

Iodogen (Thermo Fisher), first described by Fraker and Speck in 1978, is 1,3,4,6-tetrachloro-3α,6α-diphenylglycouril, an *N*-haloamine derivative with oxidizing properties similar to those of IODO-BEADS and chloramine-T. The compound is insoluble in aqueous solution, thus making it a type of solid-phase radioiodination reagent. However, unlike IODO-BEADS wherein the oxidizing group is immobilized on another support material, Iodogen must be plated out on the surface of a reaction vessel prior to iodination. Due to the reagent's stability, the plated reaction vessels can be prepared well in advance and stored in a desiccator until needed (Marwell and Fox, 1978). Alternatively, pre-coated tubes now are available (Thermo Fisher).

Iodogen
1,3,4,6-Tetrachl ro-
3α,6α-diphenylglycouril
MW 432.09

The reaction of Iodogen with iodide ion in solution results in oxidation with subsequent formation of a reactive, mixed halogen species, ICl (Figure 12.8); ^{124}I, ^{125}I, or ^{131}I can be used in this reaction. The ICl then rapidly reacts with any sites within target molecules that can undergo electrophilic substitution reactions. Within proteins, any tyrosine and histidine side-chain groups can be modified with iodine within 30 s to 30 m. In addition, crosslinking or modification reagents possessing phenyl rings with activating groups present (e.g., electron-donating constituents, such as OH or NH_2) can be iodinated using Iodogen. The incidence of side reactions appears to be negligible.

Since Iodogen is insoluble in aqueous solution and is plated on the surface of the vessel during the iodination reaction, it is possible to stop the reaction simply by removing the aqueous phase. The plating technique is important for the successful use of this reagent. Failure to plate properly the Iodogen reagent on the surface of the reaction vessel may cause the oxidizing agent to become suspended in the reaction medium. However, even with well-plated vessels, there is some potential that a portion of the iodinating reagent can break off in small pieces and contaminate the aqueous phase. For this reason, it is not advisable to stop the iodination reaction only by removing the supernatant as in the case of Iodobeads (Section 2). To be certain that the iodination has stopped, an aliquot of sodium metabisulfite can be added to ensure complete cessation of the oxidative process. Alternatively, immediate separation of the iodinated protein from the reactants by gel filtration can be used to stop the reaction (any suspended particles of Iodogen will be filtered out on the top of the gel).

Specific radioactivity of 1×10^5 cpm of ^{125}I per microgram of protein easily can be obtained using Iodogen. Iodination efficiencies are typically 60% or better and may be controlled by regulating the amount of I^- concentration added to the reaction.

When iodinating intact cells, Iodogen can be used to radiolabel the outer cell surface proteins or be directed more toward the inner membrane areas simply by modulating the reaction conditions. Membrane proteins in hydrophobic regions can be labeled to a greater extent by including a small excess of carrier iodide, using high salt conditions, or employing detergents to disrupt the membrane integrity. Cell surface hydrophilic proteins may be preferentially labeled by not including components that increase cell permeability, by the use of carrier-free iodide, and using short reaction times (Markwell and Fox, 1978).

Hussien *et al.* (2011) compared iodogen to chloramine-T for relative effectiveness and yield of radioiodination of etodolac, a molecule used for inflammation imaging *in vivo*. The results indicated that the yield of iodination was slightly higher for iodogen (88% *versus* 83%) and the reaction required less iodogen than chloramine-T to result in similar yields. Iodogen is being used frequently to prepared radiolabeled peptides, proteins, and other probes for imaging or therapeutic use (Kuntner *et al.*, 2011; Tran *et al.*, 2011; El-Bary *et al.*, 2012).

The following protocol describes the use of Iodogen for the radioiodination of proteins and peptides.

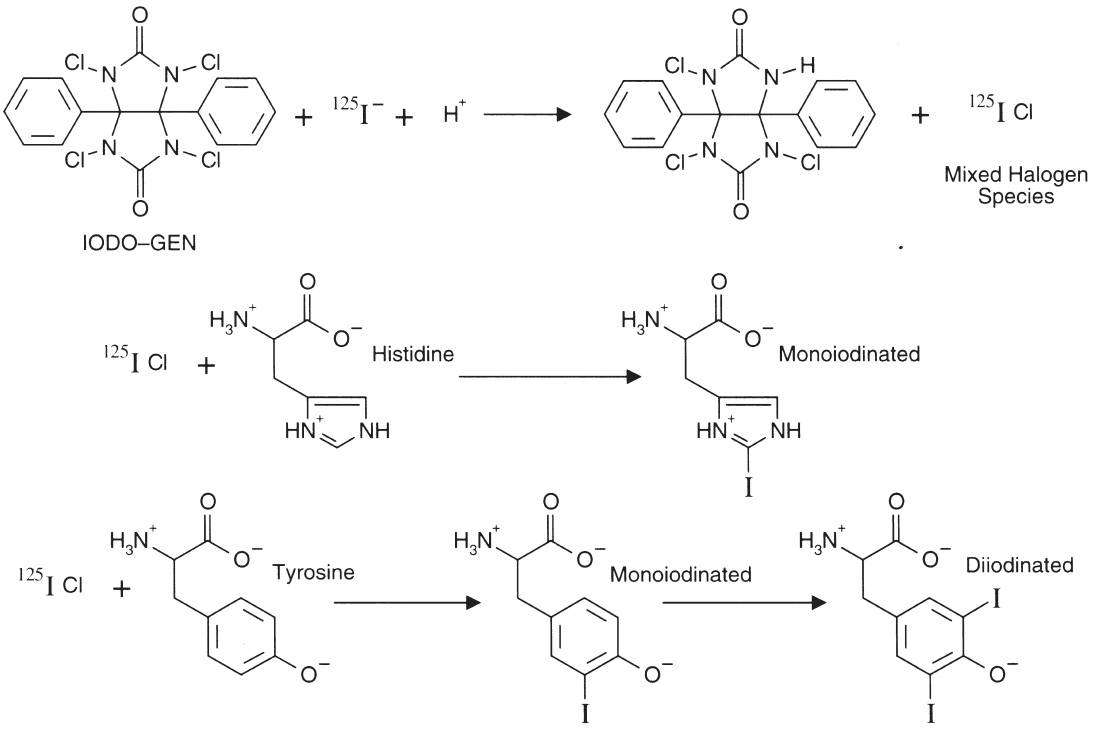


FIGURE 12.8 Iodogen is a water-insoluble oxidizing agent that can react with $^{125}I^-$ to form a highly reactive mixed halogen species, ^{125}ICl. This intermediate can add radioactive iodine atoms to tyrosine or histidine side chain rings.

Protocol

Caution: Handle all radioactive substances according to the radiation safety regulations instituted at each facility approved to handle such materials. Use adequate precautions to protect personal safety and the environment from contamination. Dispose of radioactive waste by following approved guidelines.

1. In a fume hood, dissolve 10 to 100 µg of Iodogen (Thermo Fisher) in 100 to 500 µl of chloroform, methylene chloride, or DMSO. The use of 10 µg of Iodogen per 100 µg of protein or 10^7 cells to be iodinated will result in good incorporation yields.
2. Add the Iodogen solution to a clean, dry, glass reaction vessel in an amount needed for the quantity of protein to be labeled. Slowly evaporate the solvent in the vessel using a stream of dry nitrogen or other inert gas. Do not use a strong gas jet, since rapid evaporation or turbulence in the solvent solution will cause uneven Iodogen distribution with possible clumping. Do not merely leave the vessel to dry in a hood, since contaminants or moisture may get into the reagent film. If done properly, the plating process should leave a film of Iodogen on the inner surface of the vessel that is difficult to see—looking like a slight clouding of the glass. After solvent evaporation, seal the container with nitrogen and store in a desiccator until needed.
3. Dissolve the protein to be iodinated in a buffer compatible with its known biological stability. Conditions ranging from pH 4.4 to pH 9 and temperatures from 0°C to 37°C can be used with good results. The amount of protein to be labeled should be contained in a volume of 100 µl or less. The sample buffer should not contain reducing agents, antioxidants, 2-mercaptoethanol, DTT, cysteine, glycerol, high detergent concentrations, or anything that may interfere with the iodination reaction or dislodge the plated Iodogen.
4. Rinse the plated reaction vessel once with sample buffer to remove any loose particles of Iodogen that may not be strongly adhered to the surface of the glass.
5. Add carrier-free $Na^{125}I$ to the reaction vessel in a ratio of about 500 µCi per 100 µg protein.
6. React for 10 to 15 min at room temperature. Optimization of the reaction time and the amount of ^{125}I added to the reaction may have to be done to obtain the best radioactivity incorporation and retention of protein activity.
7. Remove the sample from the reaction vessel. This process should terminate the iodination reaction, unless small Iodogen particles break off from the sides of the vessel. To ensure safe handling, carrier NaI may be added to the reaction mixture to a final concentration of 1-m*M*.
8. Remove excess reactants by gel filtration using a desalting resin.

2.4. Lactoperoxidase-Catalyzed Iodination

An enzyme-catalyzed process also may be used to form reactive iodine species capable of iodinating proteins and other molecules (Marcholonis, 1969; Morrison and Bayse, 1970). The enzymatic approach utilizes lactoperoxidase in the presence of H_2O_2 to oxidize $^{125}I^-$ to I_2. The iodine thus formed may react with tyrosine or histidine sites within proteins, forming radiolabeled complexes (Fu *et al.*, 2011; Hadjikakou *et al.*, 2011; Amiri *et al.*, 2012). Unlike the use of chemical oxidants for iodination, the enzymatic reaction is very pH dependent—the optimum being between pH 6 and 7. If H_2O_2 is directly added to the reaction medium, it must be highly pure with no stabilizing agents such as metals, since they inhibit the oxidation process.

An alternative to direct addition of H_2O_2 is to form it *in situ* through the use of a second enzymatic reaction. Enzymobeads (originally from Bio-Rad, but no longer commercially available) used immobilized lactoperoxidase along with immobilized glucose oxidase to create the necessary oxidative environment. The glucose oxidase reaction transformed added glucose in the iodination medium to the required H_2O_2. As it was formed, the lactoperoxidase (coupled in tandem to the same beads) would catalyze the formation of I_2 (Figure 12.9). The immobilized enzymes create an iodination environment that is more oxidatively gentle than direct addition of a soluble chemical oxidant like chloramine-T.

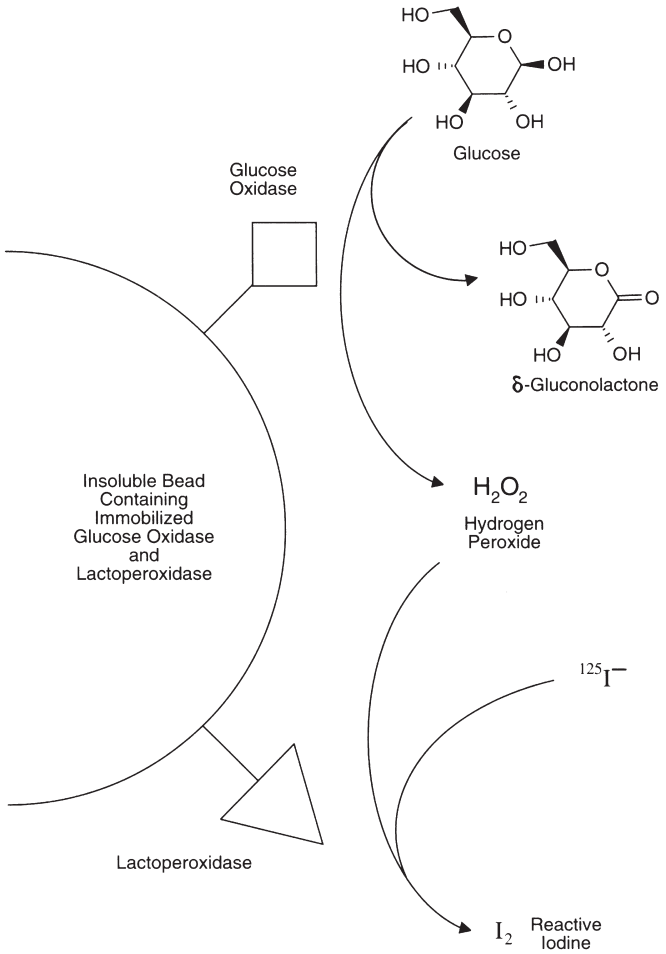

FIGURE 12.9 The immobilized glucose oxidase/lactoperoxidase system radioiodinates proteins through the intermediate formation of hydrogen peroxide from the oxidation of glucose. H_2O_2 then reacts with iodide anions to form reactive iodine (I_2). This efficiently drives the formation of the highly reactive H_2OI^+ species that is capable of iodinating tyrosine or histidine residues (see Figure 12.2).

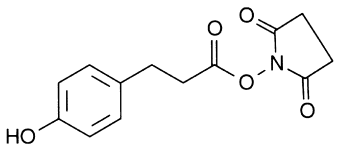
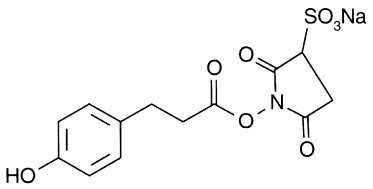
2.5. Iodinatable Modification and Crosslinking Agents

Radioiodination can be performed using an indirect approach that utilizes a radiolabeled crosslinking or modification reagent which is then used to label the target molecule. One advantage of indirect labeling over direct modification of tyrosine or histidine residues in proteins is to be able to control the iodination to occur with functional groups other than just using indigenous amino acids. In addition, the ability to add a radiolabeled modification agent to a molecule can facilitate the radioactive tagging of substances that normally do not have radioiodinatable sites. Another major advantage of using iodinatable modification agents is to eliminate the potential for oxidative damage to sensitive biological molecules, as may occur when an oxidant is used in direct iodination procedures.



For instance, an amine-reactive modification reagent can be radiolabeled and subsequently used to couple with ε- and N-terminal amines on a protein molecule. The protein is not exposed to oxidative conditions, and the level of radiolabeling can be discretely controlled by the molar ratio of modification reagent addition. The use of iodinatable crosslinking reagents can similarly provide radioactive tags incorporated into conjugates at the time of formation. In addition, iodinatable bioconjugation reagents that react with groups such as sulfhydryls, aldehydes, or other functionalities of limited occurrence in proteins or other macromolecules, can be used to direct the point of radiolabeling to areas away from active centers or binding sites, thus better preserving biological activity. Finally, some photoreactive crosslinking agents can be iodinated, used to label a targeting molecule, photolyzed at the point of binding to its target, and the cross-bridge of the resulting complex chemically cleaved, resulting in the transfer the radiolabel to the targeted component (Chapter 6, Section 3). This process can be used to follow the targeted molecule *in vivo* or in cellular systems.

Direct iodination of proteins and other molecules does not provide the range of experimental options available through indirect labeling. The main



disadvantage of the indirect labeling process is the additional steps needed to prepare the radiolabeled crosslinker or modification reagent before iodination of the desired molecule. The following sections discuss some of the major indirect iodination methods, including the reagents available for doing such procedures.

Bolton–Hunter Reagent

Bolton and Hunter (1973) developed the reagent *N*-succinimidyl-3-(4-hydroxyphenyl) propionate (SHPP) for the indirect radioiodination of proteins and other macromolecules (Thermo Fisher). The NHS ester end of the molecule reacts with amine groups in target molecules to form stable amide bond derivatives (Chapter 3, Section 1.4). The other end of the reagent contains a phenolic group that is ideally suited for modification with ^{125}I. Iodination of the phenol group occurs *ortho* to the hydroxyl, thus accommodating either one or two iodine substitutions per molecule (Figure 12.10).

(4-hydroxyphenyl)propionate
MW 263.26

Water-Soluble Bolton–Hunter Reagent
N-Sulfosuccinimidyl-3-
(4-hydroxyphenyl)propionate
MW 365.30

The use of the Bolton–Hunter reagent to incorporate radioactive labels into proteins results in at least as good incorporation of ^{125}I as direct labeling procedures using an oxidant. In many cases, the degree of radioiodine labeling can be much greater than that possible by direct labeling of tyrosine residues, because the total number of amines in a protein (from N-terminal and lysine side chains) is typically significantly more than the number of tyrosine residues present. The major advantage of the indirect approach, however, is that non-tyrosine-containing proteins also may be iodinated. In addition, substances sensitive to oxidant exposure can be labeled without loss of activity or structural degradation. Ultimately, any molecule containing an available amino group can be radioiodinated with SHPP, even if it does not contain a strongly activated aromatic ring system to allow direct iodine substitution. For reviews of protein modification using radiolabeled Bolton–Hunter reagent, see Langone (1980, 1981) and Wilbur (1992). For its use in labeling cellular components, see Katz *et al*. (1982) and Davies and Palek (1981). The reagent has found widespread use in radioiodination of many different compounds and proteins (Waentig *et al.*, 2011; Zhou *et al.*, 2011).

SHPP is relatively insoluble in aqueous environments and must be dissolved in an organic solvent prior to addition to a reaction medium. Suggested solvents include dioxane and DMSO that are low in water content to avoid hydrolysis of the NHS ester.

A water soluble version of the original Bolton–Hunter reagent is also available, called sulfo-SHPP or sulfosuccinimidyl-3-(4-hydroxyphenyl)propionate (Thermo Fisher). This compound contains a negatively charged sulfonate group on the NHS ring structure, which provides enough hydrophilicity to allow direct addition to aqueous reaction mediums.

The following procedure describes the iodination process for the Bolton–Hunter reagent and its subsequent use for the radiolabeling of protein molecules. Modification of other macromolecules can be carried out using the same general method. For particular labeling applications, optimization of the level of iodine incorporation may have to be done to obtain the best specific radioactivity with retention of biological activity.

Protocol

Caution: Handle all radioactive substances according to the radiation safety regulations instituted at each facility approved to handle such materials. Use adequate precautions to protect personal safety and the environment from contamination. Dispose of radioactive waste by following approved guidelines.

1. Dissolve SHPP (Thermo Fisher) in dry dioxane or DMSO at a concentration of 0.5 mg/ml. Prepare fresh. If sulfo-SHPP is used, dissolution in organic solvent is unnecessary, although it may better facilitate the addition of a small quantity to the aqueous reaction and also prevent hydrolysis prior to initiating the iodination reaction.
2. Dissolve chloramine-T (Sigma) in 50-m*M* sodium phosphate, pH 7.5 (reaction buffer), at a concentration of 100 µg per 25 µl of buffer. Prepare fresh.
3. Prepare 0.5 mCi Na^{125}I dissolved in 2 µl of reaction buffer. Prepare fresh.
4. In a suitable reaction vessel (such as a glass ReactiVial, Thermo Fisher), add 2 µl of the SHPP solution and 2 µl of the Na^{125}I solution to 25 µl of reaction buffer. Once the Bolton–Hunter reagent is in an aqueous environment, the NHS ester end

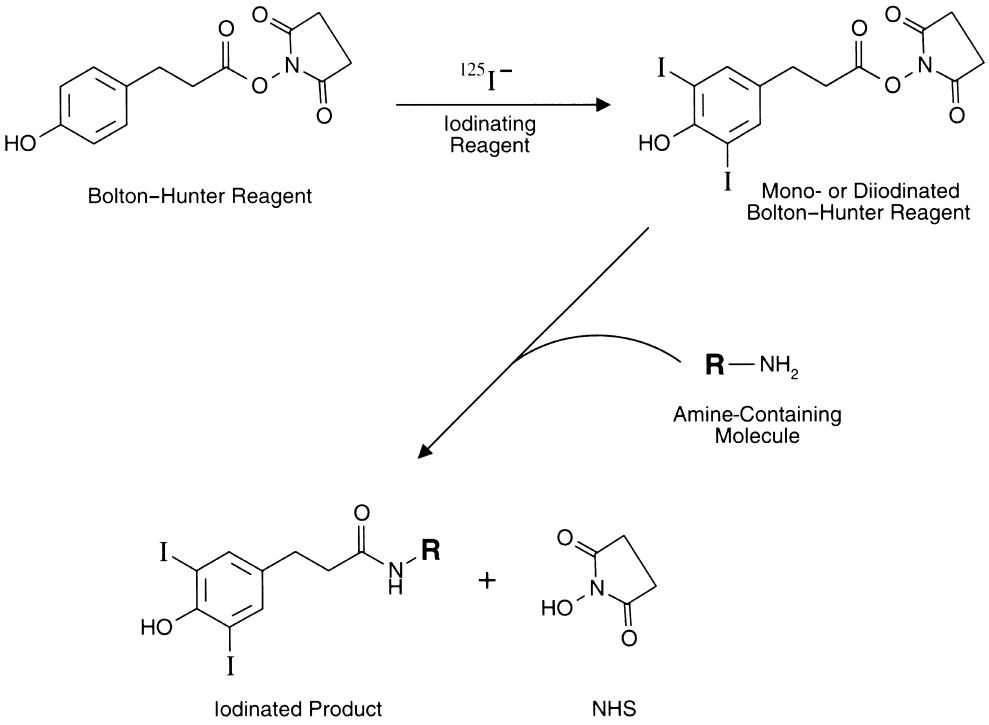

FIGURE 12.10 The Bolton–Hunter reagent may be radioiodinated at its phenolic ring structure prior to reaction with an amine-containing molecule to form an amide bond modification.

of the compound will hydrolyze; therefore, all aqueous handling of the reagent from this point on should be done quickly to preserve enough amine-coupling activity to label the protein after the iodination reaction.

5. Immediately add 25 µl of the chloramine-T solution to the SHPP solution. Mix well.
6. React for 15 s with mixing.
7. Add to the iodination reaction 5 µl of DMF and 100 µl of benzene. Mix to extract the iodinated Bolton–Hunter reagent into the organic phase.
8. Remove the aqueous phase and transfer the organic phase into a clean glass vial or tube.
9. Remove the organic solvent by evaporation using a steady, but gentle, stream of nitrogen.
10. Dissolve the equivalent of 250 ng of a protein to be labeled in 2 to 2.5 µl of ice-cold 50-m*M* sodium borate, pH 8.5.
11. Add the protein solution to the dried, iodinated Bolton–Hunter reagent.
12. React for 2 h on ice. An overnight reaction may be performed at 4°C.
13. Remove excess labeled Bolton–Hunter reagent by gel filtration or dialysis.

The Bolton–Hunter reagent also may be used to modify a molecule prior to the iodination reaction. In this case, an amine-containing protein or other molecule is coupled via the NHS ester end of the reagent to form an amide-bond derivative. This derivative is then iodinated using any of the iodination reagents discussed in this section. This approach can be useful in preparing stable Bolton–Hunter derivatives that can be stored for extended periods until requiring iodination, eliminating the relatively short half-life of ^{125}I-labeled probes.

Iodinatable Bifunctional Crosslinking Agents

Bifunctional crosslinking agents containing an activated aromatic ring system may be radioiodinated using similar procedures as that described previously for the Bolton–Hunter reagent. Certain conjugation compounds have been designed with the potential for radiolabeling in mind. For instance, there are a number of photoreactive phenyl azide crosslinkers that possess an activating hydroxyl group on their phenyl rings. The phenolic group provides sites of facile iodination *ortho* and *para* to the hydroxyl.

The heterobifunctional crosslinker ASBA (4-(*p*-azidosalicylamido)butylamine) (Chapter 6, Section 6.1) is an example of this type of iodinatable photoreactive reagent. The phenyl azide group may be radiolabeled using any standard iodination process (described previously) before coupling of its primary amine end to a carbonyl group on a macromolecule. After allowing the modified molecule to bind to a target, the complex may be photolyzed and the covalent conjugate detected by its radioactivity.

The homobifunctional photoreactive BASED (Chapter 5, Section 5.1) has two photoreactive phenyl azide groups, each of which contains an activating hydroxyl. Radioiodination of this crosslinker can yield one or two iodine atoms on each ring, creating an intensely radioactive compound. Crosslinks formed between two interacting molecules are reversible by disulfide reduction, thus allowing traceability of both components of the conjugate.

An extremely versatile iodinatable heterobifunctional is APDP (*N*-[4-(*p*-azidosalicylamido) butyl]-3′-(2′-pyridyldithio)propionamide) (Chapter 6, Section 4.2). One end of the crosslinker can couple with sulfhydryl-containing molecules, while the other end is a nonselective photoreactive phenyl azide. Again, the phenyl ring contains an activating hydroxyl group, providing radioiodination capability. Modification of a sulfhydryl-containing molecule may be done after iodination of the reagent. After the labeled molecule is allowed to interact with a target molecule, the photoreactive process can be initiated to form a covalent conjugate. Subsequently, the crosslinks may be cleaved using a disulfide reducing agent, thus transferring the radiolabel to the second molecule.

SASD (sulfosuccinimidyl-2-(*p*-azidosalicylamido) ethyl-1,3′-dithiopropionate) (Chapter 6, Section 3.2) behaves in a similar manner, except that it contains an amine-reactive end that can be coupled to proteins and other molecules. Its photoreactive end can be iodinated using any of the radioiodination reagents discussed previously. Just as in the case of APDP, SASD crosslinks can be cleaved by a disulfide reductant to transfer the radioactive component to a second molecule.

Finally, the small amine-reactive and photoreactive crosslinker NHS–ASA (Chapter 6, Section 3.1) can be iodinated to provide a non-cleavable radioactive conjugate.

Figure 12.11 shows the iodination products resulting from labeling these reagents with ^{125}I. Any of the iodination reagents described previously can be used to radiolabel these compounds prior to their incorporation into target molecules. However, the insoluble iodination reagents are probably the best choice, since the separation of radiolabeled compound from excess oxidant simply involves removing the solution.

There are many other compounds that have been investigated for their use in indirect radiolabeling of

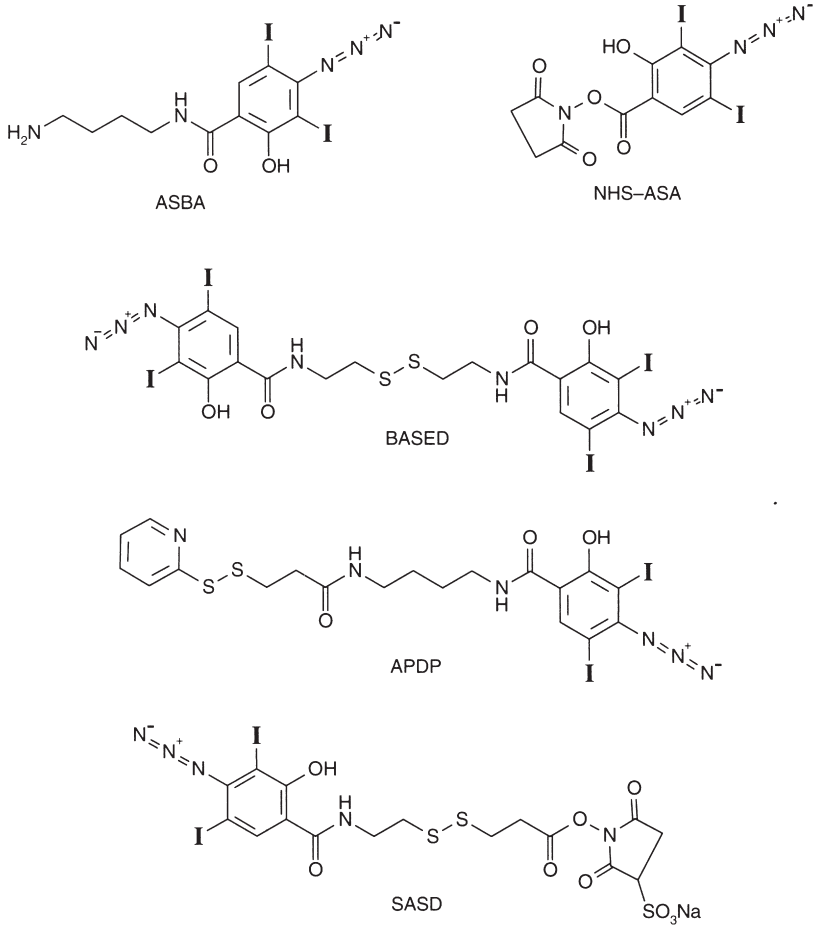

FIGURE 12.11 Some common crosslinking agents that are capable of being radioiodinated. The sites of iodination are shown in bold.

proteins. For an excellent overview of these chemical reactions, see Wilbur (1992).

3. MASS TAGS AND ISOTOPE TAGS

Mass spectrometry has become one of the most important tools for analyzing proteins in complex biological samples. The ability to separate proteins and peptides at high resolution has made possible the simultaneous identification of hundreds of proteins within samples (for reviews, see Bantscheff *et al.*, 2012; Sabidó *et al.*, 2012; Siuzdak, 2006; Hamdan and Righetti, 2005; and Gingras *et al.*, 2005). Proteins can be analyzed for their presence or compared between samples for their relative expression levels. One cell population treated with a drug candidate, for instance, can be compared by mass spectrometry to another sample as control to assess the effect of the drug on expression levels of certain proteins.

There are several ways that proteins can be analyzed using mass spectrometry. Whole proteins can be separated using the electrospray ionization (ESI) technique or by using matrix-assisted laser desorption/ionization (MALDI). Both of these methods inject intact proteins into the mass spectrometer, ionize them, and separate the resultant charged components by their individual mass/charge ratios. These methods work well for small and medium-sized proteins in samples of low complexity, but analysis of larger proteins or highly complex samples is difficult. Alternatively, proteins first can be proteolytically digested using an enzyme such as trypsin and then the peptide products analyzed by mass spectrometry. This proteolysis method is more universally applicable, because analysis of peptide fragments allows mass spectrometry separation to be done for all proteins regardless of their original intact mass prior to digestion. The peptides typically are subjected next to a higher energy secondary mass spectrometry separation that fragments them into their component amino acids, which then can be identified by their masses. Samples then are analyzed by correlation of the peptide amino acid sequences to online databases of mass spectrometry information, which can identify the parent protein that each peptide came from.

However, the interpretation of mass spectrometry data on whole samples can be daunting, especially when analyzing proteolytically digested samples, which results in many times more species to analyze per protein than intact proteins. In order to reduce the complexity of sample analysis, a number of techniques have been developed to fractionate the proteome prior to mass spectrometry separation. For instance, two-dimensional electrophoresis can separate proteins both by charge and by molecular weight and allow picking of only certain spots for subsequent mass spectrometry analysis. However, 2D electrophoresis is severely limited in its sensitivity for picking up low- or medium-copy proteins (Gygi *et al.*, 2000). Alternatively, affinity separations on resins or surfaces can be carried out to capture only those proteins having certain epitopes or chemical characteristics, such as post-translational modifications. In addition, nanoliter HPLC separations in one or two dimensions can be done to fractionate the peptides in complex samples by charge, size, or hydrophobicity before being injected into the mass spec.

Another major technique to simplify the analysis of protein samples is to use mass tags. Mass tags are modification reagents that contain a reactive group for coupling to biomolecules and another component of known mass, which behaves predictably upon MS separation. The mass tag may also contain a functional group for capture and separation on an affinity support, which permits further fractionation of the proteome. MS analysis of mass tagged peptides can be done by focusing only on those peptides that contain an additional mass component representing the tag's known mass contribution. Thus, all other peaks on the MS spectrum can be ignored, which greatly reduces the complexity of the sample. Mass tag reagents have been developed with reactive groups to modify specifically only certain low frequency amino acids within proteins. For instance, a thiol-reactive iodoacetyl group on a mass tag can be used to modify only those peptides having cysteine residues, thus removing from the analysis window all other peptides not containing cysteine.

The design of mass tags can also be combined with stable isotope labels to create more than one mass unit for each tag type (Schneider and Hall, 2005; Helsens *et al.*, 2011). For example, certain hydrogen atoms on one mass tag can be replaced with deuterium atoms on another derivative. Everything else on the tag is identical except for the isotope substitutions. Thus, the two mass tag analogs will differ in molecular weight by exactly the mass difference represented by the isotopic substitutions. Such tags can be used to modify a test sample with the stable isotope tag *versus* a control sample modified with the normal tag. If the two samples are then combined and analyzed by mass spectrometry, their signal peaks generated from the tagged peptides will differ in mass units by the isotopic mass differences in the two tags. Identification of the peptides from both samples is done by looking for peptide peak pairs differing by the characteristic mass amount, therefore greatly reducing the complexity of sample analysis and allowing simultaneous investigation of two samples. In this way, a test sample's protein expression levels can be compared to a control sample by measuring the different areas of the paired peptide peaks. The ability to analyze protein expression in two samples is vitally

important to drug discovery and life science research applications studying the proteome.

Mass tags also can be broad spectrum in their modification properties to derivatize all peptides as they are formed upon proteolysis. For instance, one of the simplest mass tagging systems is to use the oxygen isotope ^{18}O in the water ($H_2{}^{18}O$) used during the enzymatic digestion of a protein sample (Miyagi and Rao, 2007). Upon hydrolysis by trypsin, the resultant C-terminal carboxylates that are formed each incorporate two ^{18}O atoms. Thus, peptides formed from ^{18}O digestion will be four mass units heavier than peptides formed by proteolysis using normal water. Mass spectrometry analysis of this difference can identify the peptide pairs resulting from a control sample and a test sample run simultaneously.

Other broad-spectrum mass tag modification agents are designed to modify all amine groups and yield tags on every peptide at their N-terminal amines. For instance, small molecule tags using deuterium-labeled tags and regular hydrogen-labeled ones, such as in the use of isotopically labeled propionic anhydride (Zappacosta and Annan, 2004), provide differentiation in the mass spectrometry signals of peptides from test samples and controls. To eliminate interference, side chain lysine amines are blocked by guanidination with *O*-methylisourea hemisulfate and cysteine thiols are blocked with iodoacetamide (Leitner and Lindner, 2004). Some mass tag reagents of this type are able to differentiate peptides from six to ten samples analyzed at the same time (see section on isobaric tags, this chapter).

The following sections describe some of the major mass tag types and discuss the general protocols for their use.

3.1. ICAT Reagents

Isotope-coded affinity tags (ICATs) are bifunctional mass tagging agents containing a reactive group on one end of the molecule and an affinity capture group on the other end (Aebersold, 2003; Gygi *et al.*, 1999; Roepstorff, 2012) (Figure 12.12). In addition, a portion of the tag can contain stable isotope substitutions, usually designed to be in the cross-bridge between the reactive group and the biotin handle. The original ICAT reagent contained eight deuterium atom substitutions on the outer ends of an ethylene oxide spacer. The isotope tagged version thus differs from its normal atom analog by exactly 8 mass units.

Most ICAT-style compounds contain a thiol-reactive iodoacetyl group on one end and a biotin handle on the other end of a spacer arm (Figure 12.13). Reagents of this type are highly specific for reacting with cysteine thiols in proteins to result in stable thioether modifications containing a terminal biotin group (Figure 12.14).

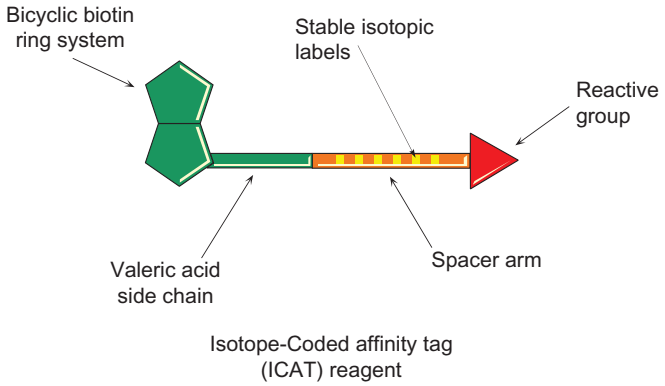

FIGURE 12.12 The general design of an ICAT reagent consists of a biotinylation compound with a spacer arm containing stable isotope substitutions. The reactive group is used to label proteins or peptides at particular functional groups and the biotin affinity tag is used to isolate labeled molecules using immobilized (strept)avidin.

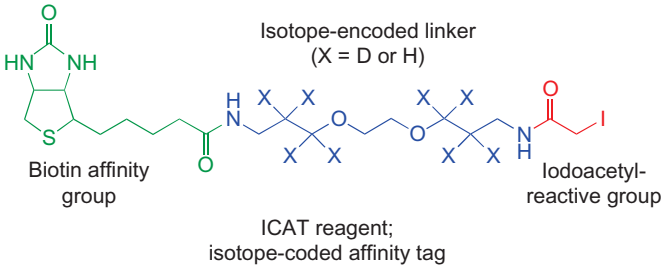

FIGURE 12.13 The original design of the ICAT compound. The iodoacetyl group provides reactivity with thiol groups. The isotopically labeled spacer arm typically is substituted with eight deuterium atoms.

After enzymatic digestion, modified peptides then can be isolated using immobilized (strept)avidin, which specifically binds only to those peptides containing the biotin tag and allows the other peptides to be discarded. Thus, the sample complexity can be reduced to analyze only peptides that contain a cysteine residue, which in the human proteome represents about 26.6% of the total tryptic peptides in a sample. This translates into the ability to cover 96.1% of all the proteins in the human proteome by targeting only cysteine-containing peptides (Zhang *et al.*, 2004; Yan and Chen, 2005).

ICAT reagents can be used to compare two different samples by mass spectometry analysis. For instance, one cell population can be treated with a drug candidate, while another one remains untreated and acts as a control. Alternatively, one cell population can represent a disease state and the control population is the normal cell line. After cell lysis, the proteins in each sample are denatured and reduced to make available all of the cysteine thiols for modification. One sample is then reacted with the heavy atom ICAT reagent, while the other sample is reacted with the normal

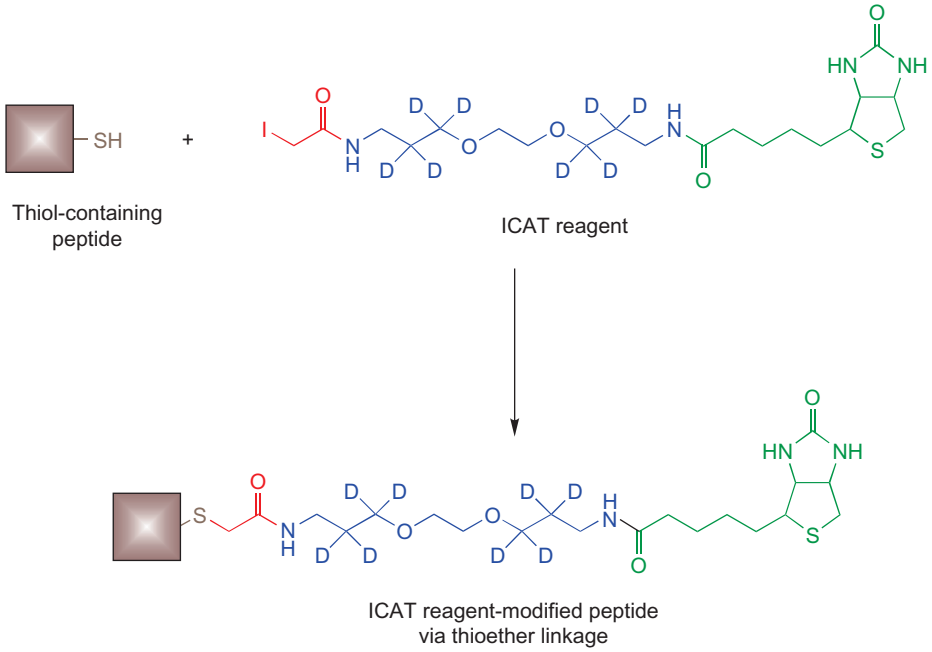

FIGURE 12.14 The ICAT reagent reacts with cysteine-containing peptides to form a thioether bond.

isotope compound. The two samples are then combined and enzymatically digested with trypsin to generate peptide fragments, some of which will contain ICAT-labeled cysteine groups. This combined peptide sample is affinity separated on an immobilized (strept) avidin column (or monomeric avidin column), which binds biotin-labeled peptides from both sample populations equally. After removal of the non-biotinylated peptides by washing the column followed by elution of the ICAT-labeled peptides, the sample is subjected to capillary reverse-phase chromatography leading into ESI or MALDI mass spectrometry analysis. The final HPLC separation again reduces the complexity of the sample set by further fractionating the peptides based on comparative hydrophobicity. In the MS spectrum, the relative peptide concentrations are determined by comparing all peaks separated by exactly the mass unit differential between the heavy atom mass tag and the normal atom mass tag. Each peptide sequence is then identified by fragmentation of the peptides into amino acid ions in a second-dimension MS separation (MS/MS). Comparison of the amino acid sequence of each peptide peak to known sequence databases can identify the protein from which it came. Thus, the resultant peptide peak ratios are directly proportional to the relative amounts of the corresponding proteins present in the cell population.

The original ICAT design was found to have a number of deficiencies that often prevented the reagent from providing acceptable MS results. First, the deuterium isotope-labeled compound has a tendency to behave differently than the normal hydrogen isotope-labeled compound during reverse-phase separation (Regnier *et al.*, 2002). If the labeled peptides that are identical except for the presence or absence of a D_8-ICAT modification do not elute at precisely the same point in an HPLC separation, then the MS analysis will not provide the corresponding peak pairs necessary for quantification. To solve this problem, a second-generation ICAT compound was designed containing ^{13}C isotopic substitutions instead of deuterium atoms. This type of reagent facilitates precise chromatographic separation of the labeled peptides and thus gives far superior performance upon MS analysis.

A second problem in the original ICAT design relates to the presence of the biotin tag. The biotinylated peptides often give undesirable fragmentation patterns during MS/MS analysis, which interferes with the smooth identification of peaks. Removing the biotin tag before mass spectrometry analysis therefore would be beneficial to interpreting the MS results. Another issue with using a biotin tag is the elution step from the immobilized (strept)avidin column. Only under severely denaturing conditions is the interaction between biotin and (strept)avidin disrupted. However, even when using such conditions, the bound peptides do not always get released reproducibly from the column. The result is inefficient recovery of labeled peptides, which directly translates into a lack of precision in the MS data. Even using an immobilized monomeric avidin column does not completely solve this problem, because this

affinity support sometimes has higher-affinity binding sites or binds non-biotinylated peptides nonspecifically. To solve these issues, new cleavable ICAT designs were created that contain a bond within the cross-bridge that can be chemically broken (Li *et al.*, 2003). After binding to the (strept)avidin column, elution can be accomplished by cleaving the biotin arm, not by breaking the (strept)avidin–biotin interaction. The cleavage site can consist of a disulfide group within the cross-bridge (Turecek, 2002) that can be reduced for elution from the (strept)avidin column or it can consist of an acid cleavable linker arm (e.g., a carbamate bond) within the ICAT structure (Fauq *et al.*, 2006) (Figure 12.15). Both methods dramatically improve the recovery of labeled peptides from the affinity column and thus provide increased precision in the samples leading into the LC–MS analysis. The ^{13}C-labeled, acid-cleavable ICAT reagent has been used to identify successfully low-level protein expression in highly complex samples (Hansen *et al.*, 2003).

In another ICAT design, termed a "catch-and-release" tag, the compound contains a constrained, sterically hindered disulfide linkage with bulky alkyl groups on both sides. The hindered nature of the disulfide makes it stable to standard protein reduction procedures, but it can be specifically reduced upon the addition of tris(2-carboxyethyl)phosphine (TCEP) (Gartner *et al.*, 2007) (Figure 12.16). This allows proteins to be labeled with the catch-and-release ICAT compound that have undergone reduction using dithiothreitol (DTT) to cleave protein disulfides but not affect the disulfide group in the reagent cross-bridge. Only after capture of labeled peptides on a (strept)avidin column is the cross-bridge cleaved by the addition of TCEP and the labeled peptide recovered.

A variation on the ICAT mass tag concept was made by immobilizing the label on a solid phase (Zhou *et al.*, 2002). Using this design, cysteine-containing peptides are modified directly on a beaded insoluble support. After washing away non-cysteine peptides, the linked

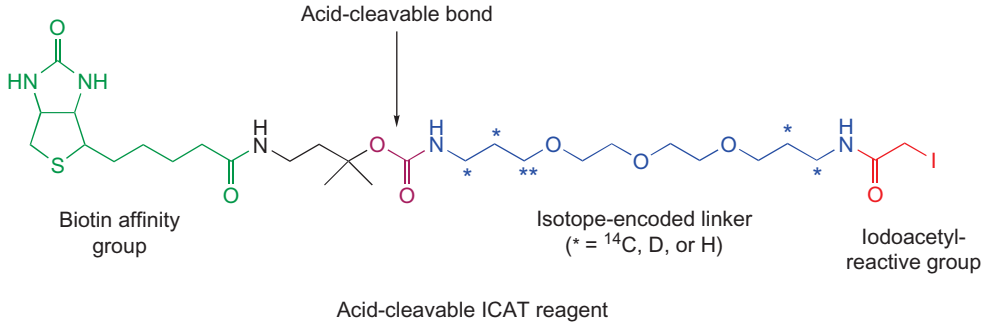

FIGURE 12.15 A more advanced ICAT design uses an acid-cleavable spacer arm to facilitate elution of labeled peptides from a (strept)avidin affinity column. The use of ^{14}C isotopes instead of deuterium labels permits precise reverse-phase separations prior to mass spectrometry that show no elution peak time differences between isotope-labeled and normal atom-labeled peptides.

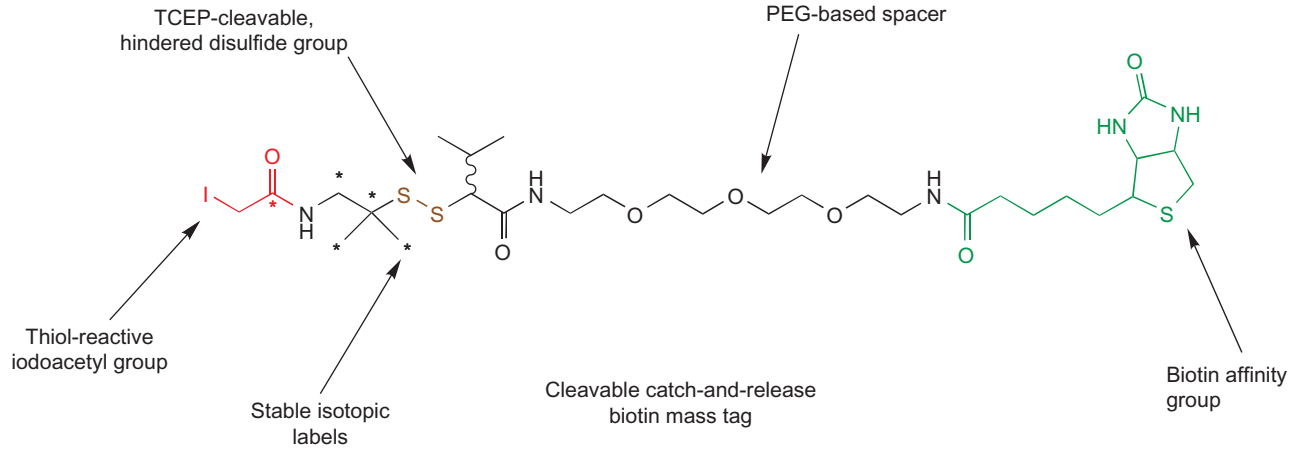

FIGURE 12.16 A catch-and-release ICAT design incorporates a gem-methyl group and an isopropyl group on either side of a disulfide bond within its spacer arm. The hindered disulfide permits the use of standard reducing gel electrophoresis conditions using DTT without reduction. After purification on a (strept)avidin affinity column, however, the disulfide group can be cleaved with TCEP, which provides recovery of the labeled peptides prior to mass spectrometry separation.

peptides can be cleaved from the matrix by use of a photo-cleavable group and eluting off the peptides with an isotope tag modification. This approach results in cleaner and more efficient isolation of tagged peptides and simplifies the ICAT labeling process (Figure 12.17).

Another novel mass tag design involves a spectrally visible ICAT variant developed to include a fluorescent group for detection purposes (Lu *et al.*, 2004). Like the original ICAT reagent, the VICAT compound includes a thiol-reactive iodoacetyl group, a cleavable cross-bridge, an isotopically labeled portion, and a biotin handle. It also has another arm, however, that contains the chromogenic label, which is detectable by absorption at 493 nm and emission at 503 nm. This group allows detection of peptides in samples separated by chromatographic or electrophoretic means. Quantification of the fluorescent tag in isolated peptides can provide absolute information regarding the level of proteins present in a cell.

ICAT-type compounds are designed to enrich for peptides containing one particular amino acid residue, usually cysteine. The affinity capture step removes other non-cysteine peptides and thus reduces the complexity of the MS data set. ICAT reagents can also be designed with a different reactive group that is able to covalently couple to other amino acid groups (or even sites of post-translation modification) to change the selectivity of the peptide population being analyzed. However, it is best to target amino acids or functional groups present in limited amounts within proteins, otherwise the tag may capture more peptides than could be conveniently measured by mass spectrometry. Han *et al.* (2007) developed a hydrazide–ICAT compound to identify proteins modified by 2-alkenals derived from

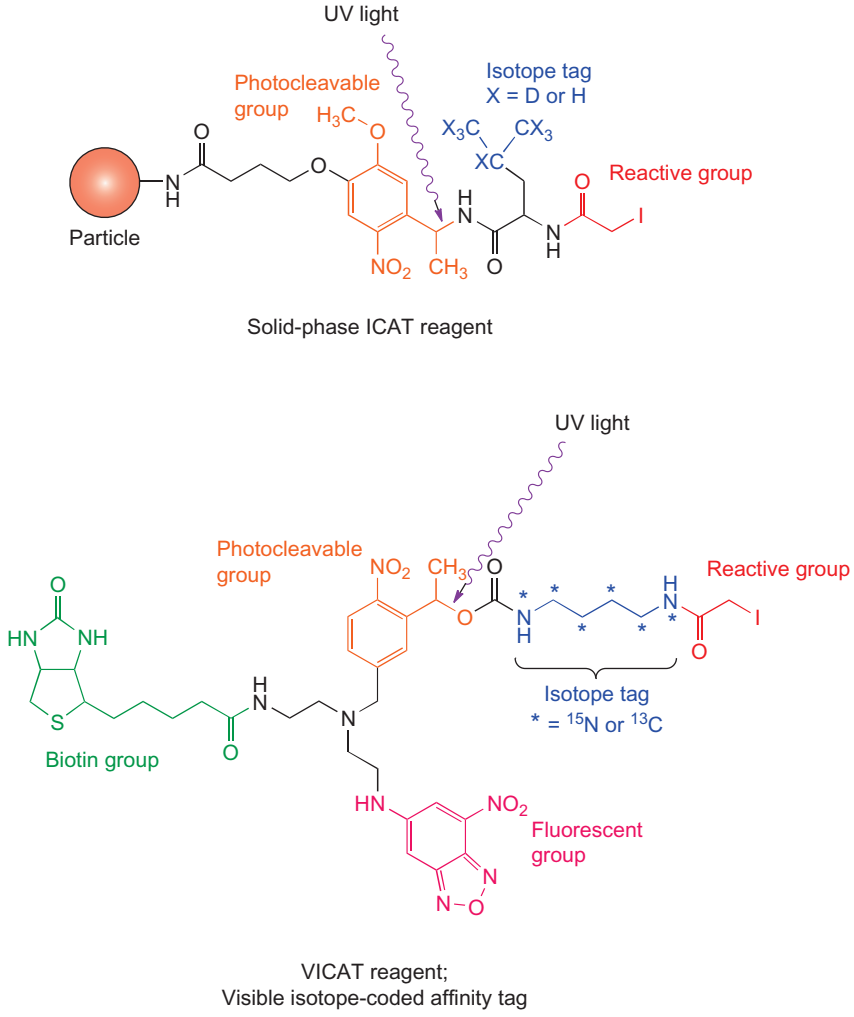

FIGURE 12.17 The solid-phase ICAT reagent provides a thiol-reactive iodoacetyl group to capture cysteine peptides, a spacer containing stable isotopic labels, and a photocleavable group that can release the captured peptides for mass spectrometry analysis. The VICAT mass tag is a solution-phase labeling agent that also has a photocleavable site to release isolated peptides from a (strept)avidin affinity resin. This compound adds a fluorescent group to better detect labeled peptides as they are being isolated from a sample.

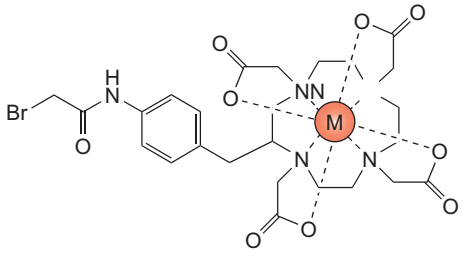
lipid peroxidation (LPO). This type of mass tag should be useful for the study of other oxidative changes on proteins, such as those resulting in aldehyde or ketone modifications (see Chapter 2, Section 1). The ICAT reagents are being used for analyzing the global differential expression of proteins in particular cell lines (Helsens *et al.*, 2011), to map protein interaction surfaces (Crane, 2011), and to discover biomarkers related to specific disease states (Abonnenc and Mayr, 2012).

The following protocol describes the use of an acid-cleavable ICAT reagent, currently available from Applied Biosystems. This is not meant to be a detailed method describing every aspect concerning the use of mass spectrometry, but only to describe the modification reaction of the ICAT compound with proteins.



Protocol

1. Grow cells to 70 to 80% confluence and harvest by scraping the cells into 5 ml PBS, 5-m*M* EDTA, pH 7.4. Aliquot cell counts of approximately $2.5–5 \times 10^6$ for processing. Lyse cells using a detergent lysis buffer (e.g., Poppers, Thermo Fisher) or by mechanical means. Centrifuge and discard the cellular debris. Measure the total protein concentration using the BCA assay (Thermo Fisher) and adjust the protein concentration to 1.5 mg/ml using 50-m*M* Tris, 0.1% SDS, pH 8.0. Separately process a test sample and a control sample made up of different cell populations.
2. Reduce disulfides in the two protein samples by the addition of 2 µl of 50-m*M* TCEP (Thermo Fisher) to each 100-µl aliquot of protein solution. Cover and boil the samples for 10 min in a water bath to completely denature and reduce the proteins. Avoid the use of thiol-containing reductants, such as DTT, as these will react with the iodoacetyl group on the ICAT compound.
3. Dissolve one vial of heavy isotope, cleavable ICAT reagent (Applied Biosystems) in 20 µl acetonitrile (use a fume hood for handling solvents). Dissolve a second vial containing the normal isotope ICAT compound in 20 µl acetonitrile. Vortex mix each vial to dissolve.
4. Add 100 µg of the control protein solution to one vial of dissolved normal isotope ICAT reagent. Mix to dissolve. Add 100 µg of the test protein solution to one vial of dissolved heavy isotope ICAT reagent. Mix to dissolve.
5. React both solutions for 2 h at 37°C.
6. Combine the test sample with the control sample in a single vial. Mix well.
7. Prepare a solution of TCPK–trypsin in 50-m*M* ammonium bicarbonate, pH 8.0, at a concentration of 100 ng/µl. Add 10 µl of the trypsin solution to every 10 µg of combined, labeled protein solution from step 6. Incubate at 37°C for 12 to 16 h or overnight with mixing.
8. Centrifuge the digested peptide mixture to remove any insoluble material. The biotinylated peptides then are purified on 20 µl immobilized monomeric avidin column. The column is first primed with elution buffer (0.4% TFA in 30% acetonitrile) and then washed with binding buffer (100-m*M* ammonium bicarbonate, pH 8.0). The sample is applied and washed through with binding buffer until all not-bound peptides are completely removed. The acetonitrile/TFA elution is subsequently used to cleave off the biotin group from the eluted peptides.

   Note: Additional fractionation may be done to reduce further the complexity of the sample, such as the use of ion-exchange chromatography. The eluted, labeled peptides finally are analyzed by LC–MS/MS.

3.2. ECAT Reagents

Element-coded affinity tags represent a new type of isotope tag for mass spectrometry analysis (Corneillie *et al.*, 2003, 2004; Whetstone *et al.*, 2003; Meares *et al.*, 2007). This system uses a bifunctional metal chelate group that securely coordinates a lanthanide metal ion. A reactive group also is present for the modification of certain amino acids in proteins, which typically consists of a bromoacetyl group. This group reacts similarly to an iodoacetyl group and forms thioether linkages with cysteine thiols. The ECAT design includes a DOTA chelating group (Section 1.2) containing four nitrogen atoms and four carboxylates to complex with any of the lanthanide series metal ions *via* eight coordination bonds (Figure 12.18). Simply by using different lanthanide elements within the complex the result will be a unique set of isotope tags having different mass signatures by MS. At least in theory, up to 15 different

(*S*)-2-(4-(2-bromoacetamido)benzyl)-DOTA
Lanthanide metal chelate
MW: 738.67
(without lanthanide)

FIGURE 12.18 The ECAT mass tag consists of a DOTA metal chelate group that can coordinate a lanthanide metal ion and a bromoacetyl group for coupling to cysteine-containing proteins.

ECAT mass tag compounds could be created by using all of the different lanthanide metals representing elements 57 to 71. In addition, the lanthanides are naturally mono-isotopic in that they occur mainly in nature with only a single isotope. Only cerium contains a high percentage of another isotope in nature (88% ^{140}Ce and 11% ^{142}Ce); all the other lanthanides are >97% a single isotope. This is important for mass spectrometry separations, as the resultant peaks will not contain extraneous mass signatures due to multiple isotopes.

The ECAT reagent bromoacetamidobenzyl–DOTA (BAD) can be used like an ICAT tag to label only those peptides containing cysteine residues (Figure 12.19), thus reducing the total number of peptides having to be analyzed in a mass spectrometry separation. Unlike the ICAT reagent design, the ECAT compound does not contain a biotin handle for affinity separation. Instead, a monoclonal antibody has been developed with specificity for the DOTA chelate containing a bound lanthanide metal. The antibody will recognize any lanthanide element bound in the chelate and thus function as an affinity ligand for separating ECAT-labeled peptides. The affinity of the monoclonal for ECAT chelate structure allows highly stringent washes to be done prior to elution of the labeled peptides. The affinity column typically is washed with low-pH, high-salt, high-pH, and 30% acetonitrile before elution is done. This removes all traces of nonspecifically bound peptides, so they can't interfere with the mass spec analysis. The ECAT-labeled peptides are then eluted with 20% acetonitrile containing 0.1% TFA.

The ECAT system has an advantage over ICAT reagents in that it is available with more mass signatures than is achievable using ^{13}C- or ^{2}H-labeled tags, which are difficult to synthesize. In addition, it is not hampered by the binding idiosyncrasies of a biotin group interacting with (strept)avidin or the fragmentation problems a biotin tag gives on MS analysis. The ECAT chelate does not generate fragmentation products during the mass spec analysis. Also, the mass defect characteristic of lanthanide metals results in a mass signature upon MS separation that occurs in a relatively unoccupied region of the m/z spectrum (Schneider and Hall, 2005). Thus, identification of ECAT-labeled peptides potentially is simpler than using ICAT reagents.

Another variant of ECAT reagent technology has been developed to analyze the products of protein oxidation (Lee *et al.*, 2006). Called O-ECAT, for "oxidation-dependent, carbonyl-specific element coded affinity tag," the compound contains the same DOTA lanthanide chelating group, but instead of a thiol-reactive bromoacetyl group it has an aldehyde- or ketone-reactive aminoxy group (Figure 12.20). The aminoxy functional group can covalently link to aldehydes or ketones to give an oxime bond that is stable under aqueous conditions (Figure 12.21).

The O-ECAT reagent is a superior alternative to the use of 2,4-dinitrophenylhydrazine (DNPH) (Chapter 2, Section 1.1) in the study of protein oxidation. DNPH modification produces detectable complexes, but it does not provide information as to what amino acids are involved. O-ECAT modifies carbonyl end products of protein oxidation and in addition can provide exact

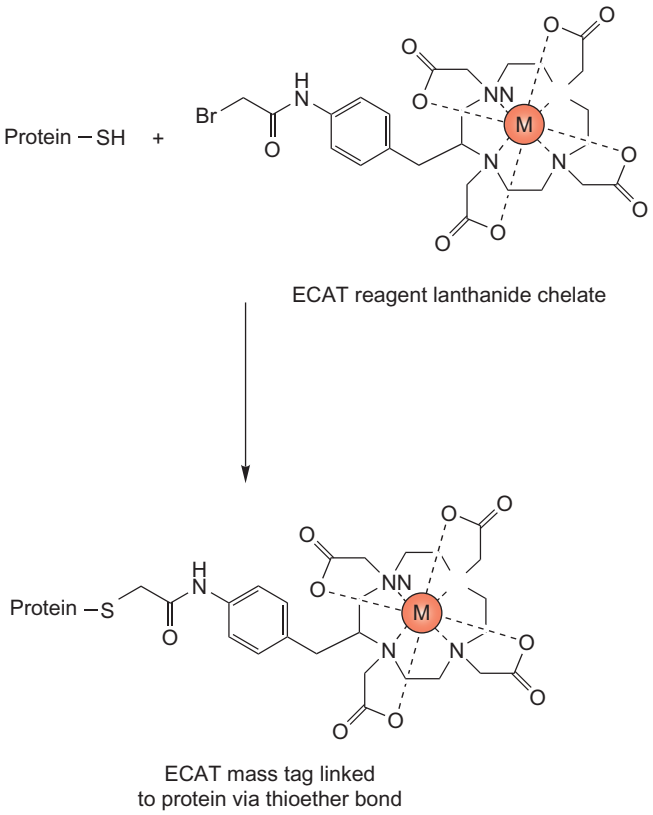


FIGURE 12.19 Reaction of the ECAT reagent with a cysteine-containing protein results in the formation of a stable thioether bond.

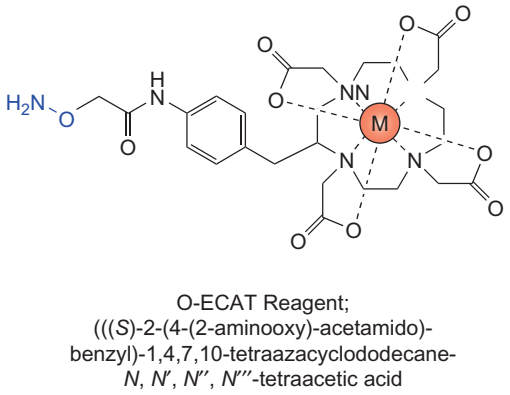

FIGURE 12.20 The O-ECAT reagent structure contains a DOTA chelating group and a terminal aminooxy group for coupling to aldehyde and ketone sites of oxidation within biological molecules.

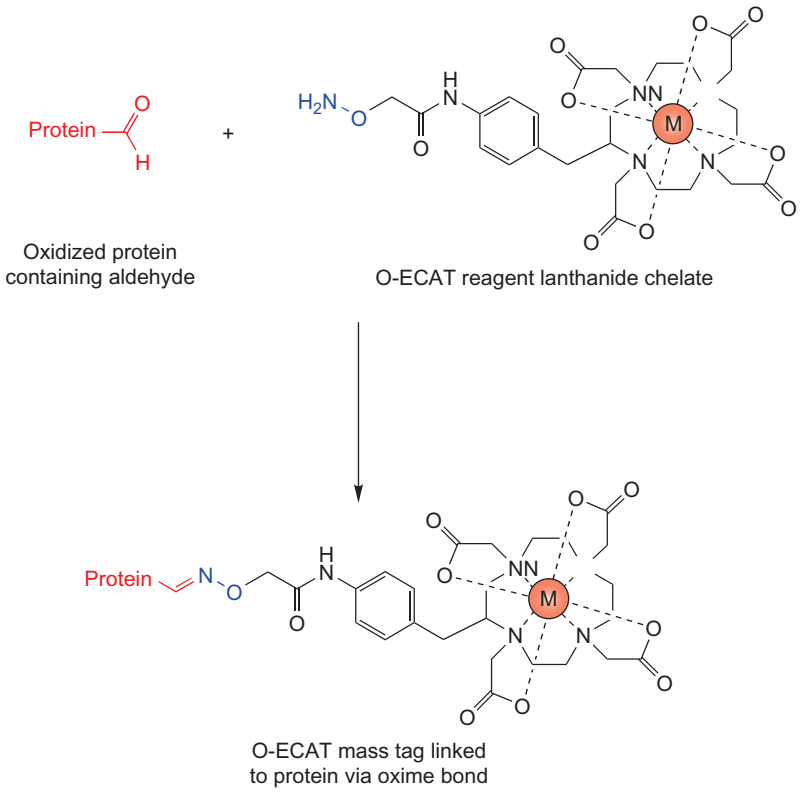

FIGURE 12.21 The O-ECAT mass tag can covalently link to any oxidized proteins containing aldehydes, forming an oxime bond.

information as to the amino acids that were oxidized. Mass spectrometry analysis of modified proteins performed after proteolysis gives the exact amino acid sequences including the sites of O-ECAT reagent modification. The same antibody that is specific for the metal chelate portion of the standard ECAT reagent also can be used to capture and detect the O-ECAT-labeled proteins or peptides. Thus, O-ECAT-modified proteins can be detected in western blots or the sites of oxidation quantified using ELISA-based assays. The technology is being used to study carbonylation of biomolecules as a result of oxidative stress and other oxidation processes in cells and tissues (Møller *et al.*, 2011; Rao and Møller, 2011).

3.3. Isobaric Mass Tags

The use of mass tagging reagents to analyze proteomic data has greatly improved the ability to compare samples for protein expression differences. However, a major limitation of the ICAT procedure (Section 3.1) is that it can only compare two samples simultaneously, usually a test and a control. Even with the ECAT design (Section 2) using multiple lanthanide metals to make a series of different mass tag signatures, it is difficult to extend the analysis to multiple samples, because of the sheer number of peaks that result in the mass spectrometry separation.

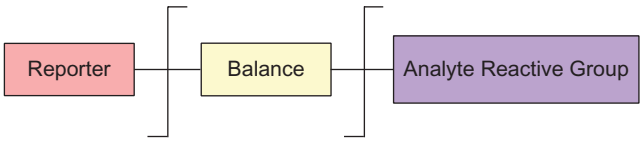

FIGURE 12.22 The general structure of an isobaric mass tag reagent. The reactive group facilitates coupling to discrete sites on peptides, such as amines. The reporter group creates a unique mass signal in MS^2 analysis and its total mass is exactly balanced by the balance group by changing the stable isotopic labels to provide the opposite mass differential as that of the reporter group. The result is that all isobaric tags have the same initial molecular mass, but upon fragmentation in MS^2 the reporter group is released and it provides the unique mass signal to identify the sample being analyzed.

A new type of mass tag extends the benefits of stable isotopic labeling of peptides for mass spectrometry to the analysis of multiple samples and multiple proteins separated simultaneously within the same mass spectrometry run. An isobaric tag consists of a reactive group for coupling to peptides followed by an isotopically labeled mass normalization group, a cleavable linker, and another isotopically labeled group, called a mass reporter (Figure 12.22). For every isotopic substitution in the mass reporter region, the mass normalization group has an inverse mass substitution. Using this balancing

process, the total molecular mass of the entire tag always stays the same—thus the name "isobaric tag." A series of isobaric labels can be created by careful selection of the isotopic substitutions in the reporter group, which are exactly balanced in the normalization group.

If there are enough potential isotopic substitution sites in the isobaric tag design, a set of four to ten tags can be created in which each has a different reporter mass, but all of them have the same total molecular weight. Proteome Sciences and Thermo Fisher, Applied Biosystems (now ABSciex), and PerkinElmer/Agilix (now discontinued) each have developed isobaric tag sets based on the reporter group/normalization group blueprint for multiplexed sample analysis. Figure 12.23 shows examples of isobaric tag design that were obtained from company advertising, scientific publications, or the associated patents. Most of the tags also contain a tertiary amine group or a guanidino group to aid in the ionization of the labeled peptide and provide better mass spectrometry signals.

In use, a protein sample is first proteolytically digested and labeled with an individual isobaric tag. The most common isobaric tag design contains an amine-reactive NHS ester group to label each peptide at its N-terminus. Therefore, within a given sample all of the different peptides after labeling will have a unique isobaric tag modifying them with a characteristic reporter group mass. Unlike the use of an ICAT tag that targets only cysteine-containing peptides, modification of the N-terminus of every peptide ensures 100% coverage of the proteome. If multiple samples are being analyzed, then each peptide sample is separately labeled with a different isobaric tag in the series. After labeling, all of the samples then are combined and separated chromatographically to reduce the total sample complexity.

Since each isobaric tag in a set is structurally identical except for its isotopic substitution pattern, all of them perform identically with regard to peptide modification and chromatographic separation. Multiple peptide samples then can be labeled separately with different tags in a series. The samples can then be combined, subjected to fractionation typically done by multidimensional protein identification technology (MudPIT) (Lin *et al.*, 2003), and injected into a mass spectrometer for analysis. As each peak comes off the MudPIT separation system and goes into the mass spectrometer, it contains the same sequences of labeled peptides from each sample that happen to elute under the instant conditions of salt strength and solvent addition being used at that moment. The only difference in the peptide mixtures within a given chromatographic peak, then, is the type of isobaric label attached to them, which is indicative of the sample it came from. Thus, the peptides representing a particular sample will all be labeled with a tag having a characteristic reporter group mass. Another set of peptides with the same amino acid sequence but coming from another sample will be labeled with a different isobaric tag having another reporter group mass signature.

It is only upon tandem mass spectrometry analysis that the isobaric labels can be distinguished and the peptides identified. For instance, if four samples were each labeled with a different isobaric tag, in the first dimension of a MS separation a given peptide from each sample will appear in the same peak, because the peptides will all have the same sequences and the isobaric tags labeling them will all have the same mass signatures. Therefore, their mass:charge ratios will all be the same and they will be indistinguishable at this point. However, upon MS/MS separation wherein additional energy is used to promote fragmentation of the labeled peptides within the peak, usually by collision-induced dissociation (CID) or electron capture dissociation (ECD), the peptides will break down into their respective charged amino acids and the isobaric tags will be cleaved to release their reporter groups. From the peaks that result from this second-stage MS separation both the peptide sequence and the sample from which it came can be identified from the amino acids and the mass of the respective reporter groups.

There are many publications describing the development and use of isobaric tags. For instance, Thompson *et al.* (2003) described the development of tandem mass tags based on an isotopically labeled peptide design. A later iteration of this concept uses commercially available isotopes of alanine to form the reporter group, followed by a piperazine ring (as the charge-carrying group), a second alanine used as the mass normalization group, and a proline residue that functions as the electrospray cleavable linker (Thompson *et al.*, 2007). Ross *et al.* (2004) used a set of four isobaric tags designed around an *N*-methyl piperazine group to study the global protein expression of a wild-type yeast strain *versus* strains defective in certain pathways. These tags are part of the iTRAQ (isotope tags for relative and absolute quantitation) system from Applied Biosystems (now ABSciex). Figure 12.23 shows some of the major structural characteristics of commercial isobaric tags. Figure 12.24 illustrates the design of a multiplex isobaric set that uses a piperidine ring as the reporter group, showing all of the various isotopic modifications done to balance the reporter and normalization group to create six unique tags. The use of tandem mass tags (TMTs; Proteome Sciences and Thermo Fisher) in relative protein quantitation has been reviewed (Dayon and Sanchez, 2012).

Isobaric labels thus permit quantitative information regarding protein expression levels in multiple samples analyzed simultaneously by MS. The multiplexed capability of these reagents allows the measurement of

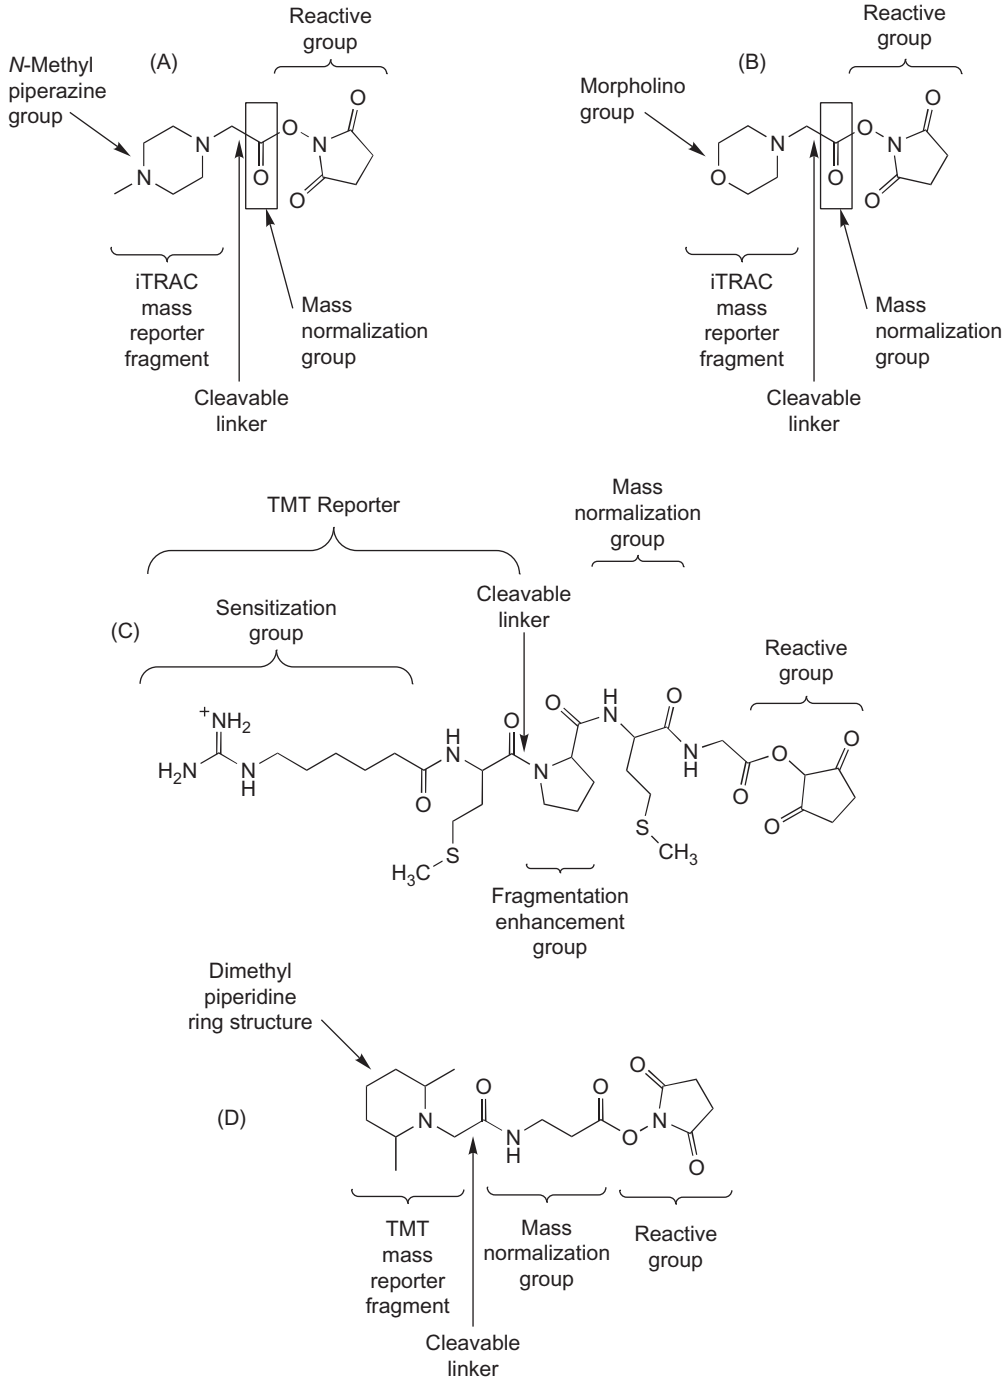

FIGURE 12.23 A number of isobaric tags have been developed having different structural motifs. (A and B) Isobaric tags used as part of the iTRAC reagents (Applied Biosystems). (C) An early design of isobaric tags using a core of amino acid derivatives (Proteome Sciences). (D) The TMT tag design as commercialized by Proteome Sciences. All of these isobaric tags contain a sensitization group to enhance mass spectrometry detection, which is represented either by a tertiary amine that can be protonated to carry a positive charge or a guanidino group.

peptides and proteins in diseased samples, treated samples, and normal samples all in the same experiment. In addition, since all peptides from a given protein get labeled at their N-termini, the MS analysis generates more than one peptide signal, which can be used to confirm protein identity with greater confidence than using a cysteine label, like ICAT.

The protocol for using isobaric tags differs from that described previously for the ICAT or ECAT type of reagents. In the following method, the proteins are

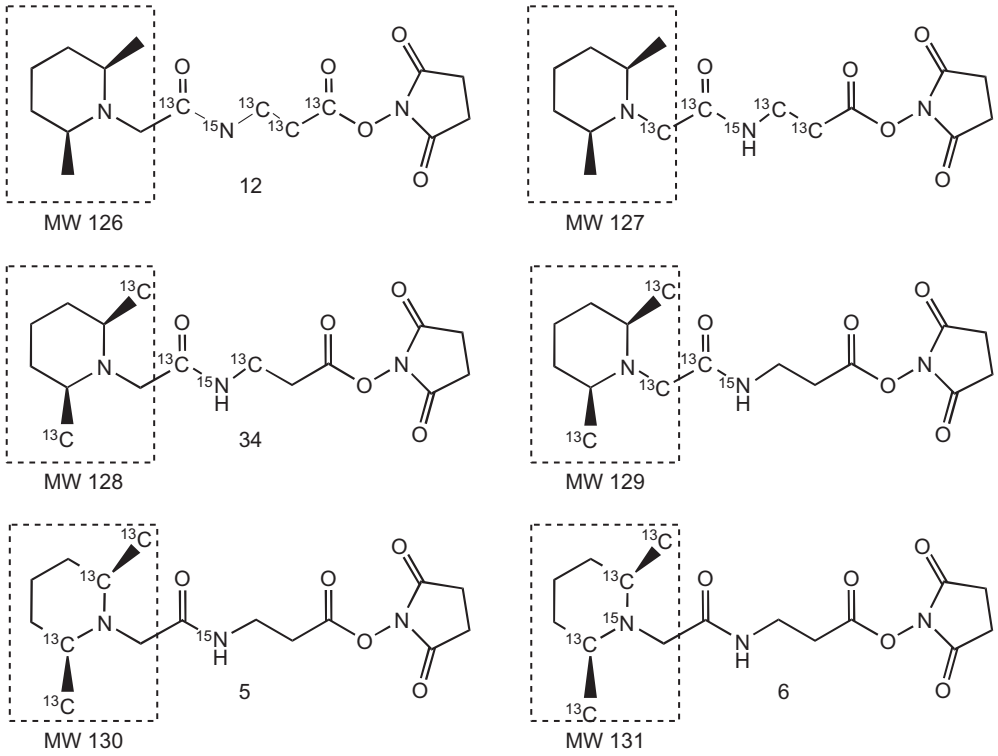

FIGURE 12.24 Isobaric tags allow multiplexed analysis of different samples by changing the mass of the reporter group and balancing that change by the opposite change in the balance group. This figure illustrates the 6-plex tag system from Proteome Sciences, which contains six different reporter groups (boxed areas). All of the reagents contain amine-reactive NHS esters for modifying lysine side chains in proteins and peptides.

denatured and the disulfides reduced and then alkylated to block them permanently. This eliminates disulfide re-association and also prevents the isobaric tags from forming thioester modification with cysteine thiols. Next, the proteins are digested with trypsin and then modified with an isobaric tag. Each sample is labeled with a different isobaric compound so that the samples can be differentiated upon MS/MS analysis.

The following protocol illustrates the modification reaction and the handling of the protein samples, but it is not meant to be instructive of mass spectrometry techniques.

Protocol

1. Grow cells to 70 to 80% confluence and harvest by scraping the cells into 5 ml of 0.1-*M* sodium borate, pH 7.5. Avoid the use of amine-containing buffers, as these will react with the NHS esters on the isobaric tags. Aliquot cell counts of approximately 2.5–5 × 10^6 for processing. Lyse cells using a detergent lysis buffer (e.g., Poppers, Thermo Fisher) or by mechanical means. Centrifuge and discard the cellular debris. Measure the total protein concentration using the BCA assay (Thermo Fisher) and adjust the protein concentration to 1 mg/ml using 0.1-*M* sodium borate, 0.1% SDS, pH 7.5. A total of 100 µg of each protein sample can be used in this protocol. Separately process test samples and a control sample made up of different cell populations. Simultaneous measurement can be done on a total number of samples equal to the number of different isobaric tags available.
2. Reduce disulfides in the protein sample by the addition of 2 µl of 50-m*M* TCEP (Thermo Fisher) to each 100-µl aliquot of protein solution (final concentration 1-m*M*). Cover and boil the samples for 10 min in a water bath to completely denature and reduce the proteins. Alternatively, reduction may be done at 60°C for 1 h. Avoid the use of thiol-containing reductants, such as DTT, as these will react with the thiol blocking agent used in the next step.
3. Add 6 µl of iodoacetamide to each sample solution and react with mixing for 30 min at room temperature.
4. Prepare a solution of TCPK–trypsin in 0.1-*M* sodium borate, pH 7.5, at a concentration of 400 ng/µl. Add 10 µl of the trypsin solution to each sample and incubate at 37°C for 12 to 16 h or overnight with mixing.

5. Dissolve the isobaric tagging reagents in acetonitrile or ethanol at a concentration of 50-m*M* (or according to the manufacturer's recommendations). Use a fume hood to handle organic solvents.
6. Add a quantity of the appropriate isobaric tag solution to each sample to provide a final concentration of 10 to 20-m*M*. This quantity of reagent will ensure a large molar excess of reagent over the concentration of peptides present in order to modify completely all peptides at their N-terminus. Note that the ε-amino groups of lysine residues also will be modified by this procedure. React for 1 h at room temperature.
7. To eliminate acylation products at tyrosine residues, add 1 µl of 15-*M* hydroxylamine solution in water to each protein sample and incubate for 30 min at 37°C (Zappacosta *et al.*, 2006).
8. Combine the contents of each labeled sample into a single tube and mix by vortexing, then centrifuge.
9. Before LC–MS/MS analysis, the sample must be cleaned up to remove excess salts, SDS, reducing agent, and cell lysis buffer components. This typically is done by using a strong cation exchange matrix. Protocols may be found for this procedure in the instruction booklets related to the use of isobaric tagging reagents (e.g., Thermo Fisher, ABSciex).

CHAPTER

13

Silane Coupling Agents

A silane compound is a monomeric silicon-based molecule containing four constituents. Since silicon is in the same family as carbon on the periodic table, it too is able to form covalent bonds with four other atoms. However, it is less electronegative than carbon and undergoes reactions that are unique compared to typical organic compounds. Silanes that contain at least one bonded carbon atom are called organosilanes. Organosilanes can also have hydrogen, oxygen, or halogen atoms directly attached to the silicon atom core. Some of these derivatives are highly reactive and can be used to form covalent linkages with other molecules or surfaces (Mittal, 2009; Borup and Weissenbach, 2010). The process of adding a silane coating (R_3Si–) to a particle or surface is called silanization or sometimes silation. (Note: The process of adding a silyl group to a functional group on a molecule is called silylation, which is a derivatization method used extensively to separate molecules in gas chromatography or as a temporary protecting group in organic synthesis.) The more useful organosilanes for silanization purposes are those that contain a functional organic component in addition to one or more silane-reactive groups. The organic portion also may contain a reactive group, which allows conjugation of the organosilane molecule to other organic compounds. Conversely, the silane-reactive groups typically are unreactive toward organic molecules, but can covalently couple to certain inorganic substrates. The advantage of this type of functional silane derivative is to promote the bonding of an organic molecule to an inorganic particle, surface, or substrate.

The general structure of a functional silane coupling agent is shown in Figure 13.1. The organic arm typically has a structure that terminates in a functional group or reactive component, which facilitates the covalent linkage to another organic molecule. The other part consists of the silane-reactive groups attached directly to the silicon atom and can be of several types. They may comprise simply a hydrogen atom (called a silicon hydride); a halogen–silicon derivative, such as a chlorine atom (called a chlorosilane); an –OH group (called a silanol); or groups containing methyl ether or ethyl ether organic constituents (called a methoxy- or ethoxysilane, respectively).

The general reactions of silane coupling agents toward inorganic substrates are illustrated in Figure 13.2. The reaction mechanism and formation of a reactive intermediate can be different from that usually encountered with organic reactive groups. Unlike most other reactive groups discussed in this book, the most common silane coupling groups (alkoxy) often must first undergo hydrolysis to form a reactive intermediate, which then couples to the substrate. The hydrolysis of an alkoxysilane produces a silanol, which actually is the highly reactive form necessary for coupling to inorganic surface hydroxyls.

The initial reaction that occurs in solution or near an inorganic substrate is condensation of the silane coupling agents together to form a polymer matrix linked together by –Si–O–Si– bonds. Concurrently, the growing silane network interacts with the inorganic substrate through the formation of a hydrogen bonding network with the –OH groups on its surface. Another condensation reaction then occurs, usually requiring heat or vacuum to remove water, which results in the formation of covalently linked organosilane polymer

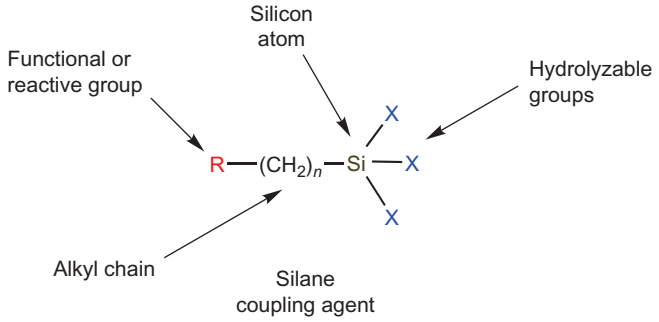

FIGURE 13.1 The general structure of a silane coupling agent includes a functional group or reactive group at the end of an organic spacer. This alkyl chain is attached to the central silicon atom, which also has up to three hydrolysable groups attached to it.

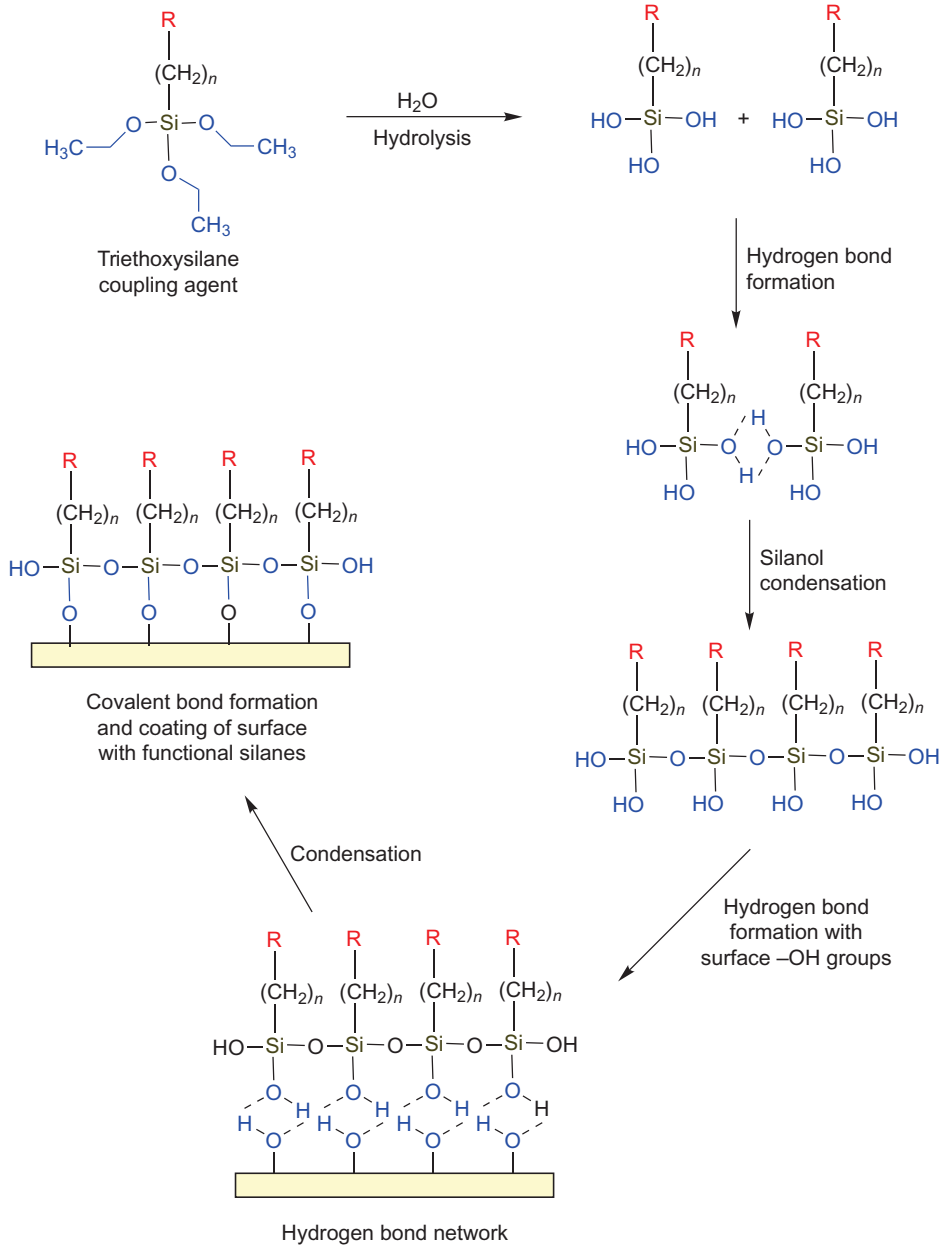

FIGURE 13.2 The reactions involved with the coupling of an organosilane compound to an inorganic surface containing available –OH groups. The first step in the reaction involves the hydrolysis of the alkoxysilane groups to form highly reactive silanols. The silanols undergo hydrogen bonding with other silanols in solution and on the substrate, resulting in a network of associated organosilane derivatives. A condensation reaction then takes place to form a polymerized coating of the organosilane on the surface of the substrate.

to the surface, forming stable siloxane linkages (or oxane bonds). The organosilane coating applied in this manner does not result in a monolayer, but a thicker polymer layer with the reactive organic components extending out from the surface. The thickness of the organo–siloxane layer is dependent on the concentration of silane coupling agent used in the reaction and the amount of water present in the solution. Gelest reports that deposition of a silane coupling agent using a 0.25% aqueous solution will result in a layer approximately three to five silanes thick.

Alkoxysilanes are used for modification of surfaces due to the instability of silanol derivatives, which will spontaneously hydrogen bond and conjugate together in solution. The formation of an alkoxy derivative of the corresponding silanol acts as a stabilizer to prevent silanol polymerization. However, alkoxysilanes typically are unreactive with substrate hydroxyl groups

under ambient temperature conditions. Ethoxysilanes are virtually unreactive to substrate –OH groups without prior hydrolysis. Methoxysilanes are the most reactive, but only react very slowly at room temperature. However, under the right conditions, both methoxy- and chlorosilane groups are sufficiently reactive to couple directly with inorganic substrate functionalities without prior hydrolysis. For instance, the addition of a catalyst to the reaction to increase the hydrogen bonding capability of substrate hydroxyls has been done to increase the reaction rate for methoxysilanes (Kanan *et al*., 2002). Also, chlorosilanes and methoxysilanes can be reacted in an organic solvent without the presence of water (i.e., in THF, toluene, or hydrocarbon solvents), if performed under refluxing conditions to drive the reaction to completion. In this case, a siloxane polymer network does not form in solution, because no hydrolysis occurs to form silanols on the silane coupling agents. Therefore, instead of a thick polymer layer forming on the substrate as in aqueous reactions, a monolayer results where each organosilane is coupled directly to the substrate *via* a siloxane bond. The reactive organic components stick out from this monolayer for eventual conjugation with biomolecules or other molecules.

Therefore, functional silanes in a sense are bifunctional compounds that can be used to attach one substance to another. They have been used for many years as adhesive agents to promote the bonding of an organic layer to an inorganic layer. Some examples are in the coupling of inorganic metals, particles, fiberglass, or fillers to organic polymers, plastics, rubber, or resins. The uses for functional silanes thus are extensive and span many industries, such as automotive, building materials, coatings, and electronics, to name but a few. For reviews of silane coupling agents and their uses, see Borup and Weissenbach (2010), Mittal (2009), Plueddemann (1991), and VanDerVoort *et al*. (1996).

Some common inorganic substrates for use with silane coupling agents in approximate order of efficiency and stability for modification include silica, quartz, glass, and the oxides of aluminum, copper, tin, titanium, iron, chromium, zirconium, nickel, and zinc. All of these substrates can have functional inorganic –OH groups on their surface that react with the silanols on the silane coupling agents to form siloxane bonds. Sometimes the surfaces require prior treatment to form the –OH groups and remove contaminants, which will interfere with the silanization process. Glass, for instance, often needs to be treated with acid (5% HCl) for several hours to remove non-binding metal ions, especially sodium, potassium, and calcium, which are ubiquitous in the environment. In addition, treatment with a mixture of 25% sulfuric acid and 15% hydrogen peroxide (piranha solution) for about 30 min is carried out to create a high density of hydroxyl functionalities suitable for silane modification. Glass slides also can be cleaned and washed prior to modification with a silane with DMSO, ethanol, and water, and then etched using 10% NaOH (w/w) in water for 1 h.

The distinctive bifunctional nature of silane coupling agents has led to their application in bioconjugate chemistry. There are many silane coupling agents commercially available that contain functional groups or reactive groups that can be used to covalently link biomolecules to inorganic substrates (Dow Corning, Gelest). Inorganic substrates treated with a suitable silane coupling agent subsequently can be used to couple antibodies, proteins, oligonucleotides, or other biomolecules containing the appropriate chemical groups for reaction. By judicious choice of the proper organo-functional component, a silane coupling agent can be used to design virtually any bioconjugation complex. The following references provide examples of how silane coupling agents have been used to modify surfaces and provide covalent linkage sites for coupling biomolecules or organic substituents: Debs *et al*. (2009), Iijima *et al*. (2009), Lin *et al*. (2011), Zhao *et al*. (2011), and Smirnov *et al*. (2012).

1. SILANE REACTION STRATEGIES

The reaction techniques that can be used with functional silane coupling agents are varied. Reactions can be performed in aqueous solution, entirely in organic solvent, in organic solutions containing a small amount of water, and even in the vapor phase. They also can be done at room temperature or under elevated temperature conditions. The choice of reaction strategy often is governed by the type of substrate initially being modified by the silane compound and the inorganic reactive groups on the silane. For instance, if the inorganic substrate can be treated by mixing or suspending it in a solution of functional silane, such as with particle coatings, then this may be simplest option for silanization. Another choice may be to dip the substrate into the silane solution, as is sometimes done with glass slides and other small surfaces that can be handled in trays or baskets. Alternatively, complex surfaces, such as those often encountered with devices, may be treated in a chamber wherein the silane compound is volatilized by heating or by being placed under vacuum. This option usually results in the uniform modification of all surfaces with a thin layer of functionalized silane by vapor phase deposition.

The following sections describe the major organosilane reaction strategies used to modify surfaces and provide suggested protocols, which may be used with the functional silane compounds described later in this chapter. Many organosilane compounds are initially only sparingly soluble in aqueous solution. Therefore,

solutions containing silanes in either 100% aqueous or in a water/organic mixture containing a large amount of the aqueous component often will appear as insoluble two-phase systems. As the alkoxy groups hydrolyze, the silanols will dissolve into the aqueous solution and the solution will become clear. However, if the solution is allowed to sit long enough, the silanols will react, form siloxane linkages, and polymerize in solution. At this point, the solution again will become cloudy due to these large polymers.

1.1. Aqueous/Organic Solvent Deposition

This method involves the deposition of functional silane onto an inorganic substrate using a dilute solution of water in organic solvent. The small amount of water at acid pH facilitates the hydrolysis of the alkoxy groups on the silane to form the reactive silanols necessary for coupling. The method of silane solution contact with the substrate may be accomplished by suspension stirring, dipping, spinning, or spraying the silane solution.

Protocol

All operations should be carried out in a well-ventilated fume hood. Use care not to inhale vapors or get reactive silanes on your skin or in your eyes.

1. Prepare a solution containing 3 to 5% water in ethanol (v/v) and adjust the pH to 4.5 to 5.5 with acetic acid.
2. Dissolve a silane coupling agent in the acidic water/ethanol solution with stirring to a final concentration of 2 to 5% (v/v). Allow hydrolysis to occur for 5 min at room temperature to form reactive silanols.
3. Contact the inorganic substrate with the silane solution for as brief as 2 min to as long as several hours, depending on the degree of organosilane polymer deposition desired on the surface. Benters *et al*. (2002) performed the reaction on glass slides in a stirring bath for 2 h. Optimization of the reaction time should be performed to determine the best performance of the modified substrate in its intended application.
4. Wash the substrate several times with ethanol or the water/ethanol mixture to remove excess silane compound.
5. Cure the organosilane-modified substrate by incubation at 110°C for 30 min or at room temperature in a low-humidity environment. Curing under vacuum also will aid in the removal of water and the formation of siloxane bonds.

1.2. Aqueous Deposition

Functional organosilanes can be applied to substrates directly from aqueous solutions, provided the silane compound is soluble in water.

Protocol

1. Dissolve an alkoxysilane in water at a concentration of 0.5 to 2.0% (v/v). If the compound is not very soluble in water, a nonionic detergent can be added to the solution at 0.1% to promote solubility.
2. Adjust the solution with acetic acid to pH 5.5.
3. Contact the substrate with the silane solution from 2 min to as long as 1 h, depending on the degree of organosilane polymer deposition desired on the surface. Optimization of the reaction time should be done to determine the best performance of the modified substrate in its intended application.
4. Remove excess solution and cure at 110 to 120°C for 30 min to remove traces of water and form the siloxane bonds.
5. Wash the substrate with water or buffer.

1.3. Organic Solvent Deposition

This method of silanization, which uses organic solvent without the addition of water, is suitable for highly reactive silane derivatives, such as chlorosilanes, aminosilanes, and methoxysilanes. This procedure will not work for ethoxysilanes, as these compounds are not reactive enough without prior hydrolysis to create the silanol. This method is convenient for use in silica particle modification and for the functionalization of metallic nanoparticles having the requisite –OH groups present (see Chapter 14, Section 5).

Protocol

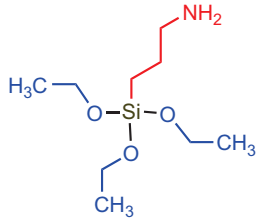
1. In a fume hood, dissolve the organosilane coupling agent containing chloro-, amino-, or methoxysilane-reactive groups in toluene, THF, or a hydrocarbon solvent at a concentration of 5% silane.
2. To ensure a thin monolayer of silane modification on the substrate, first remove all traces of water by drying it at 150°C for 4 h. This step is especially important for nanoparticle modification, as the high surface area of the particle population can hold a lot of water by hydrogen bonding. Note that if the substrate contains water, a thicker polymer layer of silane will build up on it due to hydrolysis of the reactive groups to silanols close to the surface of the substrate. After drying, wash the particles with solvent several times by centrifugation before resuspending them in the silane solution. For other substrates, submerge them in the silane solution with mixing.
3. React with gentle stirring for 12 to 24 h by heating to reflux in a fume hood.
4. Cool the reaction and wash the substrate with solvent to remove excess silane reagent and reaction byproducts. The modified substrate may be dried or washed into aqueous buffer for further conjugation with biomolecules.

1.4. Vapor-Phase Deposition

Many silane coupling agents can be applied to substrates by volatilization in an enclosed chamber under heat or vacuum. In this approach, the substrate is placed within the chamber in a fashion to allow for vapor-phase molecules to access all areas that are to be derivatized. This method is commonly used for silanizing glass slides or substrates that are difficult to suspend in a silane solution. Slides are often placed in racks within the chamber and all surfaces get modified with silane in a uniform manner. Vapor deposition also uses a very small amount of organosilane compound compared to what may be necessary to fully immerse a substrate device in solution.

Protocol

1. In an enclosed chamber made of glass or acrylic, such as a vacuum chamber, place the substrate to be modified in such a manner as to expose the surfaces to the vapor phase.
2. Place the organosilane coupling agent in a small reservoir under or next to the substrate in the chamber. If volatilization by heating is to be done, an explosion-proof heating device should be used to maintain the silane solution temperature at 50°C or above. Alternatively, apply a vacuum to the chamber until the silane compound begins to volatilize. The vacuum tubing may be clamped off to maintain vacuum within the chamber once a sufficient level of evacuation has been reached. Vapor-phase deposition usually requires that the silane have at least a 5-mm vapor pressure to achieve adequate concentration in the atmosphere within the chamber.
3. React for 4 to 24 h within the chamber to result in a uniform coating of the substrate surface with organosilane. Often surfaces are coated overnight to complete the reaction.



2. FUNCTIONAL SILANE COMPOUNDS

Functional silane compounds containing an organofunctional or organo-reactive arm can be used to conjugate biomolecules to inorganic substrates. The appropriate selection of the functional or reactive group for a particular application can allow the attachment of proteins, oligonucleotides, whole cells, organelles, or even tissue sections to substrates. The organosilanes used for these applications include functional or reactive groups such as hydroxyl, amino, aldehyde, epoxy, carboxylate, thiol, and even alkyl groups to bind molecules through hydrophobic interactions.

The following sections discuss the organosilane compounds commonly used for conjugation to inorganic surfaces. These reagents and many other silane derivatives are available from a number of commercial sources, which include Dow Corning, Gelest, and Aldrich, among others.

2.1. 3-Aminopropyltriethoxysilane (APTS) and 3-Aminopropyltrimethoxysilane

These two silane coupling agents are among the most popular choices for creating a functional group on an inorganic surface or particle. Both reagents contain a short organic 3-aminopropyl group, which terminates in a primary amine. The only difference in these compounds is the silane-reactive portion that contains either a triethoxy group or a trimethoxy group. Thus, the reagents display differences in reactivity toward substrate –OH groups related to the relative reactivity of the alkoxysilane functionalities. The trimethoxy compound is more reactive and can be deposited on a substrate using 100% organic solvent without the presence of water to promote hydrolysis of the alkoxy groups prior to coupling. In this case, the organic solvent deposition protocol described in the previous section can be used to covalently modify substrates with a layer of aminosilane compounds. The advantage of this process is that a thinner, more controlled deposition of the silane can be made to create a monolayer of aminopropyl groups on the surface.

APTS;
3-Aminopropyltriethoxysilane
MW 221.37

3-Aminopropyltrimethoxysilane
MW 179.29

When using APTS (the triethoxy version), the reaction must occur in at least a partially aqueous environment. The ethoxy groups are not reactive enough to couple spontaneously with the –OH groups on an inorganic surface without prior hydrolysis to form silanols. This is typically done in 5% water in ethanol that has been acidified with acetic acid to pH 4.5 to 5.5. The protocol described in the previous section for aqueous solvent deposition can be used with success to modify surfaces or particles with this reagent (Figure 13.3). This reaction process results in a layer containing about three to eight organosilanes in thickness, which effectively masks the underlying inorganic substrate with aminopropyl functionalities.

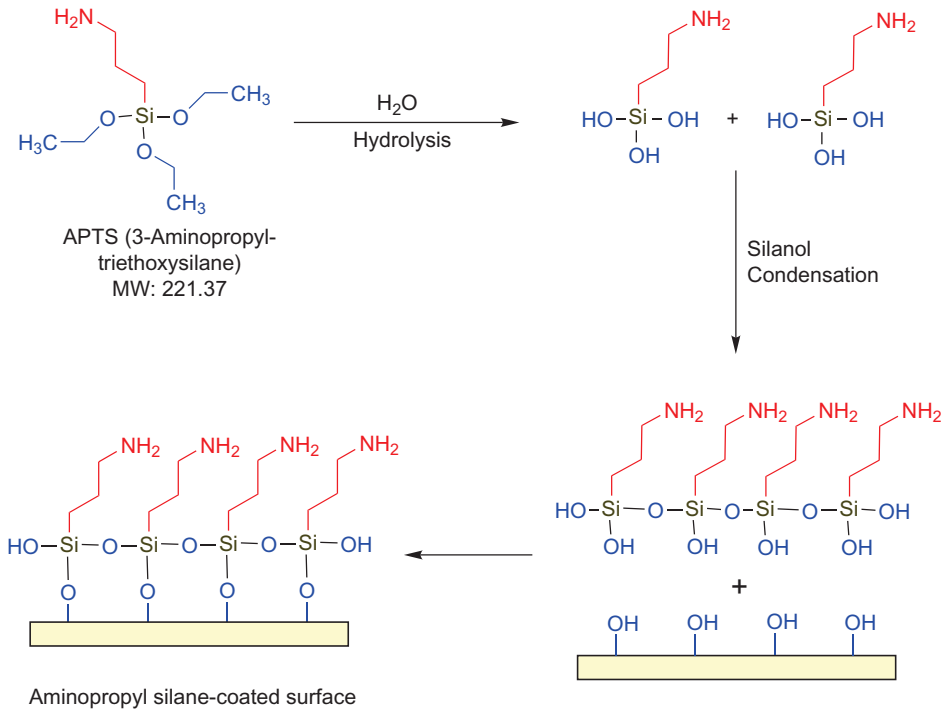


FIGURE 13.3 The deposition of APTS on inorganic substrates results in the formation of a covalent coating containing primary amine groups.

Once deposited on a substrate, the alkoxy groups form a covalent polymer coating with the primary amine groups sticking off the surface and available for subsequent conjugation. Carboxyl- or aldehyde-containing ligands may be directly coupled to the aminopropyl groups using a carbodiimide reaction (Chapter 4, Section 1) or reductive amination (Chapter 4, Section 4), respectively. Alternatively, surfaces initially derivatized with an aminopropylsilane compound can be modified further with spacer arms or crosslinkers to create reactive groups for coupling affinity ligands or biomolecules. For instance, the amine groups may be derivatized with an NHS–PEG$_n$–azide compound for use in click chemistry or Staudinger ligation reactions for linking proteins or other biomolecules (Chapter 17, Sections 5 and 6, and Chapter 18, Section 1.2). This modification forms extremely hydrophilic PEG spacers on the surface that terminate in alkyl azide groups for conjugation with alkyne or phosphine derivatives (Figure 13.4).

Other crosslinking agents that contain an amine-reactive group on one end also may be used to modify and activate the APTS-modified substrate. Surfaces may be designed to contain, for instance, reactive hydrazine or aminooxy groups for conjugation with carbonyl-containing molecules, such as aldehydes formed through periodate oxidation of carbohydrates or natively present at the reducing end of sugars and glycans (Chapter 17, Sections 2 and 3, and Chapter 2, Section 4.6).

Benters *et al*. (2002) used two approaches to modify APTS surfaces. In one instance, the amine groups were acylated using glutaric anhydride to create carboxylate functionalities, which were then activated with NHS/DCC to form the NHS ester. This derivative could be used to couple amine-containing proteins and other molecules *via* amide bond formation. In a second activation strategy, the aminopropyl groups on the surface were activated with 1,4-phenylenediisothiocyanate (PDITC) to create terminal isothiocyanate groups for coupling amines. Both methods resulted in the successful coupling of amine–dendrimers to silica surfaces for use in arrays (see Chapter 8, Section 4).

APTS has been used extensively to modify inorganic surfaces to produce organic functional groups for further coupling with ligands or additional modification reactions. The application of this reagent has involved modification of quantum dots (Chapter 10) (Li *et al*., 2012), coating ZnO nanoparticles (Zhao *et al*., 2012), synthesizing SiO_2-coated Fe_3O_4 nanoparticles with amine groups (Khosroshahi *et al*., 2012), and developing mesoporous silica nanoparticles suitable for anticancer drug delivery (Yanes and Tamanoi, 2012).

Amine surfaces prepared using an aminosilane compound can be modified to contain carboxylate groups using the following protocol involving the reaction with an anhydride, such as succinic anhydride or glutaric anhydride (Figure 13.5). After modification, the

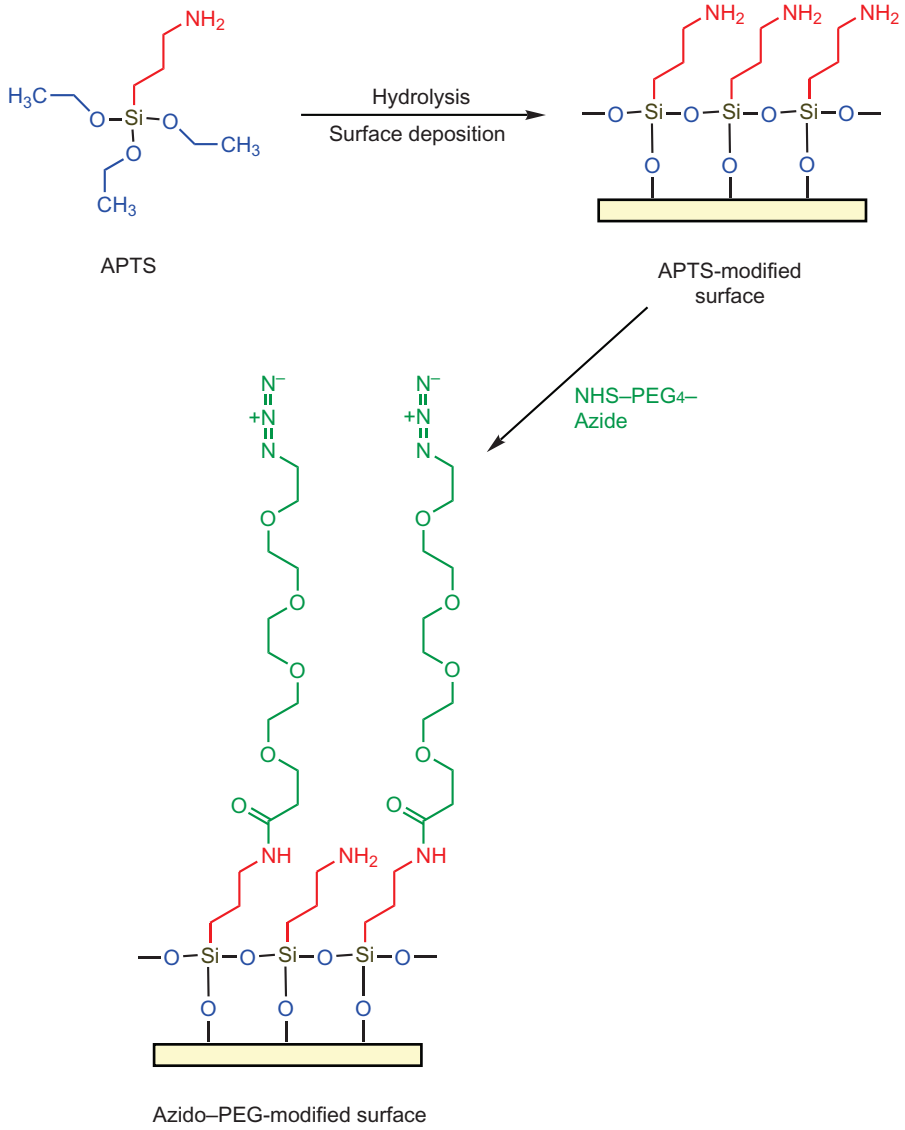

FIGURE 13.4 APTS-modified surfaces may be further derivatized with amine-reactive crosslinkers to create additional surface characteristics and reactivity. Modification with NHS–PEG_4–azide forms a hydrophilic PEG spacer terminating in an azido group that can be used in a click chemistry or Staudinger ligation reaction to couple other molecules.

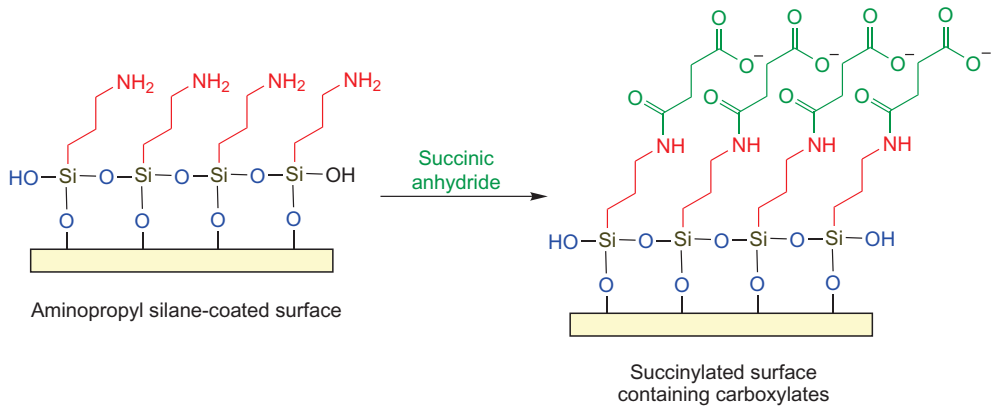

FIGURE 13.5 Modification of an APTS surface with glutaric anhydride creates terminal carboxylates for coupling of amine-containing ligands.

carboxylates then can be used to couple amine-containing molecules using a carbodiimide reaction with EDC plus sulfo-NHS (Chapter 4, Section 1.2).

Protocol

1. Dissolve glutaric anhydride (succinic anhydride also may be used) (Chapter 2, Section 4.2) in DMF at near saturation (use a fume hood). Add triethylamine to a concentration of at least 1 mg/ml to function as a proton acceptor (base).
2. Apply the anhydride solution to the aminosilane-modified surface (typically done by emersion) and mix by stirring.
3. React 2–4 h at room temperature.
4. Wash the carboxylated surface with DMF and then with water. Dried surfaces are stable indefinitely.

The carboxyl groups on the surface may be activated to an NHS ester for coupling with amine-containing biomolecules according to the following protocol, based on the method of Benters *et al*. (2002).

Protocol

1. In a fume hood, dissolve *N*-hydroxysuccinimide (NHS) in DMF (highly pure and dried over molecular sieves) at a concentration of 115 mg/ml (1 *M*) along with 206 mg/ml (1 *M*) *N*,*N*′-dicyclohexylcarbodiimide (DCC; Chapter 4, Section 1.4).
2. Add the NHS/DCC solution to the carboxylated substrate to immerse fully the surface. Mix by stirring.
3. React for 1 to 2 h at room temperature.
4. Wash the surfaces with DMF. The NHS-activated surface may be used to couple amine-containing molecules in a buffer at physiological pH (7.2–7.4) using 50-m*M* sodium phosphate.

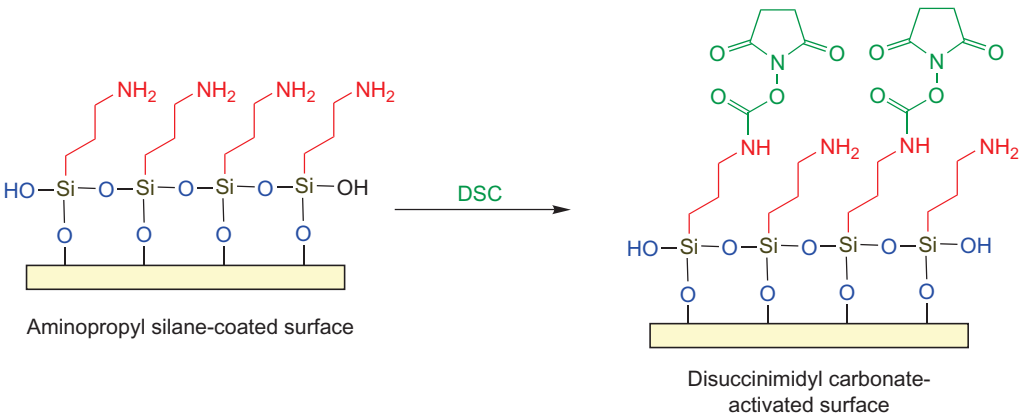
Aminosilane surfaces also may be activated by use of a bifunctional crosslinker to contain reactive groups for subsequent coupling to biomolecules. In one such reaction, *N*,*N*′-disuccinimidyl carbonate (DSC) was used to react with the amines on a slide surface and create terminal NHS–carbonate groups, which then could be coupled to amine-containing molecules (Niemeyer, 2004) (Figure 13.6). The following procedure is based on this method.

Protocol

1. Dissolve 1.5 g of DSC (Chapter 5, Section 1.7) and 5 ml of diisopropylethylamine (DIEA) in 145 ml of dry acetone (in a fume hood).
2. Add the DSC solution to the aminosilane-slides (or other aminosilane-modified surface) to immerse fully the substrate in the solution and mix by stirring.
3. React for 2 h at room temperature.
4. Wash the modified surfaces with dry acetone to remove excess reactants and reaction by-products. Dry under nitrogen. The NHS–carbonate groups on the surface are stable to storage under desiccated conditions (package under nitrogen with a desiccant).
5. Amine-containing molecules, such as proteins or amine-modified oligonucleotides, are coupled to the NHS–carbonate-activated surface by dissolving them in 50-m*M* sodium phosphate, pH 7.4, at a concentration of at least 1 to 10 mg/ml (for proteins). Spotting of biomolecules onto the activated surface may be done to create an array. Since this process usually is done using only microliter quantities or less of solution per spot, the activated surface should be kept in a humidity chamber to prevent evaporation during the coupling reaction.
6. React for 2 to 4 h at room temperature.
7. Wash the slides with coupling buffer to remove excess reactants.

2.2. Carboxyethylsilanetriol

Silane coupling agents containing carboxylate groups may be used to functionalize a surface with carboxylic acids for subsequent conjugation with amine-containing molecules. Carboxyethylsilanetriol contains an acetate organo group on a silanetriol inorganic



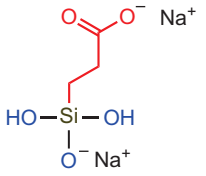


FIGURE 13.6 APTS-modified surfaces can be activated with DSC to form amine-reactive succinimidyl carbonates for coupling proteins or other amine-containing molecules.

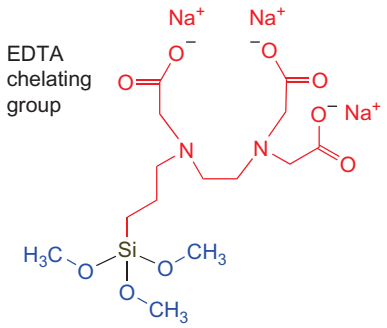
reactive end (Gelest). The silanetriol component is reactive immediately with inorganic –OH substrates without prior hydrolysis of alkoxy groups, as in the case with most other silanization reagents (Figure 13.7). This compound is supplied in a 25% aqueous solution as the monosodium salt, and it can be used just by diluting into water or buffer.

Carboxyethyl-
silanetriol, disodium salt
MW 196.14

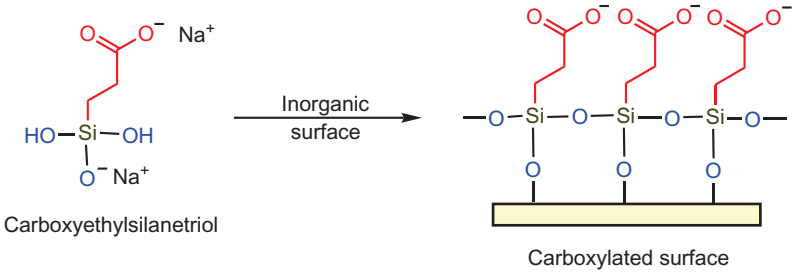
Carboxyethylsilanetriol has been used to add carboxylate groups to fluorescent silica nanoparticles to couple antibodies for multiplexed bacteria monitoring (Wang *et al*., 2007; Cai *et al*., 2012; Subbiahdoss *et al*., 2012) (see Chapter 14, Section 5). This reagent can be used in similar fashion to add carboxylate functionality to many inorganic or metallic nano-materials, which also will create negative charge repulsion to maintain particle dispersion in aqueous solutions. Covalent coupling to the carboxylated surface then can be done by activation of the carboxylic acid groups with a carbodiimide to facilitate direct reaction with amine-containing molecules or to form intermediate NHS esters (Chapter 4, Section 1).



The following protocol for using carboxyethylsilanetriol is based on the method of Wang *et al*. (2007). Other metallic particles or surfaces may be modified with this silane compound in like manner.

Protocol

1. Suspend 10 mg of silica particles in 1 ml of 10-m*M* sodium phosphate, pH 7.4, with gentle mixing.
2. Add 20 µl of the carboxyethylsilanetriol (as the 25% aqueous solution) to the particle suspension with mixing.
3. React at room temperature for 3 to 4 h with mixing.
4. Wash the modified particles several times with buffer using centrifugation for separation. A final wash with 10-m*M* MES, pH 5.5, is done to prepare the sample for coupling amine-containing molecules using a carbodiimide reaction. For suggested protocols, see Chapter 14, Section 4.2, entitled *Coupling to Carboxylate Particles*.



2.3. N-(Trimethoxysilylpropyl)Ethylenediamine Triacetic Acid (TMS-EDTA)

Another useful silanization reagent containing carboxylates actually is an effective chelator of metal ions. *N*-(Trimethoxysilylpropyl)ethylenediamine triacetic acid (TMS–EDTA) contains a trimethoxy group for coupling to –OH groups on inorganic substrates and an EDTA group for coordinating metals (minus one carboxylate, which instead functions as the linking arm attached to the silicon atom). This compound can be used to coat substrates and provide a metal-chelating functional group for use in affinity separations.

TMS–EDTA;
N-(Trimethoxysilylpropyl)ethylene-

MW 462.41

Immobilized metal affinity chromatography (IMAC) has been used for decades as an affinity method for targeting certain functional groups in proteins or other

Carboxyethylsilanetriol

Carboxylated surface

FIGURE 13.7 Carboxylethylsilanetriol can be used to modify an inorganic substrate to containing carboxylate groups for coupling amine-containing ligands.

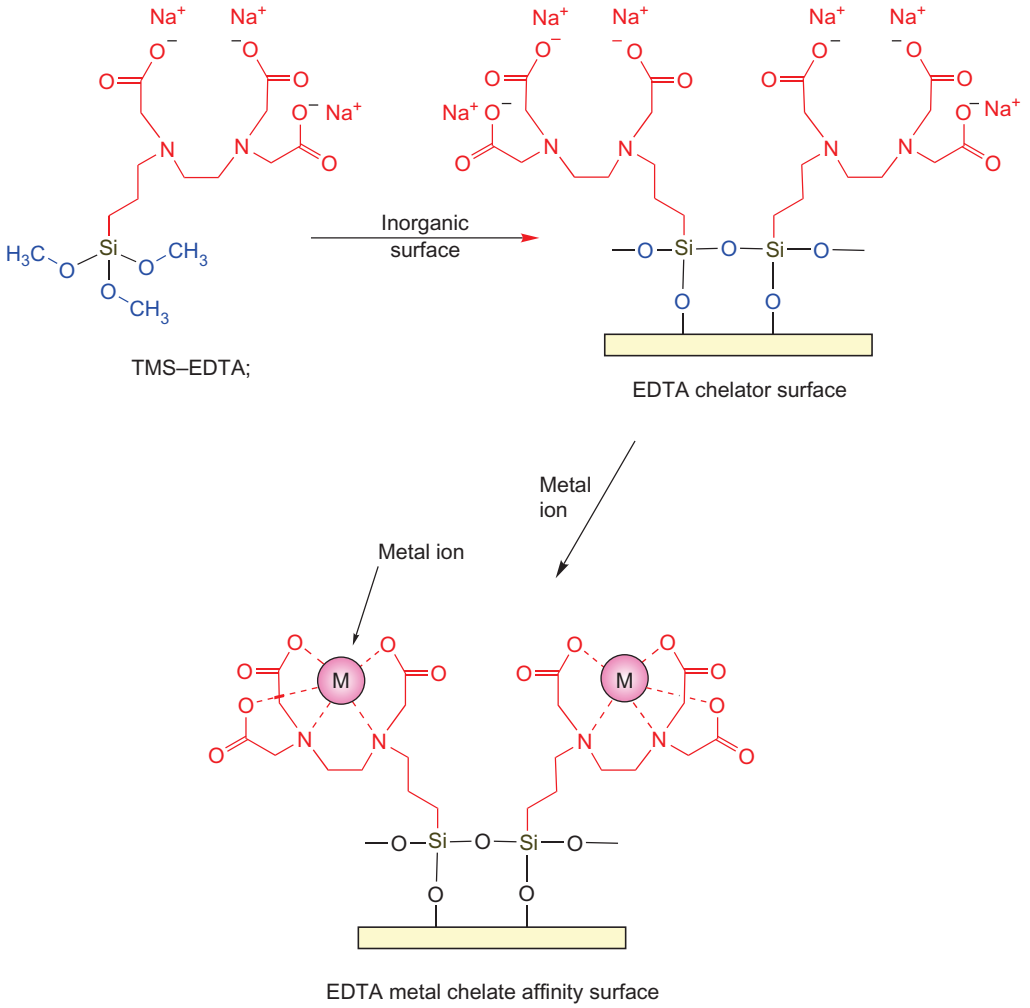

FIGURE 13.8 TMS–EDTA can be used to modify an inorganic substrate to contain EDTA chelating groups for complexation with metal ions.

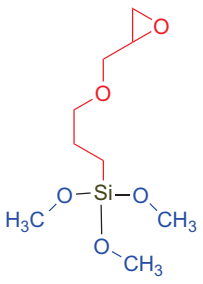
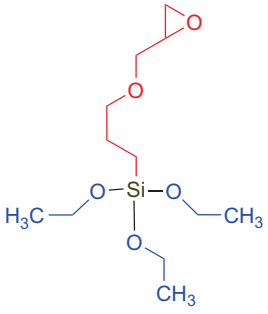
biomolecules (for reviews, see Hage, 1999; Lopatin and Varlamov, 1995; Winzerling *et al.*, 1992; Porath, 1992; and Hermanson *et al.*, 1992). Various metal ions can be chelated by EDTA affinity groups to provide directed targeting of biological groups such as phosphate modifications or histidine-rich areas in proteins. Thus, phosphorylation sites in proteins can be bound using a silane–EDTA-modified surface containing, for instance, gallium (Posewitz and Tempst, 1999). Alternatively, if the chelating groups are charged with nickel or cobalt, the binding of His-tagged proteins can be done.

The preparation of particles or surfaces that are able to capture specifically a fraction of the proteome using metal affinity separations makes possible analysis of distinct protein populations by mass spectrometry (Zhou *et al.*, 2000). The reactions and use of TMS–EDTA in modifying inorganic surfaces and coordinating metals for affinity chromatography is shown in Figure 13.8.



The coating of surfaces with TMS–EDTA can be done using the general protocol described previously in this chapter entitled Aqueous/Organic Solvent Deposition. The acidified water/organic solvent environment hydrolyzes the methoxy groups to silanols, which then polymerize and covalently link to inorganic surface –OH groups. After a surface has been modified with a chelating ligand, it is washed thoroughly with metal-free water or buffer. Finally, an aqueous solution of the appropriate metal salt is contacted with the surface and the EDTA groups will bind the metal for use in affinity separations.

It should be noted that the chelator group in TMS–EDTA is a pentadentate ligand, which will coordinate five bonds with an associated metal ion. Common IMAC ligands use tridentate or tetradentate ligands that have a greater number of available coordination sites for interaction with target molecules. Iminodiacetic acid-based chelators interact with metal ions through three bonds, typically leaving a maximum of three coordination sites left for affinity binding. Nitrilotriacetic acid–lysine (NTA) chelating groups interact with metal



ions through four coordination bonds, leaving two sites available for affinity interactions. However, the TMS–EDTA ligand holds metal ions through five coordination bonds, thus typically having only one remaining for interacting with other molecules. This property may result in lower affinities with biological molecules and change the capture behavior for specific metal interaction sites on proteins. Careful testing should be done for each application envisioned for this metal-chelating silane coupling agent. TMS–EDTA-modified particles have been used without a chelated metal ion to capture heavy metal ions for cleaning metal contaminated water (Addy *et al*., 2012).

2.4. 3-Glycidoxypropyltrimethoxysilane (GOPTS) and 3-Glycidoxypropyltriethoxysilane

Two very useful silane modification agents are glycidoxy compounds containing reactive epoxy groups. Surfaces covalently coated with these silane coupling agents can be used to conjugate thiol-, amine-, or hydroxyl-containing ligands, depending on the pH of the reaction (Chapter 3, Section 4.1). Thus, 3-glycidoxypropyltrimethoxysilane (GOPTS) or 3-glycidoxypropyltriethoxysilane can be used to link inorganic silica or other metallic surfaces containing –OH groups with biological molecules containing any three of these major functional groups. GOPTS has been used most often in bioconjugation applications, but the triethoxysilane compound also may be used in similar protocols (Figure 13.9).
